Prevention of radiation-induced cavities is best accomplished by aggressively using fluorides.[48] Generally, acidulated fluorides are the most effective, although neutral fluorides may be more acceptable to patients with mucositis. Patients are instructed to rinse daily for 1 minute with 5 to 10 mL of a fluoride rinse. Stannous fluoride gels 0.4% or sodium fluoride gel 1.1% tooth brushing agents may also be used by patients to minimize their risk of caries. Meticulous attention to oral hygiene with regular dental checkups and avoidance of sucrose is essential to minimize the development of caries.

In general, a dentist should see patients who will be receiving radiation therapy to the head and neck or chemotherapy agents with a high risk of oral complications before starting therapy. This includes patients with hematologic malignancies who will most likely experience severe myelosuppression for prolonged periods. Oral evaluation before therapy, intervention to eliminate potential sources of infection or irritation before therapy, and preventive measures taken during therapy can dramatically decrease the frequency of oral complications.[48,49] Given J.B.'s risk factors, including the dose of radiation he will receive and concomitant therapy with cisplatin, a dental examination is indicated before initiating therapy.

Mucositis and Stomatitis

CASE 94-2, QUESTION 2: J.B. successfully completed his first 2 weeks of combined chemotherapy and radiation therapy; however, 3 days into his third week, he complains of generalized burning, discomfort, and pain on the ventral surface of his tongue. On clinical observation, both the ventral surface of his tongue and the floor of his mouth appear erythematous, and several discrete lesions are present in both areas. What is the most likely explanation for J.B.'s new onset of symptoms? What treatment is indicated at this time?

Mucositis occurs as a nonspecific effect of chemotherapy and radiation therapy on the basal epithelium of the mouth. Nonkeratinized mucosa is affected most often. Thus, the buccal, labial, and soft palate mucosa, the ventral surface of the tongue, and the floor of the mouth are the most common sites of involvement. Although lesions are usually discrete initially, they often progress to produce large areas of ulceration. The lesions typically do not progress outside the mouth, but they may extend to the esophagus and involve the entire GI tract. The terms of stomatitis and oral mucositis may be used interchangeably. Mucositis may occur anywhere along the full GI tract. Signs and symptoms generally occur about 5 to 7 days after chemotherapy or at almost any point during radiation therapy. The antimetabolites (e.g., methotrexate, fluorouracil, capecitabine, and cytarabine) and the antitumor antibiotics are the chemotherapy agents that most commonly produce direct effects on the epithelial cells of the GI tract. Lesions generally regress and resolve completely in approximately 1 to 3 weeks, depending on their severity. Unlike oral toxicity seen with conventional chemotherapy, aphthous-like mucositis or stomatitis is a prevalent toxicity distinctly seen with mTOR (mammalian target of rapamycin) inhibitor therapy. Lesions typically appear during the first cycle of therapy, within the first week. Management often consists of supportive care measures and dose reductions.[50]

In severe cases, mucositis may require parenteral opioid analgesics for relief. Other signs or symptoms include decreased ability to eat and speak. Mucositis may be confused with an oral infection (particularly thrush), or mucositis and oral infections may occur concurrently. Local and systemic bacterial, fungal, or viral infections can occur and can cause a characteristic lesion; however, the lesion's appearance usually does not always correlate with the infectious agent. This particularly occurs in patients with neutropenia who cannot mount a full inflammatory response. In these individuals, the clinical appearance of an infected lesion may be muted relative to the presence or number of pathogens. Under normal conditions, the mucosa provides a natural barrier to the entry of normal oral flora, but the ulcerated mucosa allows pathogens access to the bloodstream. The patient could experience life-threatening infection or sepsis in addition to a local infection.

Treatments and Prevention

Treatment of mucositis is palliative. Topical anesthetics, including viscous lidocaine or dyclonine hydrochloride 0.5% or 1%, are often recommended. Equal portions of lidocaine, diphenhydramine, and magnesium-containing or aluminum-containing antacids can be used for their anesthetic and astringent properties. Many institutions compound mouthwash products containing these ingredients as well as antibiotics, nystatin, or corticosteroids. Corticosteroids provide anti-inflammatory properties, and the antibiotics and antifungals provide antibacterial or antifungal properties. Another topical agent, sucralfate, may provide some benefit by coating the lesion and reducing discomfort. All of these topical products provide symptom control only, and data supporting superior efficacy of one product over another in relieving pain are lacking. Furthermore, these topical products are only effective in oral and throat lesions because lesions lower in the GI tract are not reached with these local products.

All the topical anesthetic-containing preparations are recommended for use as "swish-and-spit" preparations. Generally, 5 to 10 mL is used three to 6 times a day. The longer the patient can hold the solution in the mouth, the longer the contact, and, theoretically, the better the symptom relief. Therefore, patients should be advised to hold and swish the solution around the mouth for as long as possible before spitting it out. The risk of

systemic effects from topical anesthetic preparations is slim if patients were to swallow them; however, large quantities swallowed could induce sedation and possible arrhythmias. Other palliative treatment options include topical benzocaine and ice chips. For small localized lesions, ointments such as benzocaine may be applied after the affected area has been dried with a sponge. Patients may also find ice chips soothing by allowing them to melt in their mouth. Most patients, however, require systemic analgesics to alleviate the pain. Table 94-1 provides guidelines to manage mucositis.[41]

Gelclair is a bioadherent oral gel containing polyvinylpyrrolidone, hyaluronic acid, and glycyrrhetinic acid (but no alcohol or anesthetic agent). It provides an adherent barrier over the mucosal surfaces, thereby shielding oral lesions from the effect of food, liquids, and saliva.[51] Controlled clinical data are lacking. In a study of 20 patients with head and neck cancer undergoing radiation therapy presenting with mucositis, Gelclair was compared with standard of care, including sucralfate and lidocaine. No significant difference was found between the Gelclair and standard of care in relieving general pain.[52]

J.B. appears to have a mild case of stomatitis or mucositis at this time. J.B. should be encouraged to maintain good mouth care by keeping his mouth clean. Additionally, topical anesthetics are indicated for J.B. Topical lidocaine or a mixture of topical lidocaine with diphenhydramine and an antacid, 5 to 10 mL swish and spit 3 to 6 times/day, should be recommended. If the lesions progress during the next several days, systemic opioids may be necessary. J.B. should also be carefully assessed for local infections within his mouth.

CASE 94-2, QUESTION 3: Could J.B.'s mucositis have been prevented?

Historically, treatment of chemotherapy-induced and radiation-induced mucositis has been aimed at reducing symptoms once they occur and avoiding further trauma to the oral mucosa. Cryotherapy has been marginally effective in reducing the severity of chemotherapy-induced mucositis.[53] Ice chips are placed in the mouth 5 minutes before chemotherapy begins and retained for 30 minutes. Theoretically, this will reduce blood flow to the mouth, thereby protecting the dividing cell population from toxins. Chlorhexidine gluconate 0.12% also may reduce the frequency and severity of mucositis infection,[54,55] although not all studies have shown a benefit. This solution should be used twice daily as a rinse. Side effects include occasional burning (thought to be caused by the product's alcohol content, which can be reduced by diluting it with water) and superficial brown tooth staining, which polishes off easily. Chlorhexidine may reduce the frequency and severity of mucositis by eliminating microorganisms in the oral cavity.

Table 94-1

Guidelines for the Management of Mucositis[43]

An oral care protocol which may include the following:

1. Remove dentures to prevent further irritation and tissue damage
   Maintain gentle brushing of teeth with a soft toothbrush
   Avoid mouthwashes or rinses that contain alcohol because they may be painful and cause drying of the mucosa. Consider normal saline or sodium bicarbonate oral swishes
2. Apply local anesthetics for localized pain control, especially before meals (may add an antacid or an

antihistamine). Systemic opioid analgesics, including transdermal fentanyl, may be required to control pain associated with severe mucositis. Acetaminophen is often avoided because it may mask fevers in neutropenic patients, and ibuprofen is often avoided because it may cause more bleeding in patients with thrombocytopenia

3. Ensure that adequate hydration and nutrition are maintained:
   Eat a bland diet, avoiding spiced, acidic, and salted foods
   Avoid rough food; process in a blender if necessary
   Use sugar-free gum or sugar-free hard candy to stimulate salivation and facilitate mastication
   If necessary, provide intravenous (IV) nutritional support
   Avoid extremely hot or cold foods
   Use shakes with nutritional supplements or ice cream

Despite these prophylactic measures, none of these aforementioned methods have a definitive benefit. To date, the only medication with proven efficacy is palifermin, a keratinocyte growth factor, approved for patients with hematologic malignancies undergoing HCT to reduce the incidence and duration of severe oral mucositis. For further discussion, see Chapter 101, Hematopoietic Cell Transplantation.

Other methods for decreasing the incidence and severity of mucositis symptoms include reducing the dose of radiation or cytotoxic therapy, but doing so comes at the risk of compromising treatment outcomes. Mucositis remains the dose-limiting toxicity for several anticancer regimens. Unfortunately, there are no prevention strategies that would reduce the chance of J.B. experiencing mucositis from his chemotherapy and radiation, and thus, treatment for J.B. is targeted toward relief of symptoms.

ESOPHAGITIS

Cytotoxic chemotherapy and radiation therapy can also damage the mucosal lining of the esophagus. Although dysphagia is a common symptom reported by patients with esophagitis, other causes of dysphagia should be excluded. Because patients receiving myelosuppressive cytotoxic therapy may exhibit infectious esophagitis, bacterial, viral, and fungal cultures should be completed to search for infectious causes before starting treatment for esophagitis. Symptomatic management of esophagitis is similar to the management of mucositis. Other treatment modalities, including behavioral modifications (e.g., elimination of acidic and irritating foods) and other medications (e.g., histamine-2 [H_2] receptor antagonist, antacids, and proton pump inhibitors), may help reduce esophageal irritation and improve comfort. Patients with severe esophagitis should be carefully monitored to ensure adequate oral hydration and nutritional intake, and instructed to avoid acidic or irritating foods. Symptoms should resolve in 1 to 2 weeks as myelosuppression resolves.

LOWER GASTROINTESTINAL TRACT COMPLICATIONS

Lower GI tract complications associated with anticancer therapy include malabsorption, diarrhea, and constipation. These complications may be related to structural changes that occur to the GI tract after cytotoxic or radiation therapy. Several investigators noted villus atrophy and cessation of mitosis within GI crypts in patients and animals treated with combination cytotoxic therapy.[56–58] Other investigators noted swelling and dilation of mitochondria and endoplasmic reticulum and shortening of the microvilli. These or other changes to the small and large bowel can cause decreased absorption of medications that are primarily absorbed in the upper portion of the small intestine.

Cytotoxic-induced intestinal changes also may be responsible for diarrhea, which frequently occurs with regimens containing

---

irinotecan, high-dose cytarabine, or fluorouracil. Unlike diarrhea, constipation is rare. The vinca alkaloids, which produce colicky abdominal pain, constipation, and adynamic ileus caused by autonomic nerve dysfunction (see Neurotoxicity section), can cause chemotherapy-induced constipation. Additionally, constipation is a problematic side effect of therapy with thalidomide. Constipation should be treated prophylactically with stool softeners and mild stimulants. The true incidence of diarrhea and constipation associated with chemotherapy is difficult to discern, because many medications (e.g., opioid analgesics, antiemetics, antacids) and clinical conditions (e.g., immobility, spinal cord compression) commonly associated with cancer and anticancer therapies can cause these symptoms as well.

Diarrhea

CASE 94-3

QUESTION 1: B.G., a 60-year-old woman with recurrent colorectal cancer refractory to FOLFOX (fluorouracil, leucovorin, and oxaliplatin), is beginning her first course of cetuximab and irinotecan. What instructions should she receive regarding the management of diarrhea if she experiences this complication?

Diarrhea is a common toxicity seen during cancer treatment. It is most prevalent in patients treated with fluoropyrimidines and irinotecan. In addition, it is one of the most common side effects seen with new targeted therapies. A recent review provides an excellent summary of targeted therapy-induced diarrhea.[59] Diarrhea is a toxicity in which patient education is paramount. Patients who do not recognize potentially serious symptoms, understand the role of self-management, or understand when to contact their provider are at risk of life-threatening consequences. The mechanism of diarrhea is not completely understood, is likely multifactorial, and varies depending on the therapy. Diarrhea may result from direct effects on the GI mucosa, secretory factors, dysmotility, and immunotherapy-related (ipilimumab) and parasympathetic (irinotecan) effects. Irinotecan can cause severe diarrhea, both early and late, in the course of therapy. The early-onset diarrhea and late-onset diarrhea appear to be mediated by different mechanisms. Unique to irinotecan, the early-onset diarrhea (within 24 hours after treatment) may be mediated by parasympathetic stimulation. Patients often report other cholinergic symptoms, such as rhinitis, increased salivation, miosis, lacrimation, diaphoresis, flushing, and abdominal cramping as well. These symptoms can be prevented or managed with atropine IV or SC 0.25 to 1 mg. Late-onset diarrhea (generally occurring >24 hours after treatment) can be prolonged leading to dehydration, electrolyte imbalances, and significant morbidity. In irinotecan-induced diarrhea, patients should promptly receive loperamide 4 mg with the first episode of diarrhea and repeat doses of 2 mg every 2 hours until 12 hours have passed without a bowel movement.[60] The maximum dose of loperamide (16 mg in 24 hours) does not apply for irinotecan-induced diarrhea. Fluid and electrolyte replacement should also be administered, if necessary. With the potential severe complications associated with chemotherapy-associated diarrhea, prompt treatment cannot be overemphasized.

If a patient fails to respond to adequate doses of loperamide, the somatostatin analog, octreotide, can be used to manage the diarrhea. Randomized trials comparing loperamide with octreotide in patients with acute leukemia or those undergoing HCT found loperamide to be more effective.[61,62] Nevertheless, some evidence shows that octreotide may be used to successfully manage diarrhea associated with fluorouracil and other high-dose chemotherapy regimens.[63,64] These findings have been inconsistent. Several trials in patients with colorectal cancer receiving chemoradiation or chemotherapy failed to show benefit of decreasing diarrhea with long-acting octreotide.[64,65] Octreotide produces antisecretory activity in the gut and promotes the absorption of sodium, chloride, and water from luminal content. Patients should receive doses ranging from 100 to 2,000 mcg SC 3 times daily or 20 to 40 mg of long-acting octreotide.[64,65] Although responses seem to correlate with octreotide dose, more studies are needed to determine the optimal dose. Based on current evidence, octreotide should be limited to second-line therapy for cytotoxic therapy-associated diarrhea. Other treatment options, including antibiotics, opioids, and corticosteroids, have been evaluated and are summarized in review articles.[59,66]

B.G. should be counseled on the diarrhea that is often seen with irinotecan. She should be instructed to call her clinic if she starts experiencing any diarrhea within 24 hours after administration of irinotecan so she can receive prompt atropine therapy. Additionally, she should be given a prescription and instructions for loperamide administration and oral hydration recommendations for diarrhea occurring beyond the initial 24 hours after chemotherapy.

Dermatologic Toxicities

Dermatologic toxicities associated with anticancer therapies include alopecia, hyperpigmentation, radiation recall, photosensitivity, nail changes, hand-foot syndrome, acneiform rashes, hypersensitivity reactions, and extravasations. Several reviews serve as excellent references and provide detail related to dermatologic toxicities of targeted agents.[67–70]

ALOPECIA

CASE 94-4

QUESTION 1: C.W. is a 45-year-old woman with recently diagnosed breast cancer, who underwent lymph node dissection and lumpectomy. She will receive 20 fractions, or courses, of radiation therapy to the affected breast. She will also receive chemotherapy to minimize her risk of recurrence. She is in the clinic today to receive the first of four cycles of doxorubicin and cyclophosphamide (AC). Although C.W. had minimal problems with surgery, she particularly fears receiving combination chemotherapy. You counsel C.W. about the most common toxicities by reviewing the likelihood and management of myelosuppression, nausea, and vomiting. C.W. is appropriately attentive as you discuss these issues with her; however, her overriding concern is whether or not she will lose her hair. Is C.W.'s concern typical of most cancer patients? How would you respond?

C.W.'s concern regarding hair loss is typical of cancer patients starting chemotherapy. In fact, several investigators have reported that hair loss ranks second only to nausea and vomiting as a patient's greatest fear. Because hair bulb cells replicate every 12 to 24 hours, the cells are susceptible to various cytotoxic chemotherapy agents. Normally, hair follicles independently move cyclically through phases of growth (anagen), involution or transition (catagen), and rest (telogen). Although most persons normally lose about 100 scalp hairs a day, patients with cancer can lose substantially more. Because approximately 85% to 90% of hair follicles are in the anagen phase, chemotherapy agents may partially or completely inhibit mitosis or impair metabolic processes in the hair matrix. These effects can cause a thinned or weakened hair shaft or failure to form hair. Even mild trauma, such as normal hair grooming or rubbing the head on a pillow, can fracture the thinned hair shaft and cause hair loss. Hair loss usually begins 7 to 10 days after one treatment, with prominent hair loss noted within 1 or 2 months.

Other terminal hairs, such as beards, eyebrows, eyelashes, and axillary and pubic hair, can be affected; however, these effects are somewhat variable, depending on the rate of mitosis and the percentage of hairs in the anagen phase.[71,72]

C.W. should be informed about the expected onset of hair loss, and she should be reassured that alopecia caused by cytotoxic chemotherapy is reversible. She can expect her hair to begin regenerating 1 to 2 months after therapy is completed. The color and texture of her hair may be altered; the new hair may be lighter, darker, or curlier as it regrows.

Several interventions have been proposed to prevent scalp hair loss during chemotherapy. These procedures attempt to prevent chemotherapy agents from circulating to the hair follicles with either an occlusive scalp tourniquet or an ice cap that produces a localized hypothermia and vasoconstriction. Recognizing that such devices create a refuge for tumor cells, these procedures are contraindicated in patients with hematologic malignancies and in others at risk for scalp metastases.

Concerns regarding the efficacy and safety of these devices have prevented them from availability in the US market.[72,73] Topical minoxidil has been studied with unimpressive results to date.[74]

C.W.'s concern is a legitimate one expressed by many patients with cancer, not just patients with breast cancer. C.W. is likely to experience near or complete hair loss, depending on the thickness of her hair and its growth rate. She should be told how to minimize the effect of alopecia on her appearance through the use of hair pieces or stylish head scarves, turbans, or hats. She also should be referred to volunteer groups and organizations that can help her through this difficult time. Hair pieces are tax deductible as a medical expense and are covered by some health insurance policies. If C.W. thinks she will use a hair piece, she should be advised to select a wig before hair loss begins.

CASE 94-4, QUESTION 2: Besides alopecia, what other skin or nail changes should C.W. anticipate?

NAIL AND SKIN CHANGES

Several skin and nail changes have been associated with cytotoxic and targeted anticancer agents, which C.W. may find disturbing.

The major consequences of these toxicities are cosmetic, however, and they usually resolve within 6 to 12 months after discontinuing or completing therapy.

Nail Changes

The growth of fingernails and toenails is arrested in a manner similar to hair growth. A reduction or a cessation of mitotic activity in the nail matrix causes a horizontal depression of the nail plate. Within weeks, these pale horizontal lines (Beau lines) begin to appear in the nail beds. They are most commonly seen in patients receiving chemotherapy for more than 6 months. These growth arrest lines move distally as the nail grows and normally disappears from the fingernails in approximately 6 months. Nail changes including hemorrhagic onycholysis, discoloration, and acute exudative paronychia are seen in approximately 40% of patients receiving paclitaxel and docetaxel.[67,75] Some other nail pigmentation changes that can occur after therapy with cyclophosphamide, fluorouracil, daunorubicin, doxorubicin, and bleomycin are less well understood.[76,77] Brown or blue lines deposit as horizontal or vertical bands in the nails. These lines are seen more commonly in dark-skinned patients. As with Beau lines, these pigmentation lines generally grow out with the nail. Standardized treatment recommendations for nail-related adverse events do not exist. Oral antibiotics and corticosteroids may be considered.

Dermatologic Pigment Changes

Dermatologic pigment changes are among the most common and least well-understood side effects of chemotherapy. Hypopigmentation has been reported occasionally in patients receiving cytotoxic therapy, but hyperpigmentation is more frequently reported. Usually, hyperpigmentation is not associated with an identifiable cause or systemic toxicity. It usually occurs after treatment with a wide variety of cytotoxic agents, including anthracyclines, alkylating agents, and antimetabolites. Most agents cause a diffuse, generalized hyperpigmentation, but the pigmentation changes can also be localized, involving only the mucous membrane, hair, or nails. Busulfan, cyclophosphamide, fluorouracil, dactinomycin, and hydroxyurea are examples of specific agents that can cause widespread cutaneous hyperpigmentation.[67]

Various chemotherapy agents can cause diverse patterns of hyperpigmentation. A peculiar serpiginous hyperpigmentation can occur over veins used to administer fluorouracil and bleomycin.[78,79] Some investigators have attributed this phenomenon to a subclinical phlebitis. Hyperpigmentation has also been noted over pressure points after the use of bleomycin. Thiotepa has been reported to cause hyperpigmentation in areas of skin occluded by bandages, which may be caused by secretion of thiotepa in sweat.[80] Interestingly, skin contact with thiotepa and mechlorethamine has been reported to cause hypopigmentation.[81,82] Although hyperpigmentation reactions commonly affect the skin, some rare reactions are noted in hair. Methotrexate can cause hyperpigmented banding of light-colored hair. This phenomenon has been described in a patient receiving intermittent high-dose methotrexate and has been referred to by some investigators as the “flag sign” of chemotherapy.[83] Alternatively, depigmentation of hair has been seen with several tyrosine kinase inhibitors including sunitinib, imatinib, and pazopanib. This adverse effect is attributed to c-KIT signal inhibition leading to decreased melanin synthesis.[84] To minimize a patient’s concern regarding these pigment changes, they should receive counseling before treatment.

As previously stated, pigment changes that occur in patients receiving cytotoxic chemotherapy are basically a cosmetic concern. It is important to anticipate these distressing side effects and educate patients in appropriate cases. At this time, C.W. should receive counseling, explaining that these side effects may occur because she will be receiving several agents that have been implicated in producing diffuse, as well as localized, cutaneous nail hyperpigmentation. She should be reassured that pigment changes usually resolve with time.

Hand-Foot Syndrome

Some patients receiving chemotherapy may exhibit tender, erythematous skin on the palms of their hands and sometimes on the soles of their feet. Patients may also complain of tingling, burning, or shooting sensations in their hands or feet usually not described as painful. These signs and symptoms may resolve after several days, or they may progress to bullous lesions that can desquamate. This reaction is referred to as chemotherapy-associated acral erythema or the palmar-plantar erythrodysesthesia syndrome. Agents most commonly reported to cause this reaction include cytarabine, fluorouracil, doxorubicin, liposomal doxorubicin, docetaxel, capecitabine, sorafenib, sunitinib, pazopanib, regorafenib, axitinib, and vemurafenib.[85,86] There is evidence that the application of urea-based cream may be effective in prevention of hand-foot syndrome based on study results in patients receiving capecitabine and sorafenib. Both study populations utilized 10% urea-based cream 3 times daily for 6 to 12 weeks and saw a decrease in the incidence of hand-foot syndrome.[87,88] Treatment is primarily focused on symptom control, and discontinuation of the medication or treatment interruption will help to resolve the reaction. After resolution, the medication may be initiated at a lower dose.

Acneiform–Erythematous Rash

The most common toxicities reported with the epidermal growth factor receptor (EGFR) inhibitors and EGFR monoclonal antibodies are skin related and are probably due to inhibition of the tyrosine kinase pathways in EGFR-dependent tissues, including keratinocytes in the skin. Erlotinib, gefitinib, afatinib, and lapatinib are small-molecule tyrosine kinase inhibitors that target the intracellular domain of the EGFR, and cetuximab and panitumumab are monoclonal antibodies that target the extracellular domain of EGFR. These agents are associated with skin toxicities. Skin effects occur in greater than 50% of patients who receive these treatments and are dose-dependent. A pustular or maculopapular eruption typically appears on the upper body, face, and scalp in the first 1 to 2 weeks of treatment.

The rashes are predominantly grade 1 or 2 in severity, may be associated with dry skin and itching, and completely resolve without sequelae when the drug is discontinued.[69,89] Evidence suggests that the severity of the skin rash is associated with increased efficacy of this class of agents. In a retrospective analysis of a Phase III trial in patients with NSCLC receiving erlotinib, those who experienced a rash had a significantly longer survival time than those who did not. Survival was reported to be 1.5 months in patients with no development of skin rash versus 8.5 months in those with grade 1 rash, and 19.6 months in patients exhibiting a grade 2 or 3 rash.[90] Evidence of a correlation between skin rashes and higher response rates has also been observed in patients receiving cetuximab for colorectal cancer.[91] Multiple therapies have been studied in hopes of reducing or preventing this bothersome side effect. Patients should be advised to minimize sun exposure and to keep the rash moist with lotions and creams, avoiding drying agents.[92–95] The Multinational Association of Supportive Care in Cancer (MASCC) has developed an EGFR Inhibitor Skin Toxicity Tool to assist clinicians in monitoring and reporting EGFR-induced dermatologic toxicities. In addition, MASCC has published both patient information and clinical practice guidelines for the prevention and treatment of EGFR inhibitor-associated dermatologic toxicities. Because of the prevalence and significant discomfort associated with the rash, prevention is recommended in the majority of patients in the first 6 to 8 weeks of therapy and consists of hydrocortisone 1% cream with moisturizer, sunscreen, and either minocycline or doxycycline therapy.[95]

Dry Skin

Many cytotoxic anticancer agents (especially bleomycin, hydroxyurea, and fluorouracil) and several targeted therapies (EGFR inhibitors) can cause dry skin with fine scaling on the surface. Normally, sebaceous and sweat glands provide lipids, lactates, and other products that contribute to the pliability and moisture retention of the stratum corneum. In patients receiving cytotoxic therapy, the dry skin may be caused by the cytostatic effect of agents on sebaceous and sweat glands. Topical application of emollient creams may provide some symptomatic relief of this dryness.

INTERACTIONS WITH RADIATION THERAPY

CASE 94-4, QUESTION 3: C.W. recently completed her course of total breast radiation therapy. She plans to leave for a 1-week vacation in Florida 3 days after this clinic visit. Are there any interactions between radiation therapy and sunlight exposure with cytotoxic anticancer agents? Are there any specific precautions C.W. should take, or signs and symptoms of toxicity that she should know about?

The interactions between cytotoxic therapy and radiation therapy or ultraviolet (UV) light (from both external beam and natural sources) can be divided into radiation sensitization, radiation recall, photosensitivity reactions, and sunburn reactivation (Table 94-2).

Table 94-2

Chemotherapy-Associated and Radiation-Associated Reactions

Radiation Sensitivity Reactions		
Bleomycin	Doxorubicin	Hydroxyurea
Dactinomycin	Fluorouracil	Methotrexate
Etoposide	Gemcitabine	
Radiation-Recall Reactions		
All of the above plus		
Vinblastine	Epirubicin	Capecitabine
Etoposide	Paclitaxel	Oxaliplatin
	Docetaxel	
Reactions with Ultraviolet Light		
Phototoxic Sensitivity		
Dacarbazine	Thioguanine	Methotrexate
Fluorouracil	Vinblastine	Mitomycin

Sunburn Reactivation		
Methotrexate

Radiation-recall skin disorders associated with the use of antineoplastic drugs: pathogenesis, prevalence, and management. Am J Clin Dermatol. 2000;1:113; Alley E et al. Cutaneous toxicities of cancer therapy. Curr Opin Oncol. 2002;14:212.

Several excellent reviews are available that describe each of these interactions in detail. A discussion of the important principles of the interaction between radiation therapy and cytotoxic therapy follows.[96–98] A synergistic interaction between a small number of cytotoxic agents and radiation therapy results in an enhanced radiation effect. This may be caused by an agent's ability to interfere with radiation repair. Radiation therapy can alter the molecular structure of DNA, but excision repair allows cells to remove small, damaged portions of one strand of DNA and insert new bases using the other strand as a template. This repair mechanism requires several enzymes, including DNA polymerase. Cytotoxic therapy agents can interfere with some of the enzymes and synthetic mechanisms needed to repair damaged cells. Although the synergistic effects of radiation therapy and cytotoxic therapy are often exploited therapeutically for the treatment of solid tumors, these reactions can inadvertently cause undesirable reactions in nontumor tissues, such as the skin, esophagus, lung, and GI tract. The skin is the most common target of radiation reactions.

These reactions can produce severe tissue necrosis, which can compromise organ function and delay or mandate discontinuation of future treatment courses. These reactions may be further classified as either radiation sensitivity or radiation-recall reactions. The primary distinction between radiation sensitivity reactions and radiation-recall reactions lies in the temporal relationship between radiation therapy and chemotherapy. Generally, sensitivity reactions occur when chemotherapy is given concurrently or within 1 week of radiation therapy. In comparison, recall reactions occur several weeks to years after radiation therapy, when the administration of chemotherapy induces an inflammatory reaction in tissues previously treated with radiation. Radiation recall is independent of previous, clinically apparent radiation damage. Not surprisingly, the chemotherapy agents that have been associated with

---

radiation-recall reactions are the same as those that cause radiation sensitivity reactions. Management of reactions is supportive and consists primarily of topical agents including corticosteroids.[96,98–101]

Because UV light has sufficient energy to cause photochemical changes in biologic molecules, cytotoxic agents can interact with it. The subsequent reactions are usually less severe than reactions that occur with radiation therapy, and they may be caused by a different mechanism. Photosensitivity reactions, defined as enhanced erythema responses to UV light, have been reported with specific agents (Table 94-2). Methotrexate can also reactivate sunburns, causing a similar, but less severe reaction compared with the radiation-recall reactions described previously. The reaction can be more severe than the initial sunburn, resulting in severe blisters, and it usually occurs only in patients who receive large doses of methotrexate. Although the precise incidences of photosensitivity reactions caused by chemotherapy agents are unknown, they may be more common than generally believed. For example, photosensitivity may account for many of the erythematous periodic rashes attributed to allergy.[67,102]

C.W. received doxorubicin which can interact with radiation therapy. Although not commonly reported, doxorubicin also can cause some increased erythema in the specific area of skin treated with radiation. Because C.W. may have an increased risk for a photosensitivity reaction, she should be advised to avoid direct exposure to the sunlight for several days to a week after chemotherapy. Although no data exist regarding the efficacy of sunscreens in this patient population, C.W. should be advised to use a protective sunscreen with a high sun protective factor when she cannot avoid sun exposure. Protective clothing and a hat can provide additional protection for C.W. Furthermore, she should periodically assess her skin's reaction to the sun with intermittent periods of rest and observation throughout the day.

CASE 94-4, QUESTION 4: How will C.W. know whether she has a radiation reaction? How should she be treated if such a reaction occurs?

If C.W. has a radiation reaction, she will experience "easy burning" and erythema or redness, followed by dry desquamation. With a more severe reaction, small blisters (vesicles) and oozing can develop. Necrosis with persistent painful ulceration can also occur in severe cases. Postinflammatory hyperpigmentation or depigmentation may follow. Treatment options vary, depending on reaction severity. Milder cases can be treated with topical steroids in an emollient cream base and cool wet compresses. Necrosis and ulcers are notoriously difficult to treat, however, because radiated skin does not heal well. Ulcers are often treated with surgical debridement to keep the ulcer clean. Even when the ulcers are clean, exudation and bacterial contamination can be persistent. Radiation reactions that occur in tissues other than the skin (e.g., the lungs, esophagus, GI tract) often are treated with oral corticosteroids, although data regarding the efficacy of these agents in ameliorating the symptoms or reducing the extent of damage are lacking. If C.W. experiences any of these signs or symptoms, she should immediately seek medical attention.

IRRITANT AND VESICANT REACTIONS

CASE 94-4, QUESTION 5: C.W. complained of pain and burning at the injection site immediately after the administration of her third course of IV chemotherapy with doxorubicin and cyclophosphamide. She described the sensation as being distinctly different from the mild discomfort she had experienced with previous courses.

Physical examination of the injection site revealed mild erythema and slight induration. What types of local reactions can occur after the administration of chemotherapy?

Several distinct types of local reactions (ranging from transient local irritation to severe tissue necrosis of the skin, surrounding vasculature, and supporting structures) have been reported after cytotoxic chemotherapy[68,103,104] (Table 94-3). Some reactions are characterized by immediate local burning, itching, and erythema. Some patients may also experience a "flare" reaction along the length of the vein used for treatment. More severe reactions, including irritation of the vein (or phlebitis) caused by the irritant properties of an agent or a diluent, and possibly extravasation, can occur after cytotoxic chemotherapy.[68,103] Extravasation, a potentially serious local reaction, is seen in approximately 1% of chemotherapy administration and occurs when IV medications are accidentally administered into the surrounding tissue, either by leakage or by a needle puncturing the vein, causing direct exposure and damage to surrounding tissues.

Reactions resulting from the extravasation of agents with vesicant or irritant properties are more severe. All agents with vesicant properties potentially can produce devastating reactions. Agents known to bind to DNA (i.e., the anthracyclines) have the propensity to produce the most severe damage. Treatment with a cytotoxic agent with these properties can produce phlebitis and pain; however, extravasations can cause severe local irritation or soft tissue ulcers, depending on the agent and the amount and concentration of the extravasated drug. In addition, no clear agreement exists regarding the vesicant potential of many cytotoxic chemotherapy agents, and various references may categorize agents differently based on their vesicant or irritant properties. Initially, it may be impossible to distinguish a local irritant reaction from a vesicant extravasation; therefore, if an agent with vesicant or irritant properties has been administered, the reaction should be treated as a potential extravasation.

Patients who experience an extravasation can show a range of different signs or symptoms. Infiltration of a vesicant into tissue often produces a severe burning sensation that may persist for hours. In some cases, no immediate symptoms or signs are evident. However, in the days to weeks that follow, the skin overlying the extravasation site may become reddened and firm. The redness may gradually diminish or progress to ulceration and necrosis.[103]

Table 94-3

Chemotherapeutic Drugs Reported to Produce Local Toxicities

Potential Vesicants	
Dactinomycin	Epirubicin
Daunorubicin	Streptozocin
Doxorubicin	Vinblastine
Idarubicin	Vincristine

Mechlorethamine	Paclitaxel
Mitomycin	Oxaliplatin
Potential Irritants	
Carmustine	Etoposide
Cisplatin	Mitoxantrone
Dacarbazine	Melphalan
Vinorelbine	Vindesine
Cyclophosphamide	Teniposide

Source: Doellman D et al. Infiltration and extravasation: update on prevention and management. J Infus Nurs. 2009;32:203; Boulanger J et al. Management of the extravasation of antineoplastic agents. Support Care Cancer. 2015;23(5):1459.

CASE 94-4, QUESTION 6: What factors in C.W. increase her risk of extravasation, and what administration techniques and precautions can minimize these risks?

Several factors have been associated with an increased risk of extravasation and subsequent tissue damage after administration of cytotoxic chemotherapy. Risk factors include generalized vascular disease commonly found in elderly and debilitated patients or in patients who have undergone frequent venipuncture and treatment with irritating chemotherapy (the latter causes venous fragility and instability or decreased local blood flow); elevated venous pressure, which typically occurs in patients with an obstructed superior vena cava or venous drainage after axillary dissection; prior radiation therapy to the injection site; recent venipuncture in the same vein; use of injection sites over joints, which increases the risk of needle dislodgement; and others.[68,103]

Tissue damage may be more severe if extravasation occurs in areas with only a small amount of subcutaneous tissue (e.g., the back of the hand or wrist) because wound healing is more difficult and exposure of deeper structures, such as the tendons, is increased.[103] These risks have led to the increased use of central catheters in patients receiving vesicant chemotherapy.

C.W. has several risks for extravasation. She had an axillary lymph node dissection for her breast cancer, which places her at higher risk for obstructed venous drainage. Additionally, she has had multiple venous punctures, and she is a thin woman with relatively small amounts of subcutaneous tissue.

Extravasations of agents with vesicant properties can produce devastating tissue damage that can potentially cause loss of an extremity or death. To prevent significant morbidity or mortality, major emphasis must be placed on prevention. All caretakers who administer agents with vesicant or irritant properties should be skilled in IV drug administration and receive special instruction before administering these agents. The patient also must be told how agent administration should feel and to report immediately any change in sensation, including pain, burning, or itching.

CASE 94-4, QUESTION 7: C.W.'s oncology nurse believes that the doxorubicin may have extravasated during administration. How should this be managed? Do management strategies differ for other vesicant agents?

Immediate management of a potential vesicant extravasation should include stopping the injection if the entire agent has not been administered. Various other recommended measures may minimize vesicant exposure and subsequent tissue damage (Table 94-4). These include application of cold compresses to the extravasation site and elevation of the extremity. Cold compresses have been shown to cause vasoconstriction, which can help to localize the extravasation and allow time for local vessels to displace the extravasated agent, whereas warm compresses are thought to induce vasodilation, increase drug distribution and absorption, therefore decreasing the concentration of the offending agent around the immediate site. Warm compresses are recommended for vinca alkaloids and epipodophyllotoxins.[103,104] With the exception of these two classes of agents, cooling has been shown to be more effective than warm compresses. Specific antidotes thought to inactivate the extravasated chemotherapy have been suggested; however, many of these antidotes are based on observations in a few patients or animal models, and their effectiveness, in many cases, is unsubstantiated. Antidotes recommended in some guidelines may actually worsen tissue damage (e.g., sodium bicarbonate for doxorubicin). Recommended treatments for suspected extravasation of vesicant agents are outlined in Table 94-5.[103,104]

Table 94-4

Suggested Procedures for Management of Suspected Extravasation of Vesicant Drugs

1. Stop the infusion immediately, but do not remove the needle. Any drug remaining in the tubing or needle, as well as the infiltrated area, should be aspirated
2. Contact a physician as soon as possible
3. If deemed appropriate, instill an antidote in the infiltrated areas (via the extravasated intravenous (IV) needle i possible)
4. Remove the needle
5. Apply ice to the site and elevate the extremity for the first 24–48 hours (if vinca or epipodophyllotoxin, use warm compresses)
6. Document the drug, suspected volume extravasated, and the treatment in the patient's medical record
7. Check the site frequently for 5–7 days
8. Consult a surgeon familiar with extravasations early so that the surgeon can periodically review the site, and, i ulceration begins, the surgeon can rapidly assess if surgical debridement or excision is necessary

Source: Doellman D et al. Infiltration and extravasation: update on prevention and management. J Infus Nurs. 2009;32:203; Boulanger J et al. Management of the extravasation of antineoplastic agents. Support Care Cancer. 2015;23(5):1459.

Dexrazoxane has been established as a reliable antidote for anthracycline extravasations. Dexrazoxane, an iron chelator, was studied based on evidence that it protects cardiac tissue from anthracycline-induced toxicities. Two prospective, multicenter, single-arm trials were conducted in a total of 54 evaluable patients with anthracycline extravasations. In 98.2% of patients, surgical intervention was avoided and 71% of patients were able to continue treatment regimen without any delays. Hospitalization of 41% of patients was necessary secondary to their extravasation. Toxicities included myelosuppression, increased liver function tests, nausea, and pain at the dexrazoxane infusion site.[105] Based on these results, dexrazoxane is approved for the treatment of anthracycline extravasations. Dexrazoxane is given once daily for 3 days at a dose of 1,000 mg/m^2 IV on days 1 and 2, and 500 mg/m^2 IV on day 3. Administration should start within 6 hours of extravasation.[106]

HYPERSENSITIVITY REACTIONS

Almost all anticancer agents have produced at least an isolated instance of a hypersensitivity reaction. All types of hypersensitivity reactions can occur with anticancer agents, although type I is the most common reaction documented. Type I hypersensitivity reactions are immediate reactions that are most often immunologically mediated, although there are other possible mechanisms for type I hypersensitivities. Anaphylactic or immunoglobulin E (IgE)-mediated reactions occur when an antigen interacts with IgE bound to a mast cell membrane, causing degranulation of mast cells. Major signs and symptoms of type I reactions include urticaria, angioedema, rash, bronchospasm, abdominal cramping, and hypotension. Although many reactions associated with anticancer agents probably are immunologically mediated, other mechanisms may cause type I reactions. Those include the degranulation of mast cells and basophils through a direct effect on the cell surface that releases histamine and other vasoactive substances. Activation of the alternative complement pathway can also release vasoactive substances from mast cells. When non-IgE-mediated mechanisms account for the symptoms of a type I reaction, it is called an anaphylactoid reaction (see Chapter 32, Drug Hypersensitivity Reactions).

Table 94-5

Recommended Extravasation Antidotes

Class/Specific Agents	Local/Systemic Antidote Recommended	Specific Procedure
Alkylating Agents Cisplatin[a] Oxaliplatin Mechlorethamine	1/6-M solution sodium thiosulfate	Mix 4 mL 10% sodium thiosulfate USP with 6 mL of sterile water for injection, USP for a 1/6-M solution. Into site, inject 2 mL for each mg of mechlorethamine or 100 mg of cisplatin

		extravasated
Mitomycin-C	Dimethyl sulfoxide 99% (w/v)	Apply 1–2 mL to the site every 6 hours for 14 days. Allow to air dry; do not cover
Anthracyclines Doxorubicin Daunorubicin	Cold compresses Dexrazoxane	Apply immediately for 30–60 minutes on first day Once daily for 3 days. First dose should be given within the first 6 hours. Day 1: 1,000 mg/m^2 IV Day 2: 1,000 mg/m^2 IV Day 3: 500 mg/m^2 IV
Vinca alkaloids Vinblastine Vincristine	Warm compresses Hyaluronidase	Apply immediately for 30–60 minutes, then alternate off/on every 15 minutes for 1 day Inject 150 units into site
Epipodophyllotoxins[a]	Warm compresses	Apply immediately for 30–60 minutes, then alternate off/on every 15 minutes for 1 day
Etoposide	Hyaluronidase	Inject 150 units into site
Taxanes	Cold compresses	Apply immediately for 30–60 minutes every 6 hours for 1 day
Docetaxel Paclitaxel	Hyaluronidase	Inject 150 units into site

[a] Treatment indicated only for large extravasations (e.g., doses one-half or more of the planned total dose for the course of therapy).

IV, intravenous; w/v, weight per volume.

Infiltration and extravasation: update on prevention and management. J Infus Nurs. 2009;32:203; Totect (dexrazoxane injection) [package insert]. Rockaway NTTU, Inc.; 2011.

Many of the type I hypersensitivity reactions produced by anticancer medications appear to be mediated by non-IgE mechanisms. Although little research has been conducted on the mechanism of these reactions, two features suggest that they are not mediated by IgE. First, many reactions occur during or immediately after administration of the first dose. This is in contrast to immunologic reactions that require prior exposure (i.e., one must be sensitized before becoming hypersensitized). In addition, certain symptoms or symptom complexes are more diagnostic of immunologically mediated disorders. These symptoms include urticaria, angioedema, bronchospasm, laryngeal spasm, cytopenias, arthritis, mucositis, vasculitic syndromes, and vesicular dermatitis. Although the spectrum of symptoms and their severity vary widely in the case reports, most hypersensitivity reactions that occur with anticancer agents are classified as grade 1 (transient rash, mild) or grade 2 (mild bronchospasm, moderate) by the NCI Common Terminology Criteria for Adverse Events.[1] Furthermore, a patient who has had a reaction to an agent that is not immunologically mediated can safely receive future courses of anticancer therapy if he or she receives appropriate premedication. For example, appropriate premedication allows many (>60%) patients who have previously experienced a hypersensitivity reaction secondary to paclitaxel to continue therapy; this also reduces the incidence of hypersensitivity reactions associated with short-duration infusions (i.e., 3 hours). Some agents can commonly cause hypersensitivity reactions after the first and subsequent doses of therapy.

The other types of hypersensitivity reactions are less commonly documented with cytotoxic and targeted therapy administration. Type II is hemolytic anemia. Type III results from deposition of antigen–antibody complexes that form intravascularly and in tissues that can result in tissue injury. Sensitized T lymphocytes that react with antigens causing a release of lymphokines are responsible for type IV reactions.[107] Anticancer agents most frequently reported to produce hypersensitivity reactions and their characteristic reactions are listed in Table 94-6.[108–134] Most valuable information stems from patient series and case reports. However, they often provide conflicting and contradictory information, particularly with respect to incidence, severity, characteristic symptoms, time course, and the success of rechallenge. If a patient experiences a hypersensitivity reaction and the clinician decides to continue therapy with this regimen, a full review of all of the relevant literature as well as manufacturer's data is advised. Several reviews are available to assist in this effort.[107,135,136]

Monoclonal Antibodies

CASE 94-5

QUESTION 1: S.R., a 58-year-old man with metastatic colorectal cancer, previously progressed after four cycles of FOLFOX (oxaliplatin 85 mg/m^2 IV on day 1, leucovorin 100 mg/m^2 IV on days 1 and 2, and fluorouracil 400 mg/m^2 IV bolus, followed by 600 mg/m^2 IV for 22 hours on days 1 and 2) plus bevacizumab 5 mg/kg. He also recently progressed after two cycles of second-line FOLFIRI (irinotecan 180 mg/m^2 on day 1, leucovorin 100 mg/m^2 IV on days 1 and 2, and fluorouracil 400 mg/m^2 IV bolus, followed by 600 mg/m^2 IV for 22 hours on days 1 and 2). S.R. now presents to the clinic for his first weekly dose of cetuximab (400 mg/m^2 IV load, followed by 250 mg/m^2 IV weekly). Discuss the toxicities that S.R. may expect and when they might appear. How should these side effects be managed? S.R. asks how these side effects can be prevented.

Table 94-6

Cancer Chemotherapeutic Agents Commonly Causing Hypersensitivity

Drug	Frequency	Risk Factors	Manifestations	Mechanism	Comments
Asparaginase[107]	10%–20%	Increasing doses; interval (weeks to months) between doses; IV administration; history of atopy or allergy; use without	Pruritus, dyspnea, agitation, urticaria, angioedema, laryngeal spasm	Type I	Substitute pegaspargase, but up to 32% may demonstrate mild hypersensitivity

		prednisone, mercaptopurine and/or vincristine			
Paclitaxel[107,108]	Up to 10% first or second dose	None known	Rashes, dyspnea, bronchospasm, hypotension	Nonspecific release of mediators; Cremophor EL	Premedicate with diphenhydramine corticosteroids, and H_2 receptor antagonists Paclitaxel protein-bound particles (Abraxane) may be substituted and better tolerated in some patients
Cisplatin[109–113]	Up to 20% intravesicular, 5%–10% systemic; case reports of hemolytic anemia	Increasing number of doses (typically > dose 6) Anemia: none known	Rash, urticaria, bronchospasm Anemia: hemolytic anemia	Type I Anemia: type III	Carboplatin may be substituted in some cases but cross-reactivity has been reported
Procarbazine[116–118]	Up to 15%, case reports	None known	Urticaria pneumonitis	Type I Type III	All patients rechallenged have prompt return of symptoms
Anthracyclines[119–123,125]	1%–15% depending on anthracycline	None known	Dyspnea, bronchospasm, angioedema	Unknown; nonspecific release	Cross-reactivity documented, but incidence and likelihood unknown
Bleomycin[126–128]	Common	Lymphoma	Fever (up to 42°C), tachypnea	Endogenous pyrogen release	Not technically classified as HSR; premedicate with acetaminophen and diphenhydramine
Rituximab[129]	First treatment 80%; subsequent treatments 40%	Female sex, pulmonary infiltrates, CLL or mantle cell lymphoma	Fevers, chills, occasional nausea, urticaria, fatigue, HA, pain, pruritus, bronchospasm, SOB, angioedema, rhinitis, vomiting, ↓ BP, flushing	Unknown; related to manufacturing process	Stop or ↓ infusion rate by 50%; provide supportive care with IV fluids, acetaminophen, diphenhydramine, vasopressors PRN
Trastuzumab[130]	First	None known	Chills, fever,	Unknown,	Manage with

	treatment 40%; subsequent treatments rare		occasional nausea or vomiting; pain, rigors, HAs, dizziness, SOB, ↓ BP, rash, asthenia	related to manufacturing process	acetaminophen, diphenhydramine, meperidine

Cetuximab[131]	First treatment, 15%–20%; grades 3–4, 3%; subsequent treatments uncommon	None known	Airway obstruction (bronchospasm, stridor, hoarseness), urticaria, hypotension, or cardiac arrest		Premedicate with diphenhydramine; stop or decrease infusion rate; provide supportive care with epinephrine, corticosteroids, IV antihistamines, bronchodilators, and oxygen PRN
Alemtuzumab[132]	~90% with IV administration in first week	None known	Hypotension, rigors, fever, SOB, bronchospasm, chills, rash	Unknown	Dose titration during several days; substitute with SC administration rather than IV; premedicate with acetaminophen, diphenhydramine, meperidine
Docetaxel[133]	0.9% with premedication	None known	↓ BP, bronchospasm, rash, flushing, pruritus, SOB, pain, fever, chills	Unknown	Premedicate with acetaminophen, dexamethasone, and diphenhydramine
Doxorubicin[134] liposomal	6.8%	None known	Flushing, SOB, angioedema, HA, chills, ↓ BP	Unknown, related liposomal components	Stop infusion; restart at a lower rate

Type I: Antigen interaction with IgE bound to mast cell membrane causes degranulation. Drug binding to mast cell surface causes degranulation. Activation of classic or alternative complement pathways produces anaphylatoxins. Neurogenic release of vasoactive substances. Type III: Antigen–antibody complexes form intravascularly and deposit in or on tissues.

BP, blood pressure; CLL, chronic lymphocytic leukemia; HA, headache; HSR, hypersensitivity reaction; IV, intravenous; PRN, as needed; SC, subcutaneous; SOB, shortness of breath.

The most common toxicities observed in patients receiving cetuximab include rash, diarrhea, hypomagnesemia, headache, nausea, and hypersensitivity reactions. Infusion-related reactions occur in 15% to 20% of patients receiving their first infusion. However, severe hypersensitivity reactions (including allergic and anaphylactic reactions) occur in 1% to 3% of patients. The reactions are related to the infusion of cetuximab and generally occur during or within 1 hour of completing the first dose. Patients should be premedicated with diphenhydramine before the infusion. The infusion can be stopped or the rate decreased if S.R. begins experiencing these effects. The skin rash and dry skin occurring after cetuximab administration are related to the inhibition of EGFR and were the most common side effect seen in clinical trials. The rash occurred in approximately 80% of patients and appeared in the first 1 to 3 weeks of therapy. Grade 3 or 4 skin rashes occurred in 5% to 10% of patients.[137]

Several of the monoclonal antibodies (e.g., rituximab, trastuzumab, cetuximab, ofatumumab) are associated with a higher incidence of hypersensitivity reactions than traditional cytotoxic agents. These agents are genetically engineered humanized monoclonal antibodies containing foreign proteins that can trigger the reaction. During the first infusion with trastuzumab, approximately 40% of patients experience a symptom complex, mild to moderate in severity, which consists of chills, fever, or both. These symptoms usually do not recur with subsequent injections.[135] In comparison, approximately 80% of patients receiving rituximab may experience an infusion-related reaction ranging from fever, chills, and rigors to severe reactions (7%) characterized by hypoxia, pulmonary infiltrates, adult respiratory distress syndrome, myocardial infarction, ventricular fibrillation, or cardiogenic shock with the first dose. Approximately 40% of patients receiving rituximab experience infusion-related reactions with subsequent infusions (5%–10% severe).[135] Treatment of these reactions follows the recommendations for treatment of hypersensitivity reactions that occur with more traditional agents.

Treatment

Recommended treatment of hypersensitivity reactions is reviewed in Table 94-7. If a patient experiences a severe type I hypersensitivity reaction to any anticancer agent, the treatment should be stopped. If a structural analog or another agent in the same chemical class is an effective treatment for the same cancer, subsequent therapy should use the analog or other agent to minimize the risk of future reactions. If the reaction is mild or moderate, the patient may continue with the same therapy if treatment is preceded by methods to prevent or minimize hypersensitivity reactions. General recommendations for preventing hypersensitivity reactions are found in Table 94-7. Pretreatment with corticosteroids and diphenhydramine significantly decreases the frequency and severity of hypersensitivity reactions; however, the effect of H_2 receptor antagonists and epinephrine remains controversial. Because the success of these preventive measures depends on the cause of the reaction (immunologic or anaphylactoid), the aforementioned characteristics of type I reactions should be used to assess the underlying pathogenesis. In addition, other chemicals present in the formulation or other agents administered concomitantly with the chemotherapy can cause the hypersensitivity reaction. Potential allergens included in the diluent or formulation of chemotherapy agents include Cremophor EL (present in paclitaxel), polysorbate 80 (present in docetaxel and etoposide), benzyl alcohol (present in the parenteral form of methotrexate, cytarabine, and etoposide), and methoxypolyethylene glycol (present in liposomal doxorubicin). Recognizing potential allergens can significantly affect treatment of the current reaction and minimize the risk of future reactions.

To reduce the hypersensitivity reactions observed with paclitaxel, paclitaxel protein-bound particles (Abraxane), an albumin-bound formulation of paclitaxel, has been created. Because paclitaxel protein-bound particles formulation is Cremophor EL-free and less likely to cause hypersensitivity than traditional paclitaxel, it is not necessary to premedicate patients with steroids and antihistamines. Doses between the two agents are not comparable. Although fewer hypersensitivity reactions are associated with this formulation, myelosuppression remains a dose-limiting toxicity.[108,138]

Table 94-7

Prophylaxis and Treatment of Hypersensitivity Reactions from Anticancer Drugs

Prophylaxis
IV access must be established BP monitoring must be available
Premedication
Dexamethasone 20 mg PO and diphenhydramine 50 mg PO 12 and 6 hours before treatment, then the same dose IV immediately before treatment
Consider addition of H_2 antagonist with schedule similar to dexamethasone
Have epinephrine and diphenhydramine readily available for use in case of a reaction
Observe the patient up to 2 hours after discontinuing treatment
Treatment
Discontinue the drug (immediately if being administered IV) Administer epinephrine 0.3 mg IM or SC minutes until reaction subsides
Administer diphenhydramine 50 mg IV
If hypotension is present that does not respond to epinephrine, administer IV fluids
If wheezing is present that does not respond to epinephrine, administer nebulized albuterol solution
Although corticosteroids have no effect on the initial reaction, they can block late allergic symptoms. Thus, administer methylprednisolone 125 mg (or its equivalent) IV to prevent recurrent allergic manifestations

BP, blood pressure; IV, intravenous; PO, orally.

Specific Organ Toxicities

NEUROTOXICITY

Specific Agents

CASE 94-6

QUESTION 1: A.L., a 39-year-old woman with acute lymphocytic leukemia, has been admitted to the hospital for induction chemotherapy. Methotrexate 3 g/m^2 IV once on day 1, cytarabine 2 g/m^2 IV every 12 hours on days 2 and 3 for four doses, vincristine 2 mg IV on days 1 and 8 for two doses, and dexamethasone 20 mg orally daily for on days 1 through 5 are ordered. Laboratory data obtained on admission include a WBC count of 120,000 cells/µL with 9% neutrophils, 11% lymphocytes, and 80% blasts. On day 3, A.L. is confused and she has difficulty performing a finger-to-nose neurologic examination. On day 10, she complains of numbness in her hands and feet. In addition, the clinician notes an eyelid lag and ataxia. A.L. also complains of severe constipation. What signs and symptoms of neurotoxicity is A.L. experiencing? Should the leukemia regimen be modified for future courses?

Methotrexate, Cytarabine, and Vincristine

Methotrexate causes little or no neurotoxicity when administered orally or intravenously in doses less than 1 g/m^2; however, high-dose IV methotrexate (usually >1 g/m^2) can occasionally cause acute encephalopathy. The encephalopathy that occurs after therapy with methotrexate is usually transient and reversible. Some patients may experience a progressive leukoencephalopathy after high-dose IV methotrexate. The risk of leukoencephalopathy increases with higher cumulative doses of methotrexate and concomitant cranial radiation therapy.[139,140] Posterior reversible encephalopathy syndrome has also been associated with high-dose methotrexate and intrathecal methotrexate. Chemical meningitis can occur with intrathecal administration of methotrexate and, less frequently, myelopathy or paraplegia may be observed[141] (see Chapter 95, Pediatric Malignancies). Patients receiving intrathecal therapy or high-dose methotrexate should be carefully monitored for signs and symptoms associated with neurotoxicity.

High doses of cytarabine (>1 g/m^2 in multiple doses) are associated with CNS toxicity in 8% to 37% of patients.[142,143] These neurotoxicities are dose-related and schedule-related. Doses greater than 18 g/m^2 per course increase the frequency of neurotoxicity. Older patients are more susceptible than younger patients, and the prevalence seems higher in subsequent versus initial courses of therapy. As illustrated by A.L., neurotoxicity may become evident within a few days after treatment with cytarabine and, most commonly, the neurotoxicity is manifested by a generalized encephalopathy with symptoms such as confusion, obtundation, seizures, and coma. Cerebellar dysfunction, presenting as ataxia, gait and coordination difficulties, and dysmetria (inability to arrest muscular movement when desired and lack of harmonious action between muscles when executing voluntary movement), is also commonly observed in patients receiving high-dose cytarabine therapy. These neurologic symptoms may partially resolve over days to weeks after discontinuation of therapy. Other neurologic toxicities reported with cytarabine include progressive leukoencephalopathy and chemical meningitis. Intrathecal administration of cytarabine, including the liposomal formulation, may also cause a chemical meningitis or arachnoiditis.[141,144] Leukoencephalopathy typically presents with progressive personality and intellectual decline, dementia, hemiparesis, and, sometimes, seizures. These neurotoxicities also can occur after treatment with other chemotherapy agents.

Asparaginase and pegaspargase can cause encephalopathy, which presents most commonly as lethargy and confusion. These agents are used in acute lymphocytic leukemia regimens. Severe cerebral dysfunction occurs occasionally, and patients may present with stupor, coma, excessive somnolence, disorientation, hallucination, or severe depression. Symptoms can occur early (within days of administration of asparaginase) or late, depending on the treatment schedule.[145,146] The suspected mechanism is the direct neurocytotoxic effect of aspartic acid, glutamic acid, and ammonia. The neurotoxicity is usually reversible with the acute syndrome clearing rapidly and a delayed syndrome lasting several weeks.

A.L.'s symptoms most likely are the result of CNS toxicity caused by both high-dose methotrexate and cytarabine. A decision regarding further treatment with these agents is complicated because omitting a dose or decreasing the dose of either of these agents could compromise the likelihood of a complete remission. High-dose cytarabine cerebellar toxicity may be irreversible. Therefore, the clinician may decide to discontinue cytarabine in A.L.'s future regimens. Additionally, modifications of methotrexate including dose reductions may be necessary in future therapy for A.L.

Multiple other anticancer agents including fluorouracil, fludarabine, nelarabine, procarbazine, and ifosfamide produce an encephalopathic toxicity (Table 94-8). Recognition of neurotoxicity resulting from cytotoxic chemotherapy is often difficult because of comorbid conditions such as metastatic disease and other paraneoplastic syndromes, but it is important in assessing the need for potential dose modifications or even discontinuation of the agent. Several reviews provide detailed explanations of signs and symptoms, mechanisms, and potential treatments for chemotherapy-induced neurotoxicities.[145,147] When a patient presents with any signs or symptoms of neurotoxicity, the patient should receive a neurologic examination followed by a dose reduction or discontinuation of therapy.

Table 94-8

Neurotoxicity of Selected Chemotherapeutic Agents

Acute	Chronic Encephalopathic	Cerebellar	Peripheral	Cranial	Arachnoiditis (Intrathecal	Autonomi

Encephalopathy	Syndrome	Neuropathy	Neuropathy	Neuropathy	Therapy)	Neuropat
Asparaginase	Cytarabine	Cytarabine	Bortezomib	Fluorouracil	Cytarabine	Vinblastine
Cisplatin	Methotrexate	Cisplatin	Brentuximab	Ifosfamide	Methotrexate	Vincristine
Cytarabine	Nelarabine	Fludarabine	Cisplatin		Thiotepa	Vinorelbine
Fludarabine	Thiotepa	Fluorouracil	Docetaxel

Fluorouracil

Fluorouracil can cause acute cerebellar dysfunction characterized by the rapid onset of gait ataxia, limb incoordination, dysarthria, and nystagmus. Cerebellar dysfunction occurs in approximately 5% to 10% of patients receiving fluorouracil at all treatment schedules in common use and can present weeks to months after beginning therapy. A more diffuse encephalopathy presenting as headache, confusion, disorientation, lethargy, and seizures can also occur. These symptoms can be reversed if fluorouracil is discontinued or the dose is reduced. Reports of cerebellar ataxia have also been reported with capecitabine, an oral prodrug of fluorouracil.[148,150]

Fludarabine and Nelarabine

Fludarabine can cause severe neurotoxicity when used at doses greater than 90 mg/m^2 for 5 to 7 days.[145,151,152] Symptoms include altered mental status, photophobia, amaurosis (blindness that usually is temporary without change in the eye itself), generalized seizures, spastic or flaccid paralysis, quadriparesis, and coma. Patients may progress to death even when therapy is discontinued. This neurotoxicity, however, is not common with the current recommended dosage of 20-30 mg/m^2/day for 5 days. Mild neurologic symptoms are typically reported, but severe neurotoxicity,[145,151] and optic demyelination occurs only occasionally.[153] Patients with signs or symptoms suggestive of significant neurotoxicity should receive a neurologic examination and, if warranted, therapy should be discontinued without rechallenging with a dose reduction. Nelarabine, another purine analog has dose-limiting neurotoxicity, and 18% to 37% of patients in Phase II trials showed severe grade 3 or 4 neurotoxicies.[154,155] The clinical presentation includes severe somnolence, convulsions, and peripheral neuropathy ranging from paresthesias to motor weakness. Several cases of ascending peripheral neuropathies and demyelination have been reported.[156] Therapy should be stopped if grade 2 toxicity is present because some cases have been irreversible.[157]

Ifosfamide

Ifosfamide is associated with an encephalopathy thought to result from one of its metabolites, chloroacetaldehyde. The incidence ranges from 10% to 20%; it presents hours to days after initiation of treatment with confusion and disorientation and is generally self-limiting. Methylene blue, albumin, and thiamine have been used for both prevention and treatment. Conclusive evidence to promote routine prophylaxis is not available.[158] Reported risk factors for this complication include a history of ifosfamide-induced encephalopathy, prior cisplatin exposure, concomitant opioids, concomitant CYP2B6 inhibitors, renal dysfunction, low serum albumin, increased hemoglobin, and abdominal disease.[159,160]

CASE 94-6, QUESTION 2: What is the most likely medication causing A.L.'s numbness?

Peripheral Neuropathy

Paresthesia (numbness and tingling) involving the feet and/or hands is an early subjective symptom of vincristine neurotoxicity, which often appears within the first days to weeks of therapy. Because A.L. received vincristine on days 1 and 8, it is reasonable to assume that her presentation of numbness in her extremities is secondary to her vincristine. This peripheral nerve toxicity commonly is bilateral and symmetric and is often referred to as a "stocking-glove" neuropathy. Symptoms initially consist of paresthesias, loss of ankle jerks, and depression of deep tendon reflexes. Areflexia (absent reflexes) typically occurs in about 50% to 70% of patients treated with a cumulative dose greater than 6 to 8 mg. Although older patients appear to be more susceptible to paresthesias than younger ones, almost all complain of paresthesias after combination chemotherapy that incorporates vincristine or vinblastine. Pain and temperature sensory loss are usually more pronounced than vibration and proprioception sensory loss. Patients also may display motor weakness with a foot drop or muscle atrophy. Motor weakness, which can become the most disabling symptom associated with vincristine neurotoxicity, can occasionally cause muscle wasting. Although some patients exhibit muscle atrophy, true muscle weakness seldom occurs after treatment with vincristine. Stumbling and falling that can occur with this peripheral neuropathy is not usually caused by muscle weakness; instead, it occurs in the dark when patients lose proprioception because they lack visual orientation. These complications are either partially or completely reversible, but recovery often takes several months.[161]

Other agents that often share the peripheral nerve toxicity of vincristine include vinblastine, vinorelbine, cisplatin, etoposide, oxaliplatin, paclitaxel, docetaxel, cabazitaxel, ixabepilone, bortezomib, thalidomide, and lenalidomide among others.[147] Unlike the vinca alkaloids, most of these agents cause numbness only and not a loss of reflexes, or weakness. Patients may report sensory loss and pain, however. The incidence may be related to cumulative doses as well as individual risk factors such as history of diabetic neuropathy.[162–164] Many preventive strategies have been evaluated including amifostine, glutamine, glutathione, vitamin E, and others, but many of the studies are limited by small sample sizes and are lacking placebo-controlled randomized designs.[165] The serotonin–norepinephrine reuptake inhibitor (SNRI), venlafaxine, was evaluated for the prevention of neuropathy in a randomized, double-blind, placebo-controlled Phase III trial of 48 patients receiving an oxaliplatin-based regimen. The primary endpoint was the percentage of patients with no acute neurotoxicity, which was significantly higher in the venlafaxine-treated group compared with patients receiving placebo (31.3% vs. 5.3%, respectively; $p = 0.03$). Due to the small study population and ongoing concerns about compromise of chemotherapy efficacy, this preventive strategy is not routine practice. Treatment strategies are only palliative and include adjuvant pain medications such as tricyclic antidepressants, anticonvulsants (pregabalin and gabapentin), and topical agents. Peripheral neuropathy is usually reversible, although resolution may take months. Several reviews provide detailed references for this information.[165–167]

Oxaliplatin causes peripheral neuropathies that differ from other anticancer agents. Oxaliplatin-induced neurotoxicity manifests as an acute neurosensory complex as well as a cumulative sensory neuropathy. Hyperexcitability of peripheral nerves causes an 85% to 95% incidence of paresthesia and dysesthesias of the hands, feet, and the perioral region. Laryngeal dysesthesias have been described as well. These effects are precipitated by exposure to cold. The cumulative dose-limiting chronic neuropathy is described as a sensory neuropathy that is reversible several months after completion of therapy. Dose modifications for patients with persistent neurotoxicities have been developed and typically involves delaying therapy until their condition improves.[168,169] Prevention of these toxicities with infusions of magnesium and calcium has been evaluated in a prospective, randomized double-blind study of patients ($n = 102$) with colon cancer receiving adjuvant therapy with oxaliplatin, fluorouracil, and leucovorin. Patients received either calcium gluconate 1 g IV and magnesium sulfate 1 g IV 15 minutes before and immediately after completion of

---

the oxaliplatin administration or placebo infusions. Calcium and magnesium infusions reduced the incidence of grade 2 of greater sensory neurotoxicity significantly over placebo (22% vs. 41%, respectively).[170] An additional Phase III randomized trial of 353 patients randomly assigned to receive calcium and magnesium pre-and postoxaliplatin showed no statistically significant differences in the incidence of peripheral neuropathy compared to placebo.[171] Decreased efficacy of this anticancer regimen has been reported with use of the calcium and magnesium infusions.[172] Therefore, the use of calcium and magnesium infusions remains controversial.

CASE 94-6, QUESTION 3: What is the significance of A.L.'s lid lag?

Cranial Nerve Toxicity

Cranial nerve toxicity occurs in 1% to 10% of patients receiving vinca alkaloids, and most patients present with ptosis or ophthalmoplegia,[173,174] probably related to damage to the third cranial nerve. Toxicity to other cranial nerves can cause trigeminal neuralgia, facial palsy, depressed corneal reflexes, and vocal cord paralysis—and may occur in the first few days to weeks after administration.[175] Other nerve toxicities associated with the vinca alkaloids include jaw pain, which can occur as early as after the first or second injection[176]; the pain usually resolves spontaneously and does not recur with subsequent doses. Several of the cranial nerve toxicities, especially with vincristine, may be dose-limiting because evidence shows an increased prevalence with increasing doses. A.L.'s eyelid lag probably is caused by vincristine.

Ifosfamide, vinblastine, and cisplatin have been reported to cause cranial neuropathies. Intra-arterial administration of chemotherapy agents such as carmustine may increase the risk of encephalopathy and cranial neuropathies.

Ototoxicity, characterized by a progressive, high-frequency, sensorineural hearing loss, commonly occurs with cisplatin,[177,178] most likely as a result of a direct toxic effect on the cochlea. Ototoxicity occurs more frequently at higher dosages, worsens with concurrent cranial radiation therapy, and appears to be more pronounced in children. The reversibility of cisplatin ototoxicity is questionable. At some centers, routine audiometric tests are performed in patients receiving cisplatin; as a result, these centers have a greater percentage of patients with documented decreases in audio acuity than others. Early cessation of cisplatin may result in greater hearing improvement. Although ototoxicity appears to be a major toxicity associated with cisplatin, it has been reported in patients receiving carboplatin.[178] If ototoxicity is suspected, a hearing test should be performed and therapy discontinued if alternate treatments are available.

Autonomic Neuropathy

CASE 94-6, QUESTION 4: What is the cause of A.L.'s constipation, and how might this problem have been prevented?

Vincristine, as well as vinblastine, commonly causes an autonomic neuropathy. The earliest symptoms (colicky abdominal pain with or without constipation) are reported by one-third to one-half of patients receiving these agents.[147,173] Because severe constipation can progress to or include adynamic ileus, prophylactic laxatives are recommended on a regular basis for patients receiving vincristine and vinblastine. Stimulant laxatives such as the senna derivatives or bisacodyl are believed to be the most effective agents, and stool softeners also may be used concurrently. No compelling evidence suggests, however, that laxatives prevent constipation. Other less frequent manifestations of autonomic dysfunction associated with vinca alkaloids include bladder atony with urinary retention, impotence, and orthostatic hypotension.[179,180] Patients should be monitored carefully for these signs or symptoms and receive appropriate management after diagnosis.

CARDIOTOXICITY

Cardiomyopathy

Doxorubicin

CASE 94-7

QUESTION 1: D.A., a 35-year-old man with stage IV Hodgkin lymphoma, is receiving ABVD (doxorubicin 25 mg/m^2 IV days 1, 15, bleomycin 10 units/m^2 IV on days 1, 15, vinblastine 6 mg/m^2 IV on days 1, 15, and dacarbazine 375 mg/m^2 IV on days 1 and 15) and concurrent radiation therapy to a large mediastinal mass. He comes to the clinic to receive his fifth cycle of ABVD and complains of tachycardia, SOB, and a nonproductive cough. Physical examination reveals neck vein distension, pulmonary rales, and ankle edema. Past medical history is significant for controlled hypertension. What is the most likely cause of D.A.'s current symptoms?

D.A. is experiencing symptoms of congestive heart failure (CHF) most likely caused by doxorubicin therapy. Doxorubicin, an anthracycline, can cause a dose-dependent cardiomyopathy that generally occurs with repeated administration. Doxorubicin causes myocyte damage by a mechanism that differs from its cytotoxic effect on tumor cells. Because myocytes stop dividing in infancy, they presumably would not be affected by an agent whose cytotoxicity relies on actively cycling cells. Many mechanisms have been proposed to explain the cardiac toxicity associated with anthracyclines including the formation of reactive oxygen species.[181–184] The association of anthracycline-induced cardiotoxicity with other agents administered concomitantly, monitoring techniques, and therapies to prevent and treat this condition have been reviewed.[181,185,186]

D.A.'s presentation is fairly typical of doxorubicin-induced cardiomyopathy, although he has no significant risk factors usually associated with CHF. The total cumulative dose of doxorubicin is the most clearly established risk factor for CHF.[187] Patients, such as D.A., who are receiving bolus doses of doxorubicin at the standard 3-week interval face little risk of CHF until a total dose of 450 to 550 mg/m^2 has been reached. After a patient has received a total dose greater than 550 mg/m^2, the risk of CHF rises rapidly. Patients receiving less than 550 mg/m^2 of doxorubicin face a 0.1% to 1.2% risk of experiencing CHF. Comparatively, patients receiving greater than 550 mg/m^2 face a risk that rises more or less linearly; the probability of CHF in patients receiving a total dose of 1,000/m^2 may be nearly 50%.[187]

Other factors that could increase D.A.'s risk of experiencing doxorubicin cardiomyopathy include mediastinal radiation therapy, preexisting cardiac disease, and hypertension. Young children, as well as older patients, are likely to experience CHF at a lower cumulative dose. Concurrent chemotherapy agents (e.g., cyclophosphamide, etoposide, mitomycin, melphalan, trastuzumab, paclitaxel, vincristine, bleomycin) may also potentiate doxorubicin cardiac toxicity.[181,185] When patients receive paclitaxel and doxorubicin, the risk of cardiac toxicity appears to be related to the sequence and proximity of the infusions. In a pharmacokinetic study, paclitaxel increased the AUC of doxorubicin and its active metabolite, doxorubicinol, when paclitaxel administration immediately preceded doxorubicin. Therefore, doxorubicin should be given at least 30 minutes before paclitaxel. The relationship between risk factors and the total cumulative dose of doxorubicin is sufficiently strong to warrant guidelines restricting the total cumulative dose of doxorubicin to 450 mg/m^2 in patients with one or more identified risk factors including mediastinal radiation, elderly age, and preexisting cardiovascular

---

disease (high-risk patients) and to 550 mg/m^2 in patients without any of these aforementioned risk factors (low-risk patients).

It is unusual that D.A., a 35-year-old man who has received a cumulative dose of only 200 mg/m^2 of doxorubicin, would be presenting with symptoms of CHF. Mediastinal radiation therapy, or an undiagnosed cardiac disease may, however, have contributed to this event. In addition, Hodgkin lymphoma involving the myocardium may be responsible for this presentation.

Cardiac Monitoring

CASE 94-7, QUESTION 2: Should D.A. receive routine cardiac monitoring while he is receiving doxorubicin?

Doxorubicin

Prevention of cardiomyopathy is achieved primarily by limiting the total cumulative dose. Limiting the total dose, however, cannot entirely prevent the cardiomyopathy for two reasons. First, individual tolerance to doxorubicin varies such that cardiotoxicity may occur before the arbitrary dose limit; second, some clinical situations warrant exceeding the dose limit to achieve positive chemotherapeutic outcomes.

Early efforts to prevent cardiomyopathy focused on monitoring systolic time intervals, QRS voltage loss, or ST-T segment changes on an electrocardiogram. These changes were too nonspecific or occurred too late to be useful; however, serial echocardiography (ECHO) has been useful. Current monitoring for anthracycline cardiomyopathy includes assessment of a patient's left ventricular ejection fraction (LVEF), which is a measure of the heart's systolic function by ECHO, radionuclide cardiac angiography (multiple gated acquisition [MUGA]), or endomyocardial biopsy. The use of MUGA for early detection of doxorubicin-induced cardiac dysfunction has been investigated extensively.[188] A MUGA can accurately detect functional cardiac status, but it is not particularly sensitive in detecting patients who have early myocyte damage. Augmenting the MUGA with exercise appears to give a more accurate picture of functional cardiac reserve. Because myocyte damage usually occurs days to weeks after treatment with doxorubicin, the MUGA should be obtained just before, rather than just after, a course of the agent. Although guidelines vary, most suggest regular cardiac function assessment by evaluation of LVEF by either ECHO or MUGA.[185]

D.A. should have received a baseline assessment of his LVEF either by ECHO or MUGA before his first cycle of ABVD. During courses of therapy, LVEF monitoring for D.A. would not have been routinely recommended unless he was approaching his lifetime cumulative dose or there were clinical signs or symptoms of CHF. Because D.A. presented before his fifth cycle of ABVD with symptoms of CHF, another ECHO should be performed, and his doxorubicin should be discontinued.

Additional assessments should be obtained when a patient shows signs or symptoms of CHF or when low-risk patients receive cumulative doxorubicin doses greater than 450 mg/m^2 or high-risk patients receive greater than 350 mg/m^2, if additional doses are planned. Most guidelines recommend stopping doxorubicin or obtaining an endomyocardial biopsy when there is an absolute decrease in the LVEF of greater than 10% to 20%, the LVEF is less than 40%, or the LVEF fails to increase greater than 5% with exercise. Endomyocardial biopsies, along with a quantitative assessment of morphologic changes, provide the most specific evaluation of myocardial damage induced by anthracyclines. Progressive myocardial pathology is graded on a scale (the Billingham score) of 0 (no change from normal) to 3 (diffuse cell damage in >35% of total number of cells with marked change in cardiac ultrastructure).[189] Abnormal MUGA findings and the appearance of signs and symptoms of CHF correlate with biopsy scores. Usually, a significant change in cardiac function is not seen with scores less than 2 to 2.5. Several investigators have evaluated the predictive value of this technique. With a score of 2, a patient has less than a 10% chance of experiencing heart failure if 100 mg more of doxorubicin is given.[190] The most significant risk associated with endomyocardial biopsy is perforation of the right ventricle with associated tamponade; this occurs rarely and depends largely on the experience of the individual performing the biopsy.

Other Anthracyclines

Daunorubicin differs structurally from doxorubicin only by hydroxylation of the fourteenth carbon. Cardiac toxicities are similar for both drugs, although somewhat higher cumulative doses of daunorubicin are typically tolerated.[191] Although idarubicin appears less cardiotoxic than doxorubicin in animal models and daunorubicin in some early clinical trials, other studies show equivalent myelosuppressive doses can cause cardiotoxicity comparable to that of doxorubicin and daunorubicin.[192–194] Epirubicin also has an incidence of demonstrated CHF.[195] For all of the agents in the anthracycline class, risk factors for CHF appear to be the same, and similar assessments should be undertaken to monitor for cardiotoxicity. Mitoxantrone is an anthracenedione that is structurally similar to the anthracyclines. Guidelines for monitoring doxorubicin-induced cardiotoxicity should also be followed with mitoxantrone therapy to minimize the risk for CHF.[185]

Prevention

CASE 94-7, QUESTION 3: Could D.A.'s CHF be prevented by the use of a different dose or dosing schedule or by an agent that protects the myocardium?

Altering the dose schedule of doxorubicin to more frequent, smaller doses while maintaining dose intensity has consistently resulted in reduction of cardiotoxicity without obvious compromise of antitumor effects.[196–200] Several reports suggest that peak plasma levels, as well as cumulative dose, have an important relationship to doxorubicin cardiotoxicity. Low doses of doxorubicin administered weekly or prolonged continuous IV infusions (48–96 hours) can be relatively cardiac sparing, allowing higher cumulative doses to be administered. In a retrospective, uncontrolled study of 1,000 patients receiving weekly doxorubicin, a total dose of 900 to 1,200 mg/m^2 of doxorubicin given in weekly fractions had the equivalent cardiotoxicity of 550 mg/m^2 given in every-3-week fractions.[197] Although well-designed studies comparing cardiac toxicity after bolus doses with fractionated therapy or continuous infusion are lacking, treatment that incorporates these alternative schedules should be considered in patients with preexisting risk factors who will be receiving doses greater than 450 mg/m^2 or in patients without risk factors who will be receiving doses greater than 550 mg/m^2. In patients with preexisting CHF or those who have exhibited CHF, a continuous-infusion schedule of anthracyclines rather than bolus doses may be considered. The concurrent use of drugs that might minimize the risk of cardiotoxicity without compromising efficacy can be considered as well.

Dexrazoxane is a chemoprotectant that reduces the incidence and severity of cardiomyopathy. It is indicated in women with metastatic breast cancer who have received a cumulative doxorubicin dose of 300 mg/m^2. The recommended dosing ratio of dexrazoxane to doxorubicin is 10:1 slow IV push 30 minutes before starting doxorubicin. Currently, the ASCO guidelines do not support the routine use of dexrazoxane in patients unless a plan exists to continue doxorubicin beyond a total cumulative dose greater than 300 mg/m^2.[44] Clinical trials have evaluated the benefits of dexrazoxane in children and patients receiving other anthracyclines. A meta-analysis including 10 trials with a total of 1,619 patients evaluated the use of dexrazoxane in anthracycline therapy and observed a decreased risk of clinical HF (relative risk 0.18, CI 0.1–0.32, $p < 0.001$), but there was no effect on overall survival.[201] Despite data suggesting cardioprotection with the use of dexrazoxane, it is not used routinely. Concerns exist about a possible decrease in efficacy of anthracyclines with its use as well as the potential for an increase in secondary leukemias. In the meta-analysis, there was no difference in tumor response rate reported and toxicities attributed to dexrazoxane only included an increased frequency of risk of neutropenia that resolved with count recovery.[201]

To reduce cardiotoxicity, doxorubicin that is encapsulated in liposomes can be given instead. A Phase III trial of women ($n = 509$) with metastatic breast cancer showed that efficacy with liposomal pegylated doxorubicin may be similar to conventional doxorubicin with decreased cardiotoxicity.[202] A review and meta-analysis of 55 randomized control trials in patients receiving anthracyclines showed that the risk of cardiotoxicity was significantly decreased with liposomal doxorubicin versus conventional doxorubicin (odds ratio, 0.18; 95% confidence interval, 0.08–0.38).[203] The majority of patients were women with advanced breast cancer. Despite reduced cardiotoxicity, liposomal doxorubicin has not replaced standard doxorubicin in current treatment regimens secondary to high cost and lack of evidence showing equivalency. An established equivalent dose of liposomal preparations to conventional doxorubicin is not confirmed and is variable depending on the disease state and regimen.

D.A.'s CHF may have been prevented with continuous-infusion doxorubicin or the use of dexrazoxane; however, because he had not approached a cumulative dose that warranted alternative strategies, this would not have been part of the standard management plan for a patient receiving their first several cycles of ABVD.

Management

CASE 94-7, QUESTION 4: How should D.A.'s doxorubicin-induced CHF be managed clinically?

Anthracycline-induced CHF presents similarly to other forms of biventricular CHF and occurs between 0 and 231 days after the last dose of doxorubicin (mean, 33 days). Anthracycline-induced CHF should be treated with a similar approach to cardiomyopathy induced by other means. Often these measures are ineffective. The clinical course varies, with some patients showing stable disease and others showing improvement. Before cardiotoxicity was a widely recognized toxicity, the course of anthracycline-induced CHF was characterized by a rapid progression that generally led to death in a few weeks. The clinical outcome is better now, likely because anthracycline therapy is promptly discontinued after initial presentation and there are better treatments for CHF. These include the use of spironolactone, β-blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers, and diuretics, which have decreased morbidity and mortality in non-anthracycline-induced CHF. Enalapril was evaluated to determine whether it would prevent cardiac function decline in a randomized, double-blind, placebo-controlled study of pediatric cancer patients who were at least 2 years out from treatment with anthracyclines and had evidence of CHF. Patients received enalapril at 0.05 mg/kg/day and this dose was progressively escalated to 0.10 mg/kg/day, and finally 0.15 mg/kg/day if there were no side effects. Although enalapril did not increase exercise intolerance, it did increase left ventricular end-systolic wall stress in the first year of treatment. Side effects included dizziness, hypotension, and fatigue.[204,205] An additional trial evaluated 201 patients with anthracycline-induced cardiomyopathy. Enalapril and carvedilol were initiated as tolerated as soon as LVEF impairment was observed. Complete resolution of CHF was observed in 85 (42%) of patients, and an additional 26 (13%) demonstrated a partial response. Patients who had heart failure therapy initiated closer to the time of observation of their LVEF impairment had better response. No responses were observed in patients who had heart failure therapy initiated greater than 6 months from the end of their anthracycline regimen.[206] D.A.'s cardiomyopathy should be managed conservatively with an ACE inhibitor such as enalapril and fluid restriction with the addition of diuretics as necessary.[183]

Trastuzumab

In addition to anthracyclines, trastuzumab has also been associated with increased cardiotoxicity, likely through a different mechanism. Signs and symptoms of CHF (e.g., dyspnea, increased cough, peripheral edema, S_3 gallop, and reduced ejection fraction) have been reported in 3% to 7% of patients receiving trastuzumab single-agent therapy. Of these patients, 5% had New York Heart Association (NYHA) class III or IV heart failure. The use of trastuzumab in combination with chemotherapy in patients (n = 469) with metastatic breast cancer was associated with a 27% incidence of cardiotoxicity compared with an overall 8% incidence in the anthracycline-alone arm. In these same patients, the incidence of NYHA class III or IV heart failure was 16% in the trastuzumab and chemotherapy arm versus 3% in patients receiving anthracyclines alone. Additionally, heart failure occurred in the combination paclitaxel and trastuzumab arm with an overall incidence of 13% and 2% (classes III and IV, respectively) versus a 1% incidence in the paclitaxel-alone arm.[207] A meta-analysis of five randomized trials of adjuvant trastuzumab also showed a 2.5 higher risk of cardiotoxicity following trastuzumab administration.[208] The toxicity seems to be direct and not dependent on cumulative dose or treatment duration. Trastuzumab-associated cardiac toxicity usually responds to standard medical treatment or discontinuation of the drug.[181] Before, and periodically during treatment with trastuzumab, patients should undergo cardiac evaluation to assess left ventricular ejection fraction. Therapy should be discontinued if patients exhibit a clinically significant decrease in left ventricular function.

Multitargeted Tyrosine Kinase Inhibitors

The multitargeted tyrosine kinase inhibitors exhibit a range of cardiovascular toxicities. Because these agents are dosed chronically, toxicities may develop relatively late in the course of therapy. Imatinib has been associated with the development of CHF. A single-institution series reviewed all patients (n = 1,276) who had received imatinib within their institution. Twenty-two patients (1.2%) exhibited CHF. Eleven patients continued imatinib with the addition of diuretics, β-blockers, and ACE inhibitors. Five of those who continued therapy with imatinib had dose reductions. The remaining eleven discontinued imatinib (3 secondary to disease progression, 6 secondary to CHF, and 2 were deaths).[209] Patients receiving imatinib should be monitored for symptoms and signs of heart failure.[210] Dasatinib has also been associated with heart failure and ventricular dysfunction.[211] Sorafenib and sunitinib have been associated with a decline in cardiac ejection fraction in 5% and 14%, respectively, in 86 patients treated for metastatic renal cell cancer.[212] A decline in cardiac function has also been reported in a pooled analysis of 3,689 patients with breast cancer receiving lapatinib. The incidence was 1.6% (60 patients). Twelve of the patients had prior anthracyclines and fourteen had received prior

trastuzumab.[213] There have been additional oral oncolytic agents associated with CHF including pazopanib and vemurafenib.[185] Patients experiencing cardiomyopathy on targeted agents are treated similarly to those patients with anthracycline-induced cardiomyopathy. Discontinuation of the offending agent or reduction of dose with concurrent pharmacologic management of CHF is warranted. Two reviews of proposed mechanisms and reported incidence of targeted therapy-induced cardiomyopathy therapies provide a summary of current evidence.[181,214]

Arrhythmias

Electrocardiographic (ECG) changes have been observed during or after treatment with doxorubicin, other anthracyclines, cisplatin, etoposide, paclitaxel, cyclophosphamide, mechlorethamine, and arsenic. ST-T segment changes, decreases in voltage, T-wave flattening, and atrial and ventricular ectopy are most common. Arrhythmias may occur in 6% to 40% of patients receiving bolus doxorubicin.[215] Paclitaxel also caused significant arrhythmias and conduction defects in Phase I and

II trials[216]; most patients experienced sinus bradycardia. Doxorubicin and paclitaxel are used in many outpatient regimens, so this toxicity is seen frequently. Arsenic, used in the treatment of APL, can cause QT interval prolongation and complete atrioventricular block. Dasatinib, nilotinib, lapatinib, pazopanib, and sunitinib have also demonstrated QT prolongation.[185] The underlying mechanisms for these prolongations are not yet understood. Nilotinib, with a reported incidence of 1% to 10%, carries a black box warning regarding prolongation of the QT interval. The package insert gives specific recommendations for monitoring of ECGs; baseline, 7 days after initiation, after any change of dose, and routinely thereafter.[217] QT prolongation can lead to a torsade de pointes-type ventricular arrhythmia. Before initiating therapy, an ECG should be performed, and serum electrolytes, including potassium and magnesium, should be assessed and corrected. Additionally, all medications, both anticancer and other supportive care medications that are known to prolong the QT interval, should be discontinued.[185] Many other anticancer agents not mentioned previously occasionally cause a rhythm disturbance, but these are limited to a few scattered reports and should not be considered clinically significant. Therapy should not be discontinued unless the patient experiences a serious cardiac arrhythmia.

Hypertension

An increased incidence of hypertension has been observed in patients receiving VEGF-targeted therapy including bevacizumab, sunitinib, sorafenib, axitinib, regorafenib, and pazopanib among others. Bevacizumab-related hypertension may be dose-related; it can occur at any time during therapy and is reported to have a 22% to 32% incidence. Hypertension is usually grade 3 or less and can be controlled with antihypertensive medications.[218] An increased risk of myocardial ischemia and infarction has been observed with the use of sorafenib in patients with metastatic renal cell cancer in a Phase III study.[219] Patients receiving these agents should be routinely monitored for hypertension and antihypertensives promptly initiated. In patients with uncontrolled hypertension, anticancer therapy medication may need to be dose-reduced or discontinued. Several consensus statements and guidelines have been published to assist in the hypertension management of patients in VEGF inhibitors.[220,221]

Angina and Myocardial Infarction

Fluorouracil and capecitabine have been associated with angina pectoris and myocardial infarction. In a systematic review including 30 studies, symptomatic cardiotoxicity occurred in 0% to 20% of the patients treated with fluorouracil and in 3% to 35% with capecitabine. The most common symptom was chest pain (0%–18.6%) followed by palpitations (0%–23.1%), dyspnea (0%–7.6%), and hypotension (0%–6%). It appears to occur more frequently in patients receiving multiple-day continuous infusions.[222] Direct myocyte damage is observed from animal studies; however, human studies suggest that coronary artery spasm is the most likely cause of angina. Because the chest pain associated with fluorouracil responds to nitrates, this problem, theoretically, could be managed prophylactically or therapeutically with long-acting nitrates or calcium-channel blockers.[221] Other agents have been associated with myocardial ischemia (including, but not limited to temsirolimus, docetaxel, paclitaxel, and imatinib) based on case reports in the literature.[185]

NEPHROTOXICITY

Cisplatin

CASE 94-8

QUESTION 1: T.J., a 58-year-old man with nonresectable head and neck cancer, is being treated with cisplatin 100 mg/m^2 IV on day 1 and fluorouracil 1 g/m^2/day IV on days 1 to 4. He received 1 L of normal saline (NS) before and 1 L of NS after his cisplatin on day 1. He presents today for the third cycle of this regimen. T.J.'s labs reveal an estimated creatinine clearance (CrCl) of 75 mL/minute, decreased from 110 mL/minute at baseline. Other abnormalities include serum magnesium of 1.2 mEq/L; all other electrolyte values are within normal range. Is cisplatin responsible for T.J.'s decreased glomerular filtration rate (GFR) and serum magnesium levels?

Cisplatin, a platinum heavy metal complex, is active against many solid tumors and remains as part of first-line therapy for lung, head and neck, and testicular cancers. The major dose-limiting toxicity of cisplatin is nephrotoxicity, and various renal and electrolyte disorders, both acute and chronic, have been associated with cisplatin. In the early 1970s, before the need for vigorous hydration was recognized, cisplatin often caused acute renal failure. Today, with the use of vigorous hydration, acute renal failure is uncommon; however, tubular dysfunction and decreased GFR remain problematic.

Morphologic damage is greatest in the straight segment of the proximal renal tubules where the highest concentration of platinum occurs. Acute and cumulative renal tubular damage has been demonstrated by increased urinary excretion of proximal tubular enzymes, such as β_2-microglobulin, alanine aminopeptidase, and N-acetyl glucosamine. Acute renal failure occurs from acute proximal tubular damage and presents as polyuria in the first 24 to 48 hours when urine osmolality declines, but GFR is normal. Polyuria will decline, and then 72 to 96 hours later polyuria increases again, urine osmolality declines, and the GFR declines as well and is persistent. Increases in proximal tubular enzymes correlate well with urinary excretion of protein and magnesium as well as decreased reabsorption of salt and water in the proximal tubules. T.J. has hypomagnesemia, which is the most common electrolyte abnormality caused by cisplatin. Hypomagnesemia appears to be dose-related and may occur after a single treatment. Despite replacement with oral magnesium, renal losses of magnesium and decreased serum magnesium levels can persist for months or even years after completion of cisplatin therapy. Hypocalcemia, hyponatremia, and hypokalemia occur less frequently. The cause of these electrolyte abnormalities is thought to be similar to that of hypomagnesemia in that a proximal tubular defect occurs that interferes with reabsorption of these electrolytes.[223,224]

Chronic renal toxicity associated with cisplatin presents as a decrease in the GFR. Published reports suggest that the GFR decreases by 12% to 25% in most patients receiving multiple courses.[224] The decrease appears to be persistent and only partially reversible. An increase in serum creatinine or a decrease in CrCl does not necessarily reflect the decline in GFR. T.J. is at risk for chronic renal toxicity because he has previously received two other cycles. The renal function of patients receiving cisplatin therapy should be evaluated, because dosage reductions of cisplatin may be necessary if the CrCl decreases. T.J.'s decreased GFR and low serum magnesium likely are caused by repeated cycles of cisplatin therapy. Although a dose reduction of cisplatin generally is not recommended for creatinine clearances that are greater than 60 mL/minute, the clinician should provide T.J. with adequate and aggressive hydration to prevent cisplatin nephrotoxicity. Despite preventive methods, many patients will still experience declines in GFR as seen in T.J. In addition, T.J. should receive an oral magnesium supplement. When large doses of magnesium are necessary, diarrhea often limits the use of oral supplementation. IV administration should be used if higher magnesium doses are required. Patients should undergo frequent measurements of their electrolytes, including magnesium, to minimize potential complications.

Prevention

CASE 94-8, QUESTION 2: What measures should be taken to prevent further cisplatin nephrotoxicity in T.J.?

Several measures are used to minimize or prevent cisplatin- induced nephrotoxicity, including hydration with saline and prophylactic magnesium. Incorporation of hydration with saline and magnesium is the standard of care for all patients receiving cisplatin. The patient should be vigorously hydrated with 2 to 3 L of normal saline over 8 to 12 hours to maintain a urine output of 100 to 200 mL/hour for at least 6 hours after treatment with cisplatin.[223–225] A loop diuretic (e.g., furosemide) may be required in elderly patients to eliminate excess sodium or in patients with compromised cardiac reserve, but these diuretics should not be used routinely to prevent nephrotoxicity. Additionally, mannitol (25–50 g) may be administered just before chemotherapy to prevent cisplatin-induced renal artery vasoconstriction, which can increase the concentration of platinum in the renal tubules. The use of mannitol is controversial and is not given in all practice settings. Most patients may also benefit from prophylactic magnesium supplementation.

Patients who received prophylactic magnesium 16 mEq IV daily during a 5-day course of cisplatin followed by 60 mEq orally (20 mEq 3 times daily) between courses experienced less nephrotoxicity compared with those who received no supplements in a prospective trial of 16 patients with testicular carcinoma.[226] T.J. should be encouraged to increase his oral hydration to 2 to 3 L/day for several days after this cycle of chemotherapy. Additionally, he should take oral magnesium supplementation between courses. For cycle 4 of his chemotherapy, he should receive 3 to 4 L of saline the day of cisplatin administration. He may also receive 25 to 50 g of IV mannitol before cisplatin to reduce his risk of further nephrotoxicity.

Patients who experience renal dysfunction commonly have the dose of cisplatin reduced. Guidelines to modify the dosage of cisplatin in patients with decreased renal function are available. Most suggest a 50% dosage reduction when the GFR decreases to 30 to 60 mL/minute and discontinuation when the GFR falls to less than 10 to 30 mL/minute. Percentage dose reductions are relative to the recommended dose for a specific cancer in a given combination chemotherapy regimen.[227] Because the cisplatin dose ranges from 50 to 120 mg/m^2, the precise dose for a patient with a GFR of less than 60 mL/minute must be individualized to the situation. T.J. should have another SCr drawn to estimate CrCl before his next cycle. As long as his CrCl is maintained above 60 mL/minute, then no dose reductions of his cisplatin are necessary. If a tumor type is known to be responsive to carboplatin and efficacy will not likely be compromised, substitution of carboplatin should be considered because it does not cause nephrotoxicity. Carboplatin is excreted primarily by the kidneys and the dose is calculated by the Calvert equation,[228] which accounts for decreased GFR (discussed further in Chapter 98, Lung Cancer). Therefore, patients who have decreased renal function receive lower doses than those with normal function. Other agents requiring dose adjustments or omission for renal dysfunction are shared in Table 94-9.

Other Nephrotoxic Agents

Proximal Tubule Dysfunction

Other agents reported to cause renal tubular defects include lomustine, carmustine, ifosfamide, pemetrexed, and azacytidine.[223,225] Nephrotoxicity appears to be related to the total cumulative dose for carmustine and lomustine, but not necessarily for ifosfamide. Renal abnormalities associated with high doses of bolus ifosfamide have led to the use of fractionated doses and a reduced incidence of toxicity.[223] Most patients show signs and symptoms consistent with proximal tubular dysfunction.

The primary renal lesion associated with each of these agents occurs in the proximal renal tubule and patients experience several electrolyte imbalances, such as loss of protein, glucose, bicarbonate, and potassium. Serum creatinine, bicarbonate, potassium, urinary pH, protein, and glucose should be monitored closely in patients receiving these agents. Because the reversibility of the lesions is reported to be highly variable and a significant number of patients who exhibit severe renal toxicity with these agents require dialysis,[223] patients should discontinue treatment with these agents if they show any changes in serum creatinine or electrolytes.

Proteinuria

Bevacizumab, an anti-VEGF monoclonal antibody, is associated with proteinuria and the reported incidence ranges from 21% to 46% of patients.[229] While bevacizumab is the anti-VEGF agent most noted with this toxicity, oral tyrosine kinase inhibitors that affect the VEGF receptor such as axitinib have also been associated with proteinuria.[230] Mechanisms for this toxicity include microcirculatory angiogenesis and inhibition of nitric oxide synthesis. This may lead to an increase in peripheral resistance and endothelial dysfunction. Glomerular injury from VEGF inhibition may also lead to renal thrombotic microangiopathy and glomerulonephritis. Severe nephrotic syndrome has been observed in 1% to 2% of patients.[221,229,231] Patients receiving bevacizumab should be monitored routinely for proteinuria by dipstick urinalysis. The manufacturer recommends that patients with a 2+ or greater urine dipstick reading undergo further assessment with a 24-hour urine collection. Additionally, it is recommended to delay further administration of bevacizumab when greater than 2 g of proteinuria in 24 hours is observed. Therapy may be reinitiated when the proteinuria observed is less than 2 g in 24 hours. Proteinuria is most often mild in patients and is usually reversible upon discontinuation of the agent. The highest incidence of severe proteinuria requiring permanent discontinuation has been seen in patients with metastatic renal cell carcinoma.[232]

Table 94-9

Anticancer Agents Requiring Dosage Modifications or Dosage Omissions in Renal Insufficiency

Bleomycin	Lenalidomide
Capecitabine	Lomustine
Carboplatin	Melphalan
Carmustine	Methotrexate
Cisplatin	Mitomycin
Cytarabine	Pemetrexed
Dacarbazine	Pentostatin
Fludarabine	Topotecan
Ifosfamide

CASE 94-9

QUESTION 1: J.R., a 15-year-old boy with osteogenic sarcoma of the right knee, is to be treated with chemotherapy consisting of high-dose methotrexate with leucovorin rescue, doxorubicin, and cisplatin. The dose of methotrexate is 12 g/m^2 IV administered over 4 hours. What precautions are necessary to prevent the renal and other toxicities associated with high-dose methotrexate therapy in J.R.?

Methotrexate normally is not nephrotoxic, although 90% of the agent is excreted unchanged in the urine; however, acute tubular obstruction can occur with high-dose methotrexate if appropriate precautions are not taken. Acute tubular obstruction is caused by tubular precipitation of methotrexate, which is poorly soluble at a pH less than 7.0. To prevent this, J.R. should receive hydration and brisk diuresis to produce urine output of 100 to 200 mL/hour for at least 24 hours after administration. A urine pH greater than 7.0 usually can be ensured by administration of 25 to 150 mEq/L sodium bicarbonate within the hydration fluid. J.R.'s urine output and pH must be monitored closely to prevent acute tubular obstruction during this period.[233] In addition, intrapatient and interpatient variability in methotrexate clearance is considerable, particularly with high doses of methotrexate therapy. Renal excretion of methotrexate is a complex process involving glomerular filtration, tubular reabsorption, and secretion. Acute tubular obstruction associated with high-dose methotrexate therapy can be prevented only by appropriate attention to optimal urinary output before, and for at least 24 hours after, high-dose methotrexate administration and urinary alkalization.[233]

If J.R. has existing renal insufficiency, methotrexate excretion will be decreased, leading to higher systemic exposure. As a result, myelosuppression and mucositis can become more problematic. Leucovorin (folinic acid) is a reduced form of folic acid given after methotrexate administration to selectively rescue normal cells from adverse effects such as myelosuppression and mucositis. Because leucovorin is already in reduced form, it can bypass the action of dihydrofolate reductase and not interfere with methotrexate's inhibition of this enzyme. Therefore, it is important that leucovorin rescue is initiated 24 hours after the high-dose methotrexate infusion. Blood concentrations of methotrexate obtained within 24 hours after the infusion often are not predictive of concentrations at 48 hours. Therefore, methotrexate concentrations between 24 and 48 hours after infusion must be monitored in J.R. and in all patients receiving high-dose therapy. Methotrexate levels are necessary to guide leucovorin dosing. Leucovorin rescue does not affect the renal clearance of methotrexate. A rescue agent, glucarpidase, is indicated for the treatment of toxic methotrexate concentrations in patients with delayed methotrexate clearance due to impaired renal function. Glucarpidase is a recombinant bacterial carboxypeptidase enzyme that converts methotrexate to its inactive metabolites, and provides an alternative route for methotrexate elimination in patients with renal dysfunction and signs or symptoms of methotrexate toxicity.[234]

HEMORRHAGIC CYSTITIS

Ifosfamide

CASE 94-9, QUESTION 2: After J.R.'s surgery, it is decided to add ifosfamide to his treatment. What bladder toxicity occurs with ifosfamide that requires attention before its administration?

Pathogenesis

Ifosfamide is a structural analog of cyclophosphamide belonging to the oxazaphosphorine class of antitumor alkylating agents, which must be hydroxylated and activated by the cytochrome P-450 3A4/3A5 and 2B6 enzymes in the liver. The 4-hydroxy metabolite spontaneously liberates acrolein, which is excreted in high concentrations in the urine. Acrolein is responsible for urotoxicity causing a direct irritation of the bladder mucosa. Both ifosfamide and cyclophosphamide can produce cystitis, which ranges from mild-to-severe bladder damage and hemorrhage. Cystitis is characterized by tissue edema and ulceration followed by sloughing of mucosal epithelial cells, necrosis of smooth muscle fibers and arteries, and culminating in focal hemorrhage.

Clinical Presentation

Patients with acrolein-induced hemorrhagic cystitis initially go through an asymptomatic stage characterized by complaints of brief episodes of painful urination, frequency, and hematuria. The symptoms may subside over a period of several days or weeks after discontinuing the agent. The course of acrolein-induced hemorrhagic cystitis usually is relatively benign, although death from massive refractory hemorrhage has occurred.[235] The primary factors that may predispose J.R. to hemorrhagic cystitis include the dose of ifosfamide he is receiving.

Prevention

Historically, forced hydration was the primary method used to prevent hemorrhagic cystitis in patients treated with cyclophosphamide therapy. Theoretically, hydration flushes the toxic acrolein metabolite out of the bladder so that insufficient contact time is available to set up the tissue reaction. The more urotoxic agent, ifosfamide, was introduced to the market with a uroprotective agent, mesna. This agent contains a free thiol group, which can neutralize acrolein in the bladder. When administered in an appropriate dosing schedule, mesna can prevent the bladder toxicity completely, and thus use of mesna is the current standard of care.[225,235]

The ASCO guidelines recommend a parenteral mesna dose of 20% of the ifosfamide dose given at zero, 4, and 8 hours after ifosfamide (for a total mesna dose of 60% of the ifosfamide dose).[44] The goal is to maintain prolonged mesna concentrations within the urinary tract that are uroprotective. Repeated administration is required because mesna has a much shorter elimination half-life (<1 hour) than ifosfamide. If patients receive a continuous infusion of ifosfamide, a different dosing strategy for mesna is required. To prolong mesna's protective effects, ASCO guidelines recommend an IV bolus mesna dose that is 20% of the ifosfamide dose, followed by a mesna continuous infusion that is an additional equivalent of 40% given during and for 12 to 24 hours after the end of the ifosfamide infusion.[46] This regimen ensures that mesna remains

---

in the bladder for an extended amount of time after the end of the ifosfamide infusion.

Various other mesna dosing schedules are clinically used, but no trials have compared the different regimens. Many clinicians use a 1:1 mg dose of mesna to ifosfamide when administered by continuous infusion. The dosing guidelines become less well defined, however, when patients receive higher dosages of ifosfamide (>2.5 g/m^2). The lack of data and the unique pharmacokinetic properties of ifosfamide have caused some concerns about the current dosing guidelines. The pharmacokinetics of ifosfamide are nonlinear. For example, the elimination half-life associated with doses of 2.5 g/m^2 is 6 to 8 hours, whereas with doses of 3.5 to 5 g/m^2, it is 14 to 16 hours. The current recommendations for mesna administration enable protection for approximately 12 hours after an IV bolus; thus, with higher dosages of ifosfamide, mesna should be infused beyond the recommended 8 hours after ifosfamide to maintain bladder protection.[235] Also, concern exists that the 4-hour dosing interval used with lower doses may be inadequate to maintain sufficient mesna concentrations within the bladder. To ensure maximal protection against urotoxicity, ASCO currently recommends more frequent or prolonged mesna dosage regimens to account for its short half-life.[44] Ifosfamide and mesna are compatible in solution; therefore, they can be infused together, offering greater patient convenience.

Because mesna works in the bladder, frequent urination may diminish its efficacy. Patients may be reminded to try to empty their bladder every few hours. Although forced hydration has been the mainstay for prevention of cyclophosphamide-induced hemorrhagic cystitis, it is unnecessary and potentially disadvantageous when mesna is used. This is because forced hydration can increase urination and thus the evacuation of mesna from the bladder.

Mesna is usually given IV but an oral formulation is available. The oral bioavailability of mesna is approximately 50%; therefore, patients should receive twice the standard IV dose (e.g., oral mesna 40% of the IV ifosfamide dose) 2 hours before and 4 and 8 hours after ifosfamide.[236] Others have recommended that an oral dose also be given with the ifosfamide dose. Many centers administer the first dose of mesna IV followed by oral doses at 4 and 8 hours, particularly in the outpatient clinic setting.[44] All patients receiving cyclophosphamide should receive saline diuresis or forced saline diuresis to protect urothelial tissue. When patients receive cyclophosphamide for an HCT, it is at high dose; therefore, they receive mesna and hydration. Other practices to prevent this complication include hyperhydration and the use of continuous bladder irrigation. Data comparing these methods are controversial and report varying rates of hematuria and severe hemorrhagic cystitis. These recommendations are currently supported by the ASCO consensus guideline[44] (see Chapter 101, Hematopoietic Cell Transplantation). J.R. will receive mesna at a dose of 20% of the ifosfamide dose given immediately before ifosfamide, and at 4 and 8 hours after ifosfamide (for a total mesna dose of 60% of the ifosfamide dose).

Treatment

CASE 94-9, QUESTION 3: If J.R. exhibits hemorrhagic cystitis, how should it be treated?

Once hemorrhagic cystitis develops, the agent causing the disorder must be discontinued and vigorous hydration started. If gross hematuria occurs, a large-bore urinary catheter should be inserted to avoid obstruction of the urethra by clots. Some clinicians also use continuous silver nitrate irrigation, local instillation of formalin or alum, or electrocauterization of bladder blood vessels to control bleeding. There is no consensus as to which of these methods is superior. If these measures fail, surgical intervention may be necessary to divert urine flow away from the bladder.[235,237]

PULMONARY TOXICITIES

Bleomycin and Other Agents

CASE 94-10

QUESTION 1: J.A., a 54-year-old man with stage III Hodgkin lymphoma, has received ABVD (doxorubicin 25 mg/m^2 IV days 1 and 15, bleomycin 10 units/m^2 IV on days 1 and 15, vinblastine 6 mg/m^2 IV on days 1 and 15, and dacarbazine 375 mg/m^2 IV on days 1 and 15) for six cycles. He presents to the clinic 6 months after his last cycle with dyspnea, a nonproductive cough, and fever. Chest radiograph showed diffuse bilateral infiltrates; his respiratory rate was 36 breaths/minute; and his arterial blood gases (ABG) were as follows:

pH, 7.50
PO_2, 62 mm Hg
PCO_2, 28 mm Hg
O_2 saturation, 92%

What are the possible causes of his new pulmonary findings?

J.A. is at risk for several processes that could produce diffuse pulmonary infiltrates and dyspnea. He is immunosuppressed secondary to his lymphoma and the therapy; therefore, J.A. has an increased risk for infection and may have pneumonia. In addition, the infiltrates may represent a relapse of his disease. Pulmonary infiltrates also may represent toxicity from one or more of the cytotoxic agents he received. Further diagnostic workup is necessary to establish the cause.

CASE 94-10, QUESTION 2: A bronchoscopy with bronchoalveolar lavage and a biopsy with pathologic and microbiologic evaluations were performed. Bacterial, fungal, and viral cultures were negative, and the biopsy revealed inflammation and fibrosis with no evidence of lymphoma. These results are highly suggestive of chemotherapy-induced pulmonary damage. Which of the agents that J.A. received is associated with pulmonary toxicity?

J.A. has received bleomycin and that places him at risk for pulmonary toxicity. As part of initial workup before initiating chemotherapy with ABVD, J.A. had pulmonary function tests, which were normal. Many chemotherapy agents have been associated with pulmonary toxicity and the varying types of mechanisms and clinical presentations have been reviewed (Table 94-10).[238–250] Several reviews discuss the different types of pulmonary toxicities associated with anticancer agents.[238–240,250]

Among all chemotherapy agents, bleomycin is associated with the highest incidence of pulmonary toxicity. Although several types have been reported, the most frequent is interstitial pneumonitis followed by pulmonary fibrosis.[238,243,251] Patients generally present with a nonproductive cough and dyspnea. Clinicians may detect only fine crackling bibasilar rales that often progress to coarse rales. The chest radiograph may be normal in the early stages, but patients can exhibit bilateral alveolar and interstitial infiltrates. Arterial blood gases show hypoxia and pulmonary function tests generally reveal a progressive fall in the diffusing capacity without a significant decrease in the forced vital capacity.[243,251] The most significant factor associated with the development of pulmonary toxicity is the cumulative dose of bleomycin. At total doses less than 400 units, fewer than 10% of patients may experience pulmonary toxicity. When the cumulative dose reaches 450 to 500 units, the incidence is higher. A rarer, hypersensitivity reaction produces fever, eosinophilia, and diffuse infiltrates, and this pulmonary toxicity is not dose-related. The mortality associated with bleomycin pulmonary toxicity is about 50%.[238,251] If bleomycin is discontinued while symptoms are minimal and before pulmonary function has decompensated significantly, the damage may not progress. In contrast, patients with prominent physical and radiographic findings generally die because of pulmonary complications. Other anticancer agents can potentially exacerbate the pulmonary toxicity associated with bleomycin. J.A.'s pulmonary findings are most likely suggestive of bleomycin toxicity. Unfortunately, there are no methods for reversing the pulmonary toxicity seen with bleomycin and treatment consists of supportive measures such as oxygen and steroids.

Table 94-10

Chemotherapy-Induced Pulmonary Toxicity

Drug	Histopathology	Clinical Features	Treatment/Outcome

Aldesleukin[241]	Capillary leak, pulmonary edema	Clinical presentation: ↓ BP, fever, SOB, anorexia, rash, mucositis	Stop infusion; provide supportive care to cause a quick resolution of symptoms
Bleomycin[243,251]	Interstitial edema and hyaline membrane formation, mononuclear cell infiltration pneumonitis with progression to fibrosis, eosinophilic infiltrations seen in patients with suspected hypersensitivity-type reactions	Cumulative dose-related toxicity with risk increasing substantially with total dose >450 mg or 200 units/m^2; may occur during or after treatment Clinical presentation: cough, fever, dyspnea, tachypnea, rales, hypoxemia, bilateral infiltrates, dose-related ↓ in diffusing capacity	Recovery if bleomycin is discontinued while symptoms and radiologic changes still minimal; progressive and usually fatal if symptoms severe. Avoid cumulative doses >200 mg/m^2; monitor serial pulmonary function tests. Discontinue therapy if diffusing capacity ≤40% of baseline, FVC <25% of baseline, or if any signs or symptoms suggestive of pulmonary toxicity occur. Steroids may be helpful if toxicity is result of hypersensitivity
Busulfan[238]	Pneumocyte dysplasia; mononuclear cell infiltrations, fibrosis	Does not appear to be dose-related, but no cases reported with total doses <500 mg Clinical presentation: insidious onset of dyspnea, dry cough, fever, tachypnea, rales, hypoxemia, diffuse linear infiltrate, ↓ in diffusing capacity	Fatal in most patients; progressive despite discontinuation of busulfan. High-dose steroids (50–100 mg prednisone daily) have been helpful in a few cases
Carmustine[242]		Dose-related; usually occurs with doses >1,400 mg/m^2 Clinical presentation: dyspnea, tachypnea, dry hacking cough, bibasilar rales, hypoxemia, interstitial infiltrates; spontaneous pneumothorax has been reported	May continue to progress after carmustine discontinued. No evidence that steroids improve or alter incidence. High mortality rate if symptoms severe. Serial pulmonary function studies recommended. Total cumulative dose should not exceed 1,400 mg/m^2
Chlorambucil[240]	Pneumocyte dysplasia, fibrosis	Usually occurs after at least 6 months of treatment with total cumulative doses of >2 g Clinical presentation: dyspnea, dry cough, anorexia, fatigue, fever, hypoxemia, bibasilar rales, localized infiltrates progressing to diffusing involvement of both lung fields	Fatal in most cases despite discontinuation of chlorambucil and treatment with high-dose steroids
Cyclophosphamide[239]	Endothelial swelling, pneumocyte dysplasia,	Does not appear to be schedule-related or dose-	Clinical recovery reported in about 50% of patients within

	lymphocyte infiltration, fibrosis	related and may occur after discontinuation Clinical presentation: progressive dyspnea, fever, dry cough, tachypnea, fine rales, ↓ diffusing capacity and restrictive ventilatory defect, bilateral interstitial infiltrates	1–8 weeks if therapy stopped. Some of these patients received steroid therapy; however, others have died despite steroid therapy. Occasionally, therapy has been restarted without recurrence
Cytarabine[244]	Pulmonary edema, capillary leak	Clinical presentation: tachypnea, hypoxemia, interstitial or alveolar infiltrates	Not always fatal
Gemcitabine[245]	Pulmonary edema, rare interstitial pneumonitis	Dyspnea was reported in 23% of patients; severe dyspnea in 3%; dyspnea occasionally accompanied by bronchospasm (<2% of patients); rare reports of parenchymal lung toxicity consistent with drug-induced pneumonitis	Treatment is supportive care measures. Symptoms resolve and are usually not seen with rechallenge

Fludarabine[240]	Interstitial infiltrates, alveolitis, centrilobular emphysema	Clinical presentation: fever, dyspnea, cough, hypoxia; onset 3–28 days after third or fourth course; bilateral infiltrates and effusions	Resolves spontaneously during several weeks with or without corticosteroids
Melphalan[238]	Pneumocyte dysplasia	Not dose-related Clinical presentation: dyspnea, dry cough, fever, tachypnea, rales, pleuritic chest pain, hypoxemia	Most patients die because of progressive pulmonary disease. Most reported cases occurred while patients were receiving concomitant prednisone therapy Usually progresses rapidly
Methotrexate[247] Delayed	Nonspecific changes, occasional fibrosis	No evidence that it is dose-related; daily or weekly schedules more likely to cause toxicity than monthly dosing Clinical presentation: headache, malaise prodrome, dyspnea, dry cough, fever, hypoxemia, tachypnea, rales, eosinophilia, cyanosis in up to 50% of patients, interstitial infiltrates, ↓ diffusing capacity, restrictive ventilatory defect	Most patients recover within 1–6 weeks (some may have persistent infiltrates or ↓ pulmonary function parameters). Steroids may produce more rapid resolution. May resolve despite continuation of methotrexate, but discontinuation may speed resolution. Rarely fatal
Noncardiac pulmonary edema	Acute pulmonary edema	Occurs very rarely 6–12 hours after PO or IT methotrexate	May be fatal

Pleuritic chest pain		Not related to other methotrexate toxicities or serum levels; may not occur with each course of therapy Clinical presentation: right-sided chest pain, occasional pleural effusion or collapse of lung, thickened pleural densities	Usually resolves within 3–5 days
Mitomycin[273]	Similar to bleomycin	Clinical presentation: dyspnea, dry cough, basilar rales, hypoxemia, bilateral interstitial or finely nodular infiltrates, ↓ diffusing capacity	Fatal in ~50% of cases. Complete resolution reported in some patients, including some who received steroid therapy

BP, blood pressure; FVC, forced vital capacity; IT, intrathecal; PO, oral; SOB, shortness of breath.

CASE 94-10, QUESTION 3: Why are routine pulmonary evaluations indicated in patients such as J.A. who receive bleomycin or other pulmonary toxic agents?

Dose-related decreases in diffusing capacity can occur before the onset of clinical symptoms; therefore, routine baseline and serial pulmonary function studies are recommended.[243] Bleomycin therapy should be withheld if the diffusing capacity falls to less than 40% of the baseline value, if the forced vital capacity falls to less than 75% of the baseline value, or if patients exhibit any signs or symptoms of pulmonary damage.[238,251] Some practitioners also recommend limiting the total cumulative lifetime dose to less than or equal to 450 units. Specific screening is not routinely recommended for patients receiving other pulmonary toxic agents; however, if patients exhibit any symptoms or clinical findings, therapy should be withheld until the cause can be determined. J.A. received pulmonary function tests before his first cycle of ABVD. Further tests are usually not completed, unless the patient shows signs or symptoms of SOB or difficulty breathing. J.A. did not receive any further studies during his chemotherapy courses because he had no pulmonary symptoms until 6 months after his six cycles of ABVD.

Management

CASE 94-10, QUESTION 4: How should J.A.'s agent-induced pulmonary toxicity be managed?

If pulmonary toxicity becomes evident, all suspected agents should be discontinued and the patient should receive symptomatic support based on their physical condition. As illustrated by J.A., other treatable causes of pulmonary infiltrates (e.g., infection) also should be eliminated. Often, pulmonary toxicity is irreversible and progressive, and effective treatments are unavailable. Corticosteroids are administered but probably are effective only in cases of hypersensitivity-associated pulmonary damage. Nevertheless, because other effective treatments are lacking, a trial of steroids generally is indicated for all patients; if steroids are discontinued, they must be tapered carefully to avoid clinical deterioration.

HEPATOTOXICITY

CASE 94-11

QUESTION 1: J.D., a 56-year-old man, has received two courses of therapy with cytarabine for acute myeloid leukemia. Before his therapy was started, his liver function tests (LFT) and coagulation studies were within normal limits. His current laboratory values on day 10 of his second cycle of high-dose cytarabine include the following:

Aspartate aminotransferase, 204 units/L
Alanine aminotransferase, 197 units/L
Lactate dehydrogenase, 795 units/L
Alkaline phosphatase, 285 units/L
Bilirubin, 1.2 mg/dL

Why could J.D.'s cytarabine be responsible for these laboratory abnormalities?

Elevated LFTs occur frequently in cancer patients and their causes are listed in Table 94-11. Other signs and symptoms of hepatotoxicity include jaundice, nausea, vomiting, abdominal pain, and, rarely, encephalopathy. Patients should receive an extensive workup to determine whether they require immediate attention for tumor involvement of the liver or possible infection. In addition, patients should discontinue any nonessential medications that can potentially cause hepatotoxicity. The clinician may also discontinue chemotherapy if this is the suspected cause.

Several anticancer agents, including cytarabine, have been associated with hepatocellular damage (Table 94-12).[252–263] Some agents commonly associated with hepatotoxicity include asparaginase, carmustine, cytarabine, mercaptopurine, methotrexate, irinotecan, oxaliplatin, clofarabine, and imatinib. A review of 537 cancer patients with tyrosine kinase-associated liver enzyme elevations observe that clinically significant abnormalities were unusual and transient.[264] Multiple agents have black box warnings regarding potential hepatotoxicity. The onset of hepatotoxicity with these drugs is usually within 2 months of treatment initiation and is reversible in the majority of cases. Although death from hepatotoxicity in these cases is uncommon, there have been reports of cirrhosis.[264] All of these drugs come in contact with the liver by entering the liver's blood supply; the liver uniquely receives a dual blood supply from the portal and superior mesenteric veins. The liver detoxifies or inactivates noxious substances and metabolizes many anticancer agents. The exact mechanisms by which cytotoxic and targeted agents cause hepatotoxicity are unknown, but most agents probably cause it by (a) interfering with the mitochondrial function of the hepatocyte, (b) depleting hepatic glutathione stores, (c) eliciting hypersensitivity reactions, (d) decreasing bile flow, or (e) causing phlebitis of the central hepatic vein to produce sinusoidal obstructive syndrome (also known as veno-occlusive disease). Several articles serve as excellent resources for anticancer therapy-induced hepatotoxicity.[252,253]

Table 94-11

Common Causes of Elevated Liver Function Tests in Patients with Cancer

Primary or metastatic tumor involvement of the liver
Hepatotoxic drugs (e.g., cytotoxics, hormones [estrogens, androgens], antimicrobials [trimethoprim–sulfamethoxazole, voriconazole])
Infections (e.g., hepatic candidiasis, viral hepatitis)
Parenteral nutrition
Portal vein thrombosis
Paraneoplastic syndrome
History of liver disease (including hepatitis B and hepatitis C)

Table 94-12

Hepatotoxicity From Select Antineoplastic Drugs

Drug	Type
Asparaginase[254]	Hepatocellular fatty metamorphosis

Streptozocin[263]	Hepatocellular

Several laboratory tests can serve as indicators of liver structure and function. Serum transaminases, alkaline phosphatase, and bilirubin levels should be monitored routinely in patients receiving hepatotoxic chemotherapy. Although these laboratory indices are sensitive, they are nonspecific for the type of liver disease and do not necessarily correlate with hepatic function. Serum levels of proteins produced by the liver (e.g., ferritin, albumin, pre-albumin, or retinol-binding protein) also may be helpful in assessing liver function. The decision to continue or discontinue chemotherapy in patients with apparent hepatic dysfunction can be difficult. If the chemotherapy is the suspected cause, therapy should be withheld until LFTs are within normal ranges. The clinician should also consider alternative (nonhepatotoxic) chemotherapy for future treatment. In addition, agents that are cleared predominantly via the liver may require dosage adjustments and should be administered cautiously (Table 94-13). J.A.'s cytarabine is likely responsible for his elevated liver enzymes. Therefore, costly workup should be deferred to allow recovery of liver function. Recovery should occur within 2 weeks of chemotherapy. If full recovery does not occur, further therapy (agents, doses, or both) may require modifications.

Table 94-13

Select Anticancer Agents[a] Requiring Dose Modification in Hepatic Dysfunction

Fluorouracil	Methotrexate
Daunorubicin	Paclitaxel
Docetaxel	Vinblastine
Epirubicin	Vincristine
Etoposide	

[a] The agents listed in this table are examples and are not meant to be an exhaustive list of agents that may need dose adjustments. Additionally, specific dose reductions may depend on multiple factors including treatment goals (curative versus palliative), performance status, and specific protocols.

LONG-TERM COMPLICATIONS OF ANTICANCER THERAPY

Secondary Malignancies After Anticancer Therapy

CASE 94-12

QUESTION 1: T.D., a 55-year-old woman, was diagnosed with an early-stage breast cancer and successfully treated with radical mastectomy followed by four cycles of adjuvant AC (doxorubicin 60 mg/m^2 IV on day 1, cyclophosphamide 600 mg/m^2 IV on day 1). Eighteen months after her breast cancer therapy was completed, T.D. presents to her primary care physician with complaints of fatigue, SOB, easy bruising, and sinusitis. A peripheral blood smear shows a WBC count of 120,000 cells/μL with a differential of greater than 90% leukemic blasts and a bone marrow biopsy confirms acute myeloid leukemia (AML). Subsequent cytogenetic analysis revealed abnormalities involving chromosome 11q23. What factors support the diagnosis of anticancer therapy-associated acute leukemia in T.D.?

Acute leukemia has been associated with cytotoxic therapies used to treat hematologic malignancies, solid tumors, and nonmalignant diseases.[265] It has been reported after combination chemotherapy that involves topoisomerase inhibitors, including etoposide and anthracyclines. These leukemias usually occur 1 to 3 years after the completion of chemotherapy, and myelodysplasia does not usually occur before the leukemia. Other characteristics include chromosomal abnormalities involving chromosome 11q23.[265] This challenge is an important area for research given the widespread use of these agents for many curable diseases such as Hodgkin lymphoma, breast cancer, and testicular cancer.

Acute myeloid leukemia has also been reported in patients who have had previous exposure to alkylating agents. It usually occurs 5 to 7 years after the patient finishes chemotherapy. Myelodysplastic syndrome (preleukemia changes) commonly occurs in 50% of patients before overt acute leukemia. Although all alkylating agents can cause acute leukemia, melphalan appears to be the most potent leukemogenic agent in this class; other classes of chemotherapy agents do not appear to carry as significant a risk. Large doses, continuous daily dosing, prolonged treatment periods, age older than 40 years, and concomitant radiation therapy may increase the risk of exhibiting acute leukemia. Several additional factors may increase a patient's risk of exhibiting acute leukemia.[265]

Evidence that cytotoxic agents can cause secondary lymphoid malignancies, particularly non-Hodgkin lymphoma, is also strong. Immunosuppression from the disease and its treatment rather than the particular agent may be the primary cause of non-Hodgkin lymphoma. Other secondary malignancies can occur after anticancer treatment as well. Solid tumors have been associated with superficial bladder cancer in patients treated with daily oral cyclophosphamide, and bone sarcoma has occurred after treatment with alkylating agents.[266,267] The secondary solid tumors in patients treated with other cytotoxic agents are considered coincidental.

T.D.'s AML probably occurred secondary to her previous doxorubicin. The chemotherapy agent, as well as the time course for her acute leukemia, is consistent with topoisomerase-II agent-induced malignancies. The use of adjuvant AC has been associated with an acute leukemia incidence of 0.2%. In addition, cytogenetic abnormalities occur in more than 90% of those patients who have received chemotherapy or radiation therapy and have subsequently experienced therapy-related myelodysplastic syndrome or AML.[265] Abnormalities in chromosome 11q23 are involved in many of the cases with cytogenetic abnormalities from topoisomerase inhibitors.[265] The chromosomal abnormalities of 11q23 in T.D. strongly support the diagnosis of chemotherapy-associated acute leukemia rather than de novo leukemia.

CASE 94-12, QUESTION 2: Are the therapy and prognosis of T.D. with treatment-associated AML similar to those of patients with de novo AML?

Therapy for patients with treatment-associated AML is much less effective than that of patients with de novo leukemia. Complete remissions with standard cytarabine and daunorubicin regimens are obtained in less than half of patients with treatment-associated AML compared with a complete remission rate of 70% to 80% in patients with de novo leukemia[265] (see Chapter 96, Adult Hematologic Malignancies).

The best "treatment" of therapy-associated AML is prevention. In patients such as T.D. receiving adjuvant chemotherapy for a curable malignancy, avoiding the use of agents that cause treatment-related AML should be discussed in conjunction with the benefits of therapy. Use of alternative regimens is increasing as more is learned about secondary leukemias.

Fertility and Teratogenicity

EFFECTS ON OOGENESIS

CASE 94-13

QUESTION 1: C.L., a 32-year-old woman with recently diagnosed stage II breast cancer, underwent a lumpectomy and external beam radiation therapy and is scheduled to begin adjuvant chemotherapy with doxorubicin and cyclophosphamide followed by paclitaxel (AC-T). C.L. was married 12 months before her diagnosis and wishes to have children. What are C.L.'s prospects for fertility after adjuvant chemotherapy?

Cytotoxic chemotherapy is potentially gonadotoxic in humans. Ovarian biopsies taken from women treated for cancer demonstrate loss of ova and follicular elements. This injury is evident even in prepubertal female patients treated for cancer. Ova die or become nonfunctional by direct injury to the ova or by indirect injury resulting from loss of supporting follicular cells. If the damage to the follicular elements is extensive and irreversible, fertility is impaired even if the ova are spared.

Agent-induced injury to ova and follicular elements reduces ovarian estrogen and progesterone secretion in menstruating women. This causes the hypothalamus and pituitary to secrete more follicle-stimulating hormone (FSH) and luteinizing hormone (LH), which in turn increase follicular recruitment and the number of follicles vulnerable to cytotoxic chemotherapy agents. If the gonadal toxicity is severe or prolonged, permanent ovarian failure can occur secondary to depletion of ova and follicles. Recovery of some of the affected follicles often occurs, however, and this may be manifested by irregular menses or delayed recovery of menses. If the ova are spared and follicular cells recover sufficiently, ovulation and pregnancy might occur, but premature ovarian failure is inevitable in most women treated with large doses of gonadotoxic agents given for long periods.[268]

Prepubertal girls have a greater reserve of primary follicles. Because their ovaries are not producing estrogen and progesterone, increases in FSH and LH with resultant recruitment of

follicular elements do not occur. For this reason, prepubertal girls can tolerate large doses without apparent effects even if the pathology previously described occurs. The gonadal effects of cytotoxic chemotherapy in women and girls have been described in several reviews.[268–270]

C.L. is going to receive one of the alkylating agents, which are the most potent gonadotoxic agents. Cyclophosphamide is well known for producing infertility in men and women and gonadal failure even in children. The effect is influenced strongly by the total dose of cyclophosphamide and the patient's age at the onset of chemotherapy. Nearly 100% of women older than 20 years of age experience amenorrhea when the mean total dose is 20 to 50 g. The same consequence can be expected in women older than 35 years of age who receive greater than 6 to 10 g and in women 40 years of age and older who receive more than 5 g.[271] Depending on the exact dose of cyclophosphamide in the AC-T regimen planned, C.L. may or may not fall into a dose range that would be expected to produce permanent amenorrhea.

The clinician also must consider that a synergistic gonadotoxic effect has been reported when doxorubicin is combined with cyclophosphamide. Aside from the alkylating agents, the only agents with strong evidence of gonadal toxicity include vinblastine, etoposide, and cisplatin. Several resources discuss the doses of chemotherapy agents, used both alone and in combination, and specific incidences of associated gonadotoxicity, as well as the prevalence of temporary and permanent amenorrhea.[269,271,272]

C.L. most likely will experience amenorrhea along with the signs and symptoms of menopause as both estrogen and progesterone production diminishes during cytotoxic chemotherapy. C.L. may recover from chemotherapy-induced amenorrhea months to years after completion of her therapy. Recovery may be manifested as amenorrhea interspersed with normal menstrual periods.

Pregnancy is possible during periods of normal menstruation because ovulation does occur in most instances. Premature menopause is inevitable, however. Because the greatest risk of pregnancy exists early in the course of therapy, C.L. should be counseled to practice birth control while receiving cytotoxic chemotherapy. Because oral contraceptives are contraindicated in patients with breast cancer, barrier methods (i.e., diaphragm, condoms, spermicide) should be advised.

EFFECTS ON SPERMATOGENESIS

CASE 94-14

QUESTION 1: J.K., a 25-year-old man with recently diagnosed testicular cancer, will receive systemic chemotherapy with bleomycin, etoposide, and cisplatin. What effect does systemic chemotherapy have on male gonadal function?

The primary gonadal toxic effect of cytotoxic chemotherapy agents in male patients is a progressive dose-related depletion of the germinal epithelium lining the seminiferous tubule. The clinical manifestations of germinal depletion include a marked reduction in testicular volume and azoospermia. The Leydig cells responsible for testosterone production remain morphologically intact, although mild functional impairment occurs rarely. The major toxicity of chemotherapy in men is loss of reproductive capacity. During treatment, libido and sexual activity may decline, but most men report a return to pretreatment sexual function after chemotherapy.[273]

Of the cytotoxic chemotherapy agents, alkylating agents are associated most commonly with azoospermia. Progressive dose-related oligospermia occurs in men receiving chlorambucil,[274,275] cyclophosphamide,[276,277] melphalan, busulfan, procarbazine, and nitrosoureas; procarbazine appears to be the most gonadotoxic alkylating agent in men. Doxorubicin, vinblastine, cytarabine, and cisplatin also have been associated with azoospermia,[278] and doxorubicin appears to have a synergistic toxic effect in men when given with cyclophosphamide similar to that previously described in women. Phase-specific agents, such as antimetabolites and vinca alkaloids, seem unlikely to produce azoospermia when used alone, but may play a minor role in combination chemotherapy regimens.[279]

In contrast to oogenesis, in which women are born with a full complement of ova, spermatogenesis occurs in a continuous cycle of regeneration, differentiation, and maturation beginning in the second month of embryogenesis and continuing through old age. Although different cytotoxic chemotherapy agents appear to exert more damage to germ cells in specific phases of spermatogenesis in animal models, in humans, gonadotoxic agents generally are used in sufficiently large doses to affect varying proportions of maturing sperm cells in any stage of development. This has two realistic implications. The first is that because spermatogenesis must start at the beginning after agent-induced azoospermia occurs, the length of recovery is prolonged, usually lasting at least 2 to 3 years. The second is that the relationship of age to the development of azoospermia is far less clear than the relationship of age to ovarian suppression. Although conventional wisdom holds that prepubertal boys are less likely to be affected by chemotherapy agents than adult men, the reserve of primitive sperm cells in male children is far less than it is in adults. Therefore, the spermatogenesis potential in prepubertal testes may make them more vulnerable to cytotoxic damage than those of adults. A review of the literature regarding the effects of cytotoxic chemotherapy administered to male children concluded that agents and regimens known to be toxic in men should be considered toxic in young boys.[272,273] Short of a testicular biopsy, the damage cannot be detected until puberty.

The two diseases most likely to affect young men who are concerned with their fertility are Hodgkin lymphoma and testicular cancer. The standard treatment for advanced Hodgkin disease is ABVD. Azoospermia has been observed in 35% of patients receiving ABVD and spermatogenesis nearly always recovered in these patients.[278] A similar scenario exists in patients about to start on chemotherapy for testicular cancer. Evidence to date suggests that therapy-induced azoospermia that follows treatment with vinblastine, bleomycin, and cisplatin for nonseminomatous testicular carcinoma is reversible within 2 to 3 years in approximately 50% of patients treated and that those who recover spermatogenesis are capable of impregnating their partners.[280,281] In this particular patient population, it is important to recognize that retroperitoneal lymph node dissection, which results in retrograde ejaculation, as well as cryptorchidism, which predisposes to infertility, may contribute to the lack of full recovery of fertility potential.

CASE 94-14, QUESTION 2: Aside from the use of anticancer therapy agents with less gonadal toxicity, are there means of circumventing infertility in young patients such as J.K. receiving therapy?

Sperm or gamete cryopreservation should be considered in males. A major limitation of this approach has been the finding of diminished sperm counts, sperm volume, and sperm motility in young men affected with Hodgkin lymphoma and testicular cancer even before combination chemotherapy is initiated. Although published studies suggest that the quantity and motility of sperm are important determinants of successful artificial insemination, pregnancies have been reported. Thus, sperm banking should be considered even in oligospermic men.[273,279] Oocyte cryopreservation and embryo cryopreservation now are feasible options for young women about to undergo cytotoxic chemotherapy. Even in the face of cytotoxic chemotherapy-induced ovarian failure, in vitro fertilization of an ovum and implantation into the endometrium with proper hormonal support can successfully accommodate a term pregnancy. This may be an option for females.[270,282]

In both sexes, it has been hypothesized that gonadal toxicity from cytotoxic chemotherapy could be decreased by inhibiting spermatogenesis or follicular development during therapy. Methods used to suppress gonadal function have included administration of testosterone in men, oral contraceptives in women, and gonadotropin-releasing hormone analogs in both men and women. Several reviews describe these approaches in detail,[269,270,273] and ASCO provides recommendations on preserving fertility in cancer patients.[282]

TERATOGENICITY

CASE 94-14, QUESTION 3: If J.K. regains fertility after his planned combination chemotherapy regimens, is he at risk for producing offspring with congenital abnormalities or an excess risk of cancer?

Most of the agents used to treat cancer are designed specifically to interfere with DNA synthesis, cellular metabolism, and cell division. Thus, reason exists to suspect that they may cause mutation of ova or spermatocytes exposed to these effects. The actual outcomes of pregnancies in survivors of cancer are published as case reports, small series, and retrospective case series. Nearly 1,600 children have been born to 1,078 patients previously treated for malignancy in childhood or as adults. A review of the published information suggests no evidence that spontaneous abortion, genetic disease, or congenital anomalies occur more frequently in the progeny of cancer survivors. Similarly, there does not appear to be an increased risk of malignancy in the offspring of patients treated for cancer.[272] The likely explanation for this is that ova and sperm cells affected by cytotoxic chemotherapy usually are killed. The risk of producing an abnormal offspring thus would be highest at the time of chemotherapy. Men and women should be explicitly discouraged from conception during chemotherapy. In general, adults surviving cancer should be advised to wait at least 2 years after completion of therapy before attempting to parent a child; this theoretically allows time for elimination of damaged germ cells. This also provides time to assess the likelihood of the necessity for further treatment that would have grave consequences on the fetus, particularly in the case of female patients.

Pediatric Malignancies

David W. Henry and Nicole A. Kaiser

	CORE PRINCIPLES	CHAPTER CASES
1	Micrometastases are present in most solid tumors at the time of diagnosis. Neoadjuvant therapy was designed to treat micrometastatic disease before surgery, in hopes of increasing survival. Although it is not clear whether neoadjuvant therapy increases survival, residual viable tumor serves as a marker of response to chemotherapy, and neoadjuvant therapy may reduce tumor size to allow more surgical options in the patient.	**Case 95-3 (Question 1)**
2	When monitoring therapy in children, one has to remember the age-related differences in measured parameters and large differences in size. Blood pressures are lower and heart rates and respirations are higher in younger children. Intake and output need to be considered in relationship to the patient's size.	**Case 95-1 (Question 3)**
3	It is important to adjust creatinine clearance measurements or estimates to adult size (i.e., per 1.73 m^2) to correctly adjust drug doses for renal function in children.	**Case 95-1 (Question 4)**
4	Infants have larger body surface area–weight ratios than older children. Further, organ function changes rapidly during the first year of life. Therefore, chemotherapy dosing guidelines in protocols generally specify how to calculate doses for smaller children and infants (i.e., converting to mg/kg dosing from mg/m^2, or halving doses).	**Case 95-2 (Question 2)**
5	Leucovorin, when used with methotrexate, reduces methotrexate-related toxicities to rapidly proliferating cells. In treating children with high-dose methotrexate and leucovorin rescue, serum methotrexate concentrations are measured so that leucovorin will be discontinued at the correct time. Renal dysfunction, fluid accumulation in the patient, or drug interactions can slow methotrexate excretion and require prolonged leucovorin rescue.	**Case 95-3 (Questions 3, 4)**
6	Rhabdomyosarcoma is a soft tissue tumor of skeletal muscle origin, and it is the most common soft tissue sarcoma of childhood, occurring in 3% of all children with cancer. The two most common histologic types in children are embryonal and alveolar. Using the combination of vincristine, dactinomycin, and cyclophosphamide with local control of surgery or radiation, it is associated with an approximate 75% failure-free survival for patients with non-metastatic disease.	**Case 95-4 (Question 1)**

7 Acute lymphoblastic leukemia (ALL) involves replacement of normal bone marrow elements because of abnormalities in cellular proliferation. Signs and symptoms relate to the deficiency in normal bone marrow elements.	**Case 95-5 (Question 1)**
8 Important prognostic variables in ALL are based on clinical and laboratory findings, including age and white blood cells at diagnosis, sex, race, immunologic classification, cytogenetics, and early treatment response/minimal residual disease.	**Case 95-5 (Question 1)**
9 The treatment of ALL is divided into phases, including remission induction therapy, central nervous system (CNS) preventive therapy, consolidation/intensification phases, and maintenance therapy. All phases are different, each using multiple agents, schedules, and toxicity.	**Case 95-5 (Questions 3, 5, 6, 10–12)**
10 Induction treatment is a combination of systemic and intrathecal chemotherapy that is administered to induce a complete remission. Given disease-induced morbidity and treatment-related complications, this early phase of therapy can be associated with considerable complications.	**Case 95-5 (Questions 2, 3)**
11 Central nervous system preventive therapy is a key component of ALL treatment. Contemporary treatment/preventive regimens are composed of intrathecal administration of antimetabolite chemotherapy. Central nervous system radiation is reserved for special situations.	**Case 95-5 (Questions 4, 5, 7, 8)**
12 The post-induction phase consists of intensified chemotherapy treatments that are tailored to the specific type of leukemia and the patient's response to prior induction therapy.	**Case 95-5 (Question 9),** **Case 95-6 (Question 4)**
13 Maintenance therapy is the longest phase of ALL treatment and consists mainly of oral antimetabolite therapy that is less myelosuppressive than therapies given during the consolidation/intensification phase. Because of its prolonged length and low disease-related morbidity, this phase is associated with the highest rates of noncompliance.	**Case 95-5 (Questions 10–12)**
14 Patients with relapsed ALL will often achieve a second remission of their disease but have a high likelihood of further relapses. Various approaches including intensified chemotherapy or stem cell transplantation have been used in the treatment of relapse.	**Case 95-6 (Questions 1–3)**
15 Non-Hodgkin lymphoma accounts for 10% of childhood cancers. It has a cure rate of more than 80%. It often presents as a mass in the mediastinum or as pleural effusions. Masses may be large; therefore, adjunctive therapies to prevent tumor lysis syndrome and nephropathy are necessary.	**Case 95-7 (Question 1)**

PEDIATRIC MALIGNANCIES

In the United States, cancer is the leading cause of disease-related death for children between 1 and 14 years of age.[1] However, 5-year survival rates for children diagnosed with many common cancers have improved to greater than 80% because of the advent of chemotherapy. Approximately 10,270 new malignancies are expected to occur in children in the year 2017. Acute leukemias are the most common malignancies of childhood (Table 95-1), and the solid tumors discussed in this chapter represent 2.5% to 7.0% of all childhood malignancies.[1] Many common pediatric solid tumors are uncommon in adults. Likewise, many tumors common in adults occur infrequently in children. In general, sarcomas and embryonal tumors are common in children, whereas carcinomas predominate in adults.

Small Round Cell Malignancies

Several pediatric malignancies present similarly to one another as small round cells, making morphologic diagnosis by traditional light microscopy difficult. The less typical forms of these diseases, such as peripheral primitive neuroectodermal tumors, extraosseous Ewing sarcoma, extranodal lymphoma, rhabdomyosarcoma, metastatic neuroblastoma, and some bone sarcomas, are even more challenging.[2] Therefore, newer techniques aimed at detecting tumor-specific antigens or chromosomal aberrations have been developed. This information may prove useful in identifying prognostic subgroups and tumor types in children and adults with cancer. For example, identification of the t(11;22) chromosomal translocation in both peripheral primitive neuroectodermal tumors and Ewing sarcomas has resulted in the classification of both into the Ewing sarcoma family of tumors.

Genetics

Table 95-1

Relative Incidence of Malignancies in Children 0 to 14 Years of Age[1]

Malignancy	Relative Incidence (%)
Acute lymphoblastic leukemia	26
Central nervous system	21
Neuroblastoma	7
Non-Hodgkin lymphoma	6
Wilms tumor	5
Acute myeloid leukemia	5
Hodgkin lymphoma	4

Rhabdomyosarcoma	3
Retinoblastoma	3
Osteosarcoma	2.5
Ewing sarcoma	1.5
Other histologic types	20

Similar to adult cancers, the association of many pediatric cancers with chromosomal aberrations or genetic defects is well confirmed. Examples include the association of Wilms tumor with congenital malformations, acute leukemias with Down syndrome, and the association of some pediatric cancers with loss of the p53 or retinoblastoma tumor suppressor genes.[2–4]

Carcinogens

The role of carcinogens in pediatric cancer is probably less prominent than in adults because of the long latency periods required. Carcinogens, however, are implicated in the etiology of some childhood cancers.[5] Postnatal exposure to ionizing radiation is associated with increased risks for acute leukemias, chronic myelogenous leukemia, and solid tumors such as brain, thyroid, bone, and other sarcomas. Treatment of pediatric malignancies with alkylators or topoisomerase II inhibitors such as etoposide or doxorubicin is associated with an increased risk of acute leukemias. Treatment of childhood acute lymphoblastic leukemia (ALL), especially in those younger than 5 years of age who received radiation, results in an increased risk of central nervous system (CNS) neoplasms, leukemia, lymphoma, and other neoplasms later in life. The only well-documented prenatal carcinogen is diethylstilbestrol, which is associated with an increased risk of vaginal or cervical cancer in offspring.[6]

Patient Age

Patient age can be a factor in pediatric cancer prognoses and their treatments. Neuroblastoma is the most common malignancy in infants; however, an infant’s prognosis is typically better than a child’s, which is attributed to the biology of the disease in this age group.[7] In contrast, infants with ALL tend to have a worse prognosis than children. The biology and location of rhabdomyosarcomas are often different in younger versus older children, with younger children having better overall survival.[8]

Age may also be associated with treatment-related toxicity. Children may have higher susceptibility to radiation-related toxicity than adults. Normal organ development may be disrupted; the skeletal system and, in children younger than 4 years of age, the brain are particularly susceptible.[7] Prepubertal girls may have a decreased risk of fertility problems from chemotherapy and, conversely, children appear to have a greater risk for anthracycline cardiovascular toxicity than adults.[9,10]

Treatment of adolescents and young adults has become an interesting issue in recent years.[11] Because of various referral practices, several of the malignancies that are most common in this age group (acute leukemias, lymphomas, sarcomas) are treated by both adult and pediatric oncologists. Historically, this has divided the available patient data for this population; thus, minimal new treatment-related information is published. Outcomes for adolescent and young adult patients have not improved as much in the last 30 years as for either younger or older patients. This age group has generally had better results when treated on pediatric protocols; the reasons are not clear, although suggestions have been made that pediatric protocols are more aggressive, pediatric oncologists are less likely to reduce doses for toxicity, biology is at higher risk, and fewer data are available on how to determine appropriate dosages in adolescents and young adults. This dilemma has led to the Children’s Oncology Group (COG) (described in the next paragraph) and adult cooperative groups joining together on investigational protocols to pool data collected from this population so that more meaningful conclusions might be drawn.

Multi-Institutional Research Groups

With the exception of a few pediatric oncology centers, most treatment centers do not have sufficient numbers of patients with specific diagnoses to scientifically establish the efficacy of therapeutic regimens within a reasonable time frame. Thus, most pediatric centers join the COG, the largest pediatric multi-institutional research group in the United States, Canada, Australia, and New Zealand. Through this mechanism, clinical trials often can be finished in 3 to 4 years, allowing for more rapid progress in the treatment of pediatric cancers. The majority of pediatric hematology and oncology patients in the United States are either treated on a COG protocol or treated based on the standard treatment arm of a current protocol. There are also trials available through smaller consortia that specialize in early phase clinical trials or pilot studies. Unlike the more common adult cancers, few alternative chemotherapy regimens are available for pediatric malignancies. With the number of childhood cancer survivors increasing, research is focusing on reducing the long-term risks and complications of treatment modalities. It is important to determine which patients are at greatest risk from their cancer and to stratify treatments according to prognoses. Ideally, the minimal treatment needed to produce cure would be given when the prognoses are good. On the other extreme, maximal treatment would be given when the prognoses are poor, and potential benefits outweigh the treatment-associated risks. Progress is already being made in this direction, and the future holds promise, especially with rapid gains in our understanding of the biology of cancers.

Late Effects

Late effects can be described as toxicities or complications that either persist or occur after therapy is finished. Most of the early data on late effects are from adult Hodgkin lymphoma patients or from children with cancer. Both groups receive aggressive therapy and often live for years or decades after treatment. Examples of late effects include joint or bone problems, heart failure, second malignancies, strokes, and cognitive dysfunction.[12] A group of pediatric institutions have been collecting data on thousands of pediatric cancer survivors and a sample of their siblings, comparing the health problems of the two groups. This study is known as the Childhood Cancer Survivor Study. In 2006, Oeffinger reported data from the study showing that more than 60% of the survivors had at least one chronic medical problem, and 27% had a severe or life-threatening health problem.[12] The overall relative risk of a health problem compared to siblings was 3.3-fold, with specific risks as high as 54-fold for joint replacements and 15-fold for heart failure. This type of knowledge has reemphasized the need for clinicians to limit therapies for low-risk patients and thus reduce late effects and enhance quality of life for survivors. A website hosted by St. Jude Children's Research Hospital contains a listing of all published studies from the Childhood Cancer Survivor Study (**www.stjude.org/ccss**). A CureSearch and Children's Oncology Group–sponsored website (**www.survivorshipguidelines.org**) contains an extensive set of guidelines for the screening and management of childhood cancer survivors. An important recommendation relating to care of cancer survivors is to ensure that they have a record of their treatments that they can keep and provide to their health care providers for the remainder of their lives.[13] This will enable the health care providers to use publications and guidelines that might help the survivor's care.

PEDIATRIC SOLID TUMORS

Neuroblastoma

DESCRIPTION, INCIDENCE, AND EPIDEMIOLOGY

Neuroblastoma is a tumor which develops from immature cells originating from the sympathetic nervous system.[14] It is the most common extracranial tumor during childhood, representing 7% of all childhood cancers. The median age at diagnosis is 19 months; 36% occur in children younger than 1 year of age and 89% before 5 years of age.[14] Of neuroblastomas, 65% are abdominal (half of these adrenal) and 20% are thoracic.[14] The majority of children older than 1 year of age at diagnosis have metastatic disease at diagnosis. Lower-risk patients, which mostly includes infants with stage 1, 2, or 4S, may have spontaneous remissions or at least a 75% to greater than 90% 5-year event-free survival.[15] Intermediate-risk patients have a 50% to 75% event-free survival, and high-risk patients a 19% to 42% 5-year event-free survival.[16] With evolving therapies for high-risk patients (see below), survival may be improved over these numbers.

PATHOPHYSIOLOGY

Neural tumors related to neuroblastoma can be ganglioneuroma (benign) or ganglioneuroblastoma (mixed benign and malignant) or pure neuroblastoma. At biopsy, multiple specimens may be required to fully assess the malignant potential of the tumor. As with other cancers, neuroblastoma results from the loss of cell-growth control because of oncogene activation, tumor suppressor gene inactivation, and related malignant processes. The association of MYCN oncogene amplification with aggressive, poor-prognosis disease was the first key genetic alteration to be identified. Recently, reports suggest that patients whose tumor is characterized by hyperdiploidy with increases in whole chromosome copy number to approximately triploidy generally have excellent outcomes, whereas segmental alterations of chromosomes resulting in diploidy or tetraploidy are associated with poor prognosis.[17,18] The latter includes loss of 1p or loss of heterozygosity at 11q, both of which are being studied in current COG protocols as risk factors that may require more aggressive treatments for patients otherwise categorized as intermediate-risk. The explanations for these correlations are not clear, but this new biology may lead to better understanding of this disease and its treatment.

CLINICAL PRESENTATION, DIAGNOSIS, STAGING, AND OTHER PROGNOSTIC FACTORS

Patients with neuroblastoma often present with a fixed, hard, abdominal mass noted on physical examination by the family or physician, and possibly other signs or symptoms, depending on the location of the primary tumor and metastases.

For example, gastrointestinal (GI) fullness, discomfort, or dysfunction can occur. Other less common but characteristic signs include proptosis with periorbital ecchymoses, increased renin hypertension, secretory diarrhea with increased vasoactive intestinal peptide, respiratory distress, nerve root compression, opsomyoclonus, and unilateral ptosis.[14] The most common sites of metastases are the bone marrow, bone, liver, and skin.[14] Because bone marrow can be involved (distant metastases), it is necessary to do a bone marrow aspirate to rule out bone marrow involvement.

A [123]I metaiodobenzylguanidine (MIBG) test is an important diagnostic tool for neuroblastoma because of its high uptake into the tumor tissue (including metastatic sites). The catecholamine metabolites vanillylmandelic acid (VMA) and homovanillic acid (HVA) are elevated in the urine of 90% of patients with neuroblastoma and are also useful in diagnosis.[14] Because infants have a better prognosis than older children with neuroblastoma, efforts have been made to screen infants using urinary concentrations of VMA and HVA. [19] To date, these efforts have resulted in the diagnosis of more infants with good-risk disease but have not reduced the number of older children diagnosed with poor-risk disease. This is thought to reflect two distinct types of biology: a relatively benign biology in infants and a relatively malignant biology in patients older than 12 to 18 months old.

Table 95-2

International Neuroblastoma Staging System (Abbreviated)

Stage 1	Local tumor with complete gross excision
Stage 2A	Unilateral localized tumor with incomplete gross excision
Stage 2B	Unilateral localized tumor, complete or incomplete excision, with ipsilateral non-adherent lymph node spread
Stage 3	Involves both sides of the midline
Stage 4	Distant lymph node or organ involvement
Stage 4S	Infants younger than 1 year of age with localized primary tumor (stage 1 or 2) with dissemination limited to liver, skin, or less than 10% of bone marrow

Source: National Cancer Institute PDQ® Neuroblastoma Treatment. Bethesda, Maryland: National Cancer Institute. Date last modified 12/15/2014. http://cancer.gov/cancertopics/pdq/treatment/neuroblastoma/HealthProfessional. Accessed May 14, 2015.

A simplified description of the international staging system is shown in Table 95-2. Twenty percent (20%) of infants (<1 year) and 59% of children have stage 4 disease at the time of diagnosis. A newer staging system has been designed by the International Neuroblastoma Risk Group task force, but it is only used in the most recent COG protocols. The new system has the designations L1, L2, M, and MS. M and MS are the same as International Neuroblastoma Risk Group stages 4 and 4S. L1 and L2 are more localized disease and are differentiated by a list of "image-defined risk factors."[20]

A large number of prognostic factors have been identified and are discussed elsewhere.[14,19] Patients are currently stratified for treatment based on age, stage, MYCN amplification, histology, and diploidy, or by the new staging system with good or bad genomics and histology. COG guidelines divide low-risk and intermediate-risk patients into four groups for the purpose of assigning treatments (Table 95-3).[19] Infants have better outcomes than older children for the same stage of disease and low-stage infants have a significant incidence of spontaneous regression or regression with minimal treatment.[14,19]

OVERVIEW OF TREATMENT

In current US clinical trials, patients with low-risk disease are typically treated with observation or surgery (groups 1 and 2, Table 95-3). Progression or recurrence may be treated with surgery, unless disease is unresectable, in which case chemotherapy is used. Two to four courses of chemotherapy may be used with initial surgery if organ-threatening symptoms are present. Intermediate-risk disease is treated with surgery and four to eight courses of chemotherapy (groups 3 and 4, Table 95-3, and chemotherapy in Table 95-4) for favorable or unfavorable histology and ploidy.[19,21] Chemotherapy for patients with low-risk or intermediate-risk disease avoids cisplatin to reduce nephrotoxicity and ototoxicity, limits the total doxorubicin dose to avoid cardiac toxicity, limits the total etoposide dose to reduce the risk of secondary acute myelogenous leukemia, and avoids ifosfamide to eliminate Fanconi renal syndrome. Radiation therapy is used only for poor responders.

Table 95-3

Example of Children's Oncology Group Neuroblastoma Risk Groups and Treatment for Low-Risk, Intermediate-Risk, and High-Risk Patients

Low-Risk; Surgery and Observation
All stage 1 patients
Patients with stages 2A or 2B, >50% resected and MYCN not amplified[a]
Infants with 4S with MYCN not amplified, favorable histology, and hyperdiploidy
Low-Risk, Group 2; Receive 2 Cycles of Chemotherapy with Surgery
Stage 2A/2B, <50% resected, or biopsy only and MYCN not amplified
Infants with Stage 3 or symptomatic 4S, MYCN not amplified, favorable histology, and hyperdiploid; increase one group if loss of heterozygosity at 1p or 11q
Stage 3, >1 year old, MYCN not amplified, favorable histology
Intermediate-Risk, Group 3; 4 Cycles of Chemotherapy with Surgerya
Infants with stage 3, MYCN not amplified, and diploidy or unfavorable histology
Stage 4, up to 18 months old, MYCN not amplified (good genomics)
Infants with stages 4S and MYCN not amplified, and either diploidy or unfavorable histology
Intermediate-Risk, Group 4; 8 Cycles of Chemotherapy with Surgery
Infants with stage 4S, unknown biology
Infants with stage 4, MYCN not amplified, with diploidy or unfavorable histology
Stage 3, up to 18 months old, MYCN not amplified and unfavorable histology

High-Risk
Biopsy, 5–6 cycles of chemotherapy, followed by definitive surgery, high-dose chemotherapy with autologous progenitor cell rescue, radiation to the primary site, and maintenance therapy. Induction chemotherapy: Vincristine, doxorubicin, and cyclophosphamide for cycles 1, 2, 4, and 6; cisplatin and etoposide for cycles 3 and 5. Consolidation: high-dose chemotherapy (carboplatin, etoposide, and melphalan) followed by autologous progenitor cell rescue. Maintenance therapy: 6 cycles of isotretinoin (2 weeks on; 2 weeks off for each cycle) concurrent with 5 cycles of dinutuximab with GM-CSF on cycles 1, 3, 5 or interleukin-2 on cycles 2 and 4.[b]
MYCN amplified and not included in previous groups.

Consult current protocols as classifications and treatment recommendations are changing rapidly. Typical correlations with the newer staging terminology: L1 and MS patients with good genomics would be in the low-risk group; L2 patients with good genomics would be in the intermediate-risk group but bad genomics in the high-risk group; MS patients with good genomics would be lower risk or with bad genomics would be high risk; M patients would be in the high risk unless they are less than 18 months old with good genomics. See Table 95-4 for details of chemotherapy regimens in low-risk and intermediate-risk patients.

[a] MYCN is an oncogene that is associated with more aggressive higher-risk neuroblastomas.

[b] GM-CSF is granulocyte-macrophage colony stimulating factor.

Date last modified 12/15/2014. **http://cancer.gov/cancertopics/pdq/treatment/neuroblastoma/HealthProfessional**. Accessed May 14, 2015.

Therapy for high-risk disease generally involves a first surgery for biopsy, aggressive chemotherapy, second-look surgery for residual tumor resection, either additional aggressive chemotherapy or high-dose chemotherapy with autologous progenitor cell rescue, radiation to the tumor bed, and maintenance therapy (Table 95-3.)[16,19] High-dose chemotherapy with autologous progenitor cell rescue raised 5-year, disease progression–free survival to 49% from historic values of 10% to 20%; however, relapses can occur later with 7-year disease progression–free survival of only 26%.[22,23] Survival can be improved (46% vs. 29% 5-year post-chemotherapy disease-free survival) for patients with higher-risk disease if standard-dose or high-dose chemotherapy is followed by maintenance with six cycles of isotretinoin 80 mg/m^2 given orally twice daily for 14 days of each 28-day cycle.[22] Addition of the anti-GD2 monoclonal antibody, dinutuximab (ch14.18), along with interleukin-2 and granulocyte-macrophage colony stimulating factor (GM-CSF), to the maintenance regimen has been shown to further increase survival.[24] Typical conditioning regimens preceding autologous progenitor cell rescue include carboplatin and etoposide with either cyclophosphamide or melphalan, or thiotepa and cyclophosphamide.

CLINICAL PRESENTATION AND DIAGNOSIS

CASE 95-1

QUESTION 1: H.K. is a 2-year-old girl with a 3-month history of constipation and progressive abdominal distension. She has a decreased appetite, 1-week history of vomiting, and she is pale and tired. She has a large retroperitoneal mass and multiple bilateral enlarged inguinal lymph nodes. Her WBC count, differential and platelets are within normal limits. Serum sodium, potassium, chloride, creatinine, and glucose are within normal limits. Her laboratory test results also include the following:

Hemoglobin (Hgb), 5.1 g/dL (normal, 11–14 g/dL)
Lactate dehydrogenase (LDH), 424 units/L
Albumin, 2.3 g/dL
Urine HVA, 570 mg/g creatinine (normal, <26 mg/g)
Urine VMA, 31 mg/g creatinine (normal, <11 mg/g)

Biopsies of the abdominal mass and bone marrow are positive for neuroblastoma cells that are MYCN amplified. The lymph nodes are negative for neuroblastoma. Scans are negative for other sites of disease. Which of these signs, symptoms, and laboratory results are consistent with a diagnosis of neuroblastoma?

Table 95-4

Typical Cycles of Chemotherapy Used in Children's Oncology Group Low-Risk and Intermediate-Risk Neuroblastoma

Cycle[a]	Drugs
1	Carboplatin, etoposide
2	Carboplatin, cyclophosphamide, doxorubicin
3	Cyclophosphamide, etoposide
4	Carboplatin, doxorubicin, etoposide
5	Cyclophosphamide, etoposide
6	Carboplatin, cyclophosphamide, doxorubicin
7	Carboplatin, etoposide
8	Cyclophosphamide, doxorubicin

[a] Each row represents a single 21-day cycle of therapy. Generally, the first four cycles are used in patients at intermediate risk with favorable histology disease, and all eight for patients with unfavorable histology. Patients at low risk whose disease is potentially organ-threatening may receive the first two to four cycles plus surgery. See Table 95-3 for common chemotherapy guidelines for neuroblastoma patients.

Source: Brodeur GM et al. Neuroblastoma. In: Pizzo PA, Poplack DG, eds. Principles and Practice of Pediatric Oncology. 6th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2010:886; National Cancer Institute PDQ® Neuroblastoma Treatment. Bethesda, MD: National Cancer Institute. Date last modified 12/15/2014. http://cancer.gov/cancertopics/pdq/treatment/neuroblastoma/HealthProfessional. Accessed May 14, 2015.

Virtually all of H.K.'s findings are consistent with neuroblastoma. The low hemoglobin and albumin and high LDH, however, are not specific for this cancer. In addition to the biopsy, the elevated urine VMA and HVA are most helpful in confirming the diagnosis of neuroblastoma. In H.K., biopsies of the bone marrow, lymph nodes, and primary tumor were necessary to demonstrate the presence or absence of neuroblastoma at more than one site for staging purposes.

TREATMENT

CASE 95-1, QUESTION 2: What stage of disease does H.K. have? What treatment will she receive?

H.K.'s abdominal disease with distant bone marrow involvement indicates stage 4 (or M) disease. Considering her age and disease stage, H.K. has a high risk of dying from her disease. Her MYCN also was amplified. Therefore, she is started on chemotherapy consisting of vincristine, doxorubicin, and cyclophosphamide for cycles 1, 2, 4, and 6, and cisplatin and etoposide for cycles 3 and 5.

CASE 95-1, QUESTION 3: H.K. is 81.5 cm tall, weighs 11.65 kg, and has a body surface area of 0.5 m^2. For her third chemotherapy cycle, consisting of cisplatin 50 mg/m^2/day on days 1 through 4 and etoposide 200 mg/m^2/day on days 1 through 3, she is given hydration fluids of 5% dextrose with 0.45% sodium chloride at 62.5 mL/hour. Urine output is 4 mL/kg/hour. How does monitoring of H.K.'s chemotherapy differ from that of an adult?

Monitoring Vital Signs for Etoposide

Although prevention and monitoring of toxicities from chemotherapy agents in children follow the same basic rules as in adults, there are some differences. When monitoring vital signs for hypotensive reactions to etoposide, normal blood pressure will be lower (hypotension is defined as a systolic blood pressure under 74 mm Hg for a 2-year-old girl) and the pulse higher (mean, 119 beats/minute for a 2-year-old) than in adults.[25] It is important to have baseline vital signs so that hypotension or tachycardia will be recognized.

Monitoring Hydration for Cisplatin

In adults receiving cisplatin, hydration is often standardized with 1 to 2 L of intravenous (IV) fluids given before the drug, 1 to 2 L with the drug, and then continuous hydration for at least 24 hours after the dose.[26] In children, hydration volumes should be calculated based on the child's size. To decrease the risk of cisplatin nephrotoxicity, most pediatric protocols recommend IV fluids at twice maintenance rates to maintain urine outputs of at least 2 to 3 mL/kg/hour. The COG calculates maintenance fluids as 1,500 mL/m^2/24 hours, so H.K. should receive 3,000 mL/0.5 m^2 = 1,500 mL during 24 hours (62.5 mL/hour). H.K.'s measured urine output is 4 mL/kg/hour, which should be adequate to prevent nephrotoxicity. Weight should also be monitored throughout cisplatin administration to assure fluid balance. Acute weight gain may require diuretics to prevent overhydration, and weight loss may indicate dehydration with impending reduction of urine output that could lead to acute nephrotoxicity. Increased IV fluids would help prevent the latter.

Adjustment of Creatinine Clearance to Adult Size

CASE 95-1, QUESTION 4: H.K.'s measured creatinine clearance (CrCl) is 39 mL/minute. Should her cisplatin be withheld or the dose adjusted because of low creatinine clearance?

Cisplatin is either not administered or administered at a reduced dosage when the creatinine clearance is less than 50 to 60 mL/minute/1.73 m^2.[27] Although H.K.'s creatinine clearance of 39 mL/minute appears to be low, it is relative to the patient's size (i.e., 39 mL/minute/0.5 m^2). Guidelines for dosing drugs cleared by glomerular filtration are based on creatinine clearance for normal adult body size, 1.73 m^2. Therefore, it is important to correct H.K.'s creatinine clearance to adult body size.[28] Multiplying by 1.73/0.5, her creatinine clearance is 135 mL/minute/1.73 m^2, so this is not a reason to withhold cisplatin. One precaution is that the accuracy of serum creatinine and creatinine clearance in assessing renal function during cisplatin therapy in children has been questioned.[29]

Partial Response and Hematopoietic Progenitor Cell Rescue

CASE 95-1, QUESTION 5: H.K. obtains a partial response to the aforementioned initial chemotherapy regimen with reduction of urine VMA and HVA concentrations and a 50% decrease in the size of the primary tumor in the abdomen. Second-look surgery is performed to debulk the tumor, and pathology results indicate that the residual tumor contains 95% mature (benign) ganglioneuroma cells, but neuroblastoma cells are still present. What further treatment has the most potential benefit for H.K.?

The best chance for prolonged disease-free survival for H.K. is dose-intensive chemotherapy combined with autologous peripheral blood progenitor cell rescue. The regimen she is receiving was designed to be followed by high-dose chemotherapy and stem cell rescue. The 2- to 3-year disease-free survival is better with high-dose chemotherapy followed by autologous progenitor cell rescue.[14,16,19,22,23] The plan for H.K. is to proceed to high-dose chemotherapy (carboplatin, etoposide, and melphalan) with an autologous progenitor cell rescue. If a complete response is achieved, she would then receive radiation to the bed of the primary tumor, followed by 6 monthly cycles of isotretinoin (cis-retinoic acid) and 5 cycles of dinutuximab with granulocyte-macrophage colony

stimulating factor (GM-CSF cycles 1, 3, 5) and interleukin-2 (cycles 2, 4). All three of these treatments, dose-intensive chemotherapy with progenitor cell rescue, isotretinoin, and the dinutuximab regimen, have been shown to independently increase survival.

Further Treatments Based on Disease Biology

With rapid advances in neuroblastoma biology being made, future alternatives may include more biologic treatments. One agent in clinical trials is ^{131}I-MIBG, a compound that delivers radiation directly to catecholamine-secreting cells such as neuroblastoma. Studies have used ^{131}I-MIBG as part of the conditioning regimen before progenitor cell rescue in patients with neuroblastoma.[30] Crizotinib, an anaplastic lymphoma kinase receptor tyrosine kinase inhibitor, has entered phase I–II clinical trials in pediatric patients and shows some promise for a small percentage of patients with neuroblastoma.[31]

Wilms Tumor

DESCRIPTION, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

Wilms tumor, also known as nephroblastoma, is a kidney tumor composed of various kidney cell types at different stages of maturation.[32] Approximately 5% of all childhood cancers are Wilms tumor, making it the most common intra-abdominal tumor of childhood.[1] The peak incidence occurs at 3 to 4 years of age.[32] Overall, Wilms tumor has an excellent prognosis. Four-year relapse free survival is greater than 50% for all categories of Wilms tumor except stage IV with diffuse anaplasia. For low-stage patients, 4-year relapse-free survival is generally greater than 86%.[32] Histology is the most important indicator of likely outcomes with diffuse anaplasia being distinctly worse than either focal anaplasia or favorable histology.

The relationship of genetic factors to Wilms tumor is demonstrated by the approximately 1.5% of patients with Wilms tumor who have family members with the disease and the approximately 10% who have aniridia, hemihypertrophy, or genitourinary anomalies.[32,33] Chromosomal aberrations at 11p13 and 11p15, known respectively as WT1 and WT2, and WTX on the X chromosome, are associated with nonfamilial Wilms tumor. Genes at these sites are involved with normal development of the urinary tract and other tissues involved in the anomalies. It is thought that the relationship between congenital anomalies and Wilms tumor may relate to methylation and inactivation of a set of neighboring genes involved with the two medical conditions.[32] The familial syndrome is related to FWT1 (17q12-21) and FWT2 (19q13.4), which have been identified more recently and about which less is known.[33] Loss of heterozygosity (LOH) at 1p and 16q correlates with increased risk of recurrence in stage III or IV disease with favorable histology. Treatment guidelines suggest increased chemotherapy for patients with these findings (Table 95-5).

CLINICAL PRESENTATION

Patients with Wilms tumor frequently present with an asymptomatic abdominal mass, although malaise and pain may be reported.[32] Hematuria and high renin hypertension each occur in approximately 25% of patients. Metastases, when present at diagnosis, most commonly involve the lungs (80%) or liver (15%).

DIAGNOSIS, STAGING, AND OVERVIEW OF TREATMENT

Diagnosis of Wilms tumor is based on biopsy and computed tomography (CT) of chest and abdomen to rule out metastatic disease. Treatment in the United States is based mostly on disease stage after surgical resection or debulking and favorable histology versus focal or diffuse anaplasia. Surgical resection is the primary treatment, followed by adjuvant chemotherapy (Table 95-5). A simplified description of the staging is as follows: stage I is limited to the kidney and can be completely removed surgically; stage II is extended beyond the kidney but can be completely excised; stage III is characterized by residual tumor confined to the abdomen; stage IV is distant metastases; and stage V is bilateral disease.[33] Metastases are present in only 15% of patients at diagnosis, and even these patients have relatively good prognoses. Notably, in Europe the majority of treatments use neoadjuvant chemotherapy before surgery. The benefits and risks of each method have been discussed elsewhere.[34] COG studies suggest surgery followed by adjuvant chemotherapy except in stage V (bilateral disease), where neoadjuvant chemotherapy is used in an attempt to preserve kidney function. Current protocols use newer regimens and also examine the possibility of surgery without chemotherapy for some very-low-risk patients.[33]

Table 95-5

Wilms Tumor Treatment Regimens by Stage and Histology

Stage I, Any Histology, and Stage II, Favorable Histology
Surgery followed by 18 weeks of vincristine and dactinomycin. Add abdominal radiation for either focal or diffuse anaplasia.[a]
Stage III or IV, Favorable Histology; Stages II, III, or IV Focal Anaplasia
Surgery followed by 24 weeks of vincristine, dactinomycin, and doxorubicin, with abdominal radiation.[b] Add pulmonary radiation if chest CT (computed tomography) shows metastases, unless there is complete resolution after chemotherapy.
Stages II through IV, Diffuse Anaplasia
Surgery followed by 24 weeks of vincristine, doxorubicin, etoposide, and cyclophosphamide with mesna, plus or minus dactinomycin and carboplatin, abdominal radiation. Stage IV: Add pulmonary radiation if chest CT (computed tomography) shows metastases, unless there is complete resolution after chemotherapy.
Stage V
Biopsy followed by neoadjuvant vincristine, dactinomycin, and doxorubicin, then complete resection or debulking followed by more chemotherapy and, if a poor response, radiation therapy; more aggressive treatment if unfavorable histology.

[a] Stage I with tumor <550 g in a patient <24 months of age: surgery alone has been used investigationally with some success.

[b] Stage III or IV with favorable histology but loss of heterozygosity at 1p and 16q: higher risk, use vincristine, dactinomycin, doxorubicin, plus outpatient cyclophosphamide and etoposide.

CLINICAL PRESENTATION AND TREATMENT

CASE 95-2

QUESTION 1: B.N. is a 34-month-old boy who is pale and irritable. He has had abdominal complaints with decreased bowel movements and reduced oral intake for 2 weeks. He has played less than normal for the last 4 weeks. B.N.'s blood pressure has intermittently been as high as 146/87 mm Hg (normal, 90th percentile, 106/69). His laboratory results include the following:

Hgb, 7.9 g/dL (normal, 11.5–13.5)
Erythrocyte sedimentation rate, 139 mm/hour (normal, <10)

B.N. has a history of hypospadias and left hydronephrosis. Scans show a right kidney mass extending through the capsule plus two distant metastases in the peritoneum. Chest radiography shows one nodule in the lung as well. Pathology from a biopsy sample shows favorable histology Wilms tumor. What treatment should B.N. receive?

B.N. has stage IV disease with favorable histology and the cells are negative for loss of heterozygosity at 1p and 16q. The expected treatment for him is 24 weeks of vincristine, dactinomycin, and doxorubicin, assuming findings at surgery are consistent with pretreatment scans. He will receive abdominal radiation; he would also receive pulmonary radiation unless the lung metastases completely disappear with chemotherapy. The series of five National Wilms Tumor studies have sought to progressively minimize toxicities from radiation and chemotherapy while maintaining the excellent cure rate. The fourth National Wilms Tumor Study Group (NWTS-4) study demonstrated that intermittent, higher doses of dactinomycin allowed higher dose intensity with less myelosuppression than lower doses given daily for 5 days. Using greater dose intensity and dose density, 6 months of therapy was shown to be as effective as 15 months of therapy given the traditional way.[35] Also, fewer clinic visits were made and estimated costs were reduced by 50%.[35,36] The NWTS-5 evaluated surgery followed by 18 to 24 weeks of chemotherapy. Chemotherapy was determined by the stage and histology findings (Table 95-5). Abdominal radiation therapy was added to chemotherapy for stage II disease with unfavorable histology (focal or diffuse anaplasia) or stages III or IV with any histology; pulmonary radiation was added for stage IV disease if the chest radiograph was positive for metastases. The latter part of the guideline has now changed to depend on whether or not the pulmonary nodules clear with chemotherapy or not. For patients with stage V, or those with inoperable tumors, surgery could be delayed until neoadjuvant chemotherapy reduces the tumor size.

Dosing Chemotherapy in Infants and Young Children

CASE 95-2, QUESTION 2: Are there any special precautions for dosing chemotherapy in B.N.?

The NWTS-2 study noted an excessive number of toxic deaths in infants with good prognosis, and this resulted in a dosing change.[37] After chemotherapy doses were decreased by 50%, severe hematologic toxicity, toxic deaths, and pulmonary and hepatic complications were reduced.[38] Importantly, no decrease in therapeutic effect was noted. Reduction of chemotherapy doses in infants is a consideration for other pediatric cancers as well.[39–41] Reasons for increased toxicity in infants may include altered pharmacokinetics or organ sensitivity as well as the larger body surface area/kilogram relative to older children and adults.[37] In NWTS-5, dosages of chemotherapy agents for Wilms tumor patients who are less than 30 kg were converted from mg/m^2 to mg/kg. By assuming the average 1-m^2 child weighs 30 kg, the dose/m^2 can be divided by 30 to arrive at a dose/kilogram, which can be used in dosing calculations. This adjustment lowers the dose by 20% to 50% in children who weigh less than 15 kg. In NWTS-5, infants younger than 12 months of age received doses that were further reduced by halving the milligram/kilogram dose.

Interaction of Chemotherapy with Radiation

CASE 95-2, QUESTION 3: Are there any dosing precautions required because of potential interactions between B.N.'s treatments?

Another medication-related problem that may arise in B.N. is the interaction of dactinomycin and doxorubicin with radiation therapy.[42–46] Two effects have been reported. One is acute enhancement of radiation effects, and the other is recurrence (recall) of radiation effects up to several weeks later, especially to skin and mucous membranes. Because B.N. is to receive abdominal and lung irradiation during his chemotherapy treatment, concurrent doses of dactinomycin and doxorubicin will need to be reduced by 50%, and held if wet desquamation of the skin at the radiation site occurs. In many of the Ewing sarcoma and rhabdomyosarcoma protocols, dactinomycin or doxorubicin is stopped during concurrent radiation treatments.

Doxorubicin Cardiotoxicity in Pediatrics

CASE 95-2, QUESTION 4: When B.N. receives lung radiation for his metastases, how will it affect the doxorubicin he is scheduled to receive?

Although it is well known that mediastinal radiation can increase the risk of anthracycline-induced cardiac toxicity,[47] the only adjustment for B.N. would be a temporary reduction of doxorubicin doses (same reductions as described in Case 95-2, Question 3). The total doxorubicin dose should be limited to no more than 5 mg/kg (150 mg/m^2 in larger children). In earlier Wilms tumor studies, the risk of congestive heart failure was 4.4% at 20 years, or up to 17.4% in patients who relapsed and received more doxorubicin.[48] Thus, cardiovascular toxicity can develop as long as 20 years after therapy is completed, with an apparent decrease in left ventricular wall thickness and increased ventricular afterload, probably related to inadequate numbers of myocytes.[49] These reports emphasize the need to minimize chemotherapy in patients with good prognosis, as the Wilms tumor studies are doing. New recommendations include better standardization of cardiac monitoring and continuation of monitoring throughout life in survivors of childhood cancer who receive cardiotoxic agents.

Dactinomycin Hepatotoxicity

CASE 95-2, QUESTION 5: B.N. is to receive vincristine 0.05 mg/kg weekly for 10 weeks; doxorubicin 1.5 mg/kg at weeks 3 and 9; 1 mg/kg at weeks 15 and 21; and dactinomycin 0.045 mg/kg at weeks 0, 6, 12, 18, and 24. During the third week of treatment, his alanine aminotransferase (ALT) is elevated to 78 units/dL. Is this related to his drug therapy?

Early in the NWTS-4, an increased incidence (14.3%) of severe hepatotoxicity (elevation of alanine aminotransferase or ALT 10 times normal with or without ascites) was reported with the pulse-intensive dactinomycin doses (0.060 mg/kg/single dose) in patients receiving no abdominal radiation.[50] Subsequently, dactinomycin doses were reduced. Still, the incidence of hepatotoxicity in patients receiving the newer 0.045-mg/kg pulse doses (3.7%), as well as those receiving the standard 0.015 mg/kg/day for 5 days (2.8%), remained elevated relative to the NWTS-3 results (0.4%),

which used the same 0.015 mg/kg/day for 5 days.[51] The reasons for the increased hepatotoxicity are not known. Liver function usually returns to baseline within 1 to 2 weeks after discontinuation of chemotherapy, although more severe problems with sinusoidal obstructive syndrome (hepatopathy, veno-occlusive disease) have also been reported.[33] Chemotherapy was restarted in some patients, although frequently at lower doses or without dactinomycin. B.N. should be monitored closely in case his liver enzymes continue to rise, especially because he will receive abdominal radiation treatments that may increase the risk of hepatic toxicity. If his ALT rises to 2 to 5 times normal, or his total bilirubin is 3 to 5 mg/dL, doses of all three of his drugs should be reduced by 50%. If his ALT or bilirubin rises above 2 to 5 times normal, the drugs should be withheld until laboratory values return to lower than the aforementioned ranges.

Osteosarcoma

DEFINITION, EPIDEMIOLOGY, PATHOPHYSIOLOGY, AND COURSE OF THE DISEASE

Osteosarcoma is a malignant osteoid-producing bone tumor that occurs most commonly in adolescents or young adults in the second or third decade of life.[52–54] A second peak incidence occurs in patients older than 50 to 60 years old. The most common manifestation at diagnosis is pain at the site, which can sometimes be present for several weeks to months. It occurs most frequently in the metaphyseal ends of the distal femur, proximal tibia, or proximal humerus, but it can occur in the flat bones as well.

The age range and bones involved suggest a malignant response associated with normal childhood growth spurts. Osteosarcoma has been associated with Paget disease in the elderly, another condition with rapid bone turnover.[53] Radiation from treatments or nuclear disasters has also been linked to osteosarcoma. Mutation of the retinoblastoma gene increases the risk of osteosarcoma, and retinoblastoma survivors and carriers need to be monitored for osteosarcoma. There are a number of other uncommon inherited conditions that are associated with an increased risk of osteosarcoma.

Typical staging systems are not used for osteosarcoma; however, presence of clinically detectable metastatic disease at diagnosis, resectability of the tumor, and tumor grade (high vs. low) are important to outcomes. Low-grade tumors are not likely to metastasize and are not treated with chemotherapy in contrast to high-grade tumors. Clinically detectable metastases are present in 15% to 20% of patients, usually in the lungs but occasionally in the same or other bones. If surgery alone is used for treatment, 80% of patients will die within 5 years of recurrent metastatic disease, indicating the presence of subclinical micrometastases at the time of diagnosis.[52–54] The degree of tumor necrosis at surgical resection is an indicator of chemosensitivity of the tumor and risk of relapse. Greater than 90% necrosis at the time of surgery after six cycles of neoadjuvant chemotherapy is associated with a 70% to 80% chance of long-term survival for non-metastatic disease, with survival dropping to around 50% for non-metastatic disease with less than 90% necrosis.

CLINICAL PRESENTATION AND DIAGNOSIS

Because osteosarcoma usually presents close to a joint in long bones, it most commonly presents with pain or a limp. It is often thought to be an athletic injury at first. In some patients, a broken arm or leg will occur, bringing attention to the mass on radiographs. Diagnosis is based on pathology from a biopsy, which should be obtained by the surgeon performing the definitive surgery; therefore, the biopsy tract can be resected with the tumor.

TREATMENT OVERVIEW

Although surgery is the main treatment of the primary tumor, chemotherapy is used to prevent development of metastases in patients with high-grade osteosarcoma. Drugs frequently used for osteosarcoma include high-dose methotrexate, cisplatin, doxorubicin, and ifosfamide. Regimens have changed minimally in the last 25 years, with the current standard treatment in COG being cisplatin and doxorubicin alternating with two cycles of high-dose methotrexate. Neoadjuvant chemotherapy is commonly given for 6 cycles and continued after surgery for 12 more cycles (for a total of 29 weeks). The tumor is relatively resistant to radiation therapy, which is usually reserved for cases in which local control cannot be achieved surgically.[54] Surgical procedures usually fit into two categories: limb preservation or salvages, or amputation with prosthetics. There are a number of versions of each type of surgery.[52,53] When chemotherapy is used with surgery in non-metastatic patients, long-term (2–5 years) disease-free survival is 50% to 85%.[52–54]

ROLE OF CHEMOTHERAPY IN TREATMENT

CASE 95-3

QUESTION 1: G.C. is an 18-year-old man with a 2- to 3-month history of left shoulder pain. A tumor is found on radiograph, and biopsy confirms a high-grade conventional osteosarcoma of the left proximal humerus. No apparent metastases are found with CT and bone scans. Renal function, left ventricular ejection fraction, and hearing tests are all within normal limits. G.C. begins neoadjuvant chemotherapy consisting of high-dose methotrexate alternating with cisplatin and doxorubicin. Six cycles of this chemotherapy (cisplatin/doxorubicin twice and high-dose methotrexate 4 times) will be given before his surgery, after which he will receive two more cycles of cisplatin/doxorubicin, each followed by two cycles of methotrexate, then two more cycles of doxorubicin, each followed by two cycles of methotrexate. What is the goal of chemotherapy? What is the role of presurgical (neoadjuvant) chemotherapy in G.C.?

Because G.C.'s osteosarcoma is in his proximal humerus, the surgeon can remove the primary tumor using one of the various operations described in the literature.[52,53] Limb salvages typically work well in the upper extremities, with fewer complications than when they are used for lower extremities. Because patients with osteosarcoma usually die from metastases, the goal of the chemotherapy is to eradicate micrometastases, which are present more than 80% of the time, as discussed in the previous section. Neoadjuvant chemotherapy of osteosarcoma was developed to treat micrometastases while waiting for limb salvage surgeries to be arranged, performed, and healed. Neoadjuvant therapy may improve limb-sparing surgery by shrinking the tumor; it also allows histologic grading of the response to initial chemotherapy at surgery, a prognostic factor for risk of relapse (see Case 95-3, Question 2). However, no convincing evidence to date indicates that disease-free survival is better for patients who receive neoadjuvant chemotherapy relative to those who receive their chemotherapy as adjuvant therapy.[54] In G.C., a titanium bone implant was placed where the diseased humerus was removed. The ease of doing this surgery may have been enhanced by neoadjuvant chemotherapy–induced shrinkage of the tumor.

PROGNOSTIC FACTORS

CASE 95-3, QUESTION 2: At surgery, G.C.'s tumor shows excellent histologic response, shown by 99% necrosis of the tumor sample. At diagnosis, his LDH was 220 units/L. How do these prognostic factors affect the choice of therapy in osteosarcoma?

Conventional staging systems do not correlate well with prognosis for most bone cancers. Clinically apparent metastases or a location that does not allow complete surgical removal of the primary tumor are associated with a poor prognosis.[52–54] Newer surgical techniques and treatments have improved the prognosis with 20% to 30% of metastatic patients cured using neoadjuvant chemotherapy and surgery. Other potential prognostic factors have been identified; however, few of these factors have been used to stratify patients to different treatment regimens. G.C. has a minimally elevated LDH consistent with a relatively small tumor mass, although this is not used to stratify for treatment. The percentage necrosis of the tumor at surgery correlates with risk of recurrence. In current studies, patients with greater than 90% tumor necrosis after six cycles of neoadjuvant chemotherapy are considered good risk and are treated with standard chemotherapy such as G.C. is receiving. Patients whose tumors have less necrosis at surgery are considered to be standard risk, and they have a higher risk of treatment failure. No treatment modifications to date have demonstrated better outcomes for these patients than the good risk protocol described above.

DELAYED CLEARANCE AFTER HIGH-DOSE METHOTREXATE

CASE 95-3, QUESTION 3: After reconstructive surgery using a titanium implant, G.C. restarts his chemotherapy. During his fourth cycle of chemotherapy, after high-dose methotrexate is given, G.C.'s peak methotrexate concentration is 1,300 micromolar (μM) and the 72-hour concentration is 0.22 μM (normal, <0.1 μM at 72 hours). Recorded urine-specific gravities are less than 1.010, urine pH is between 7 and 8, and urine output is greater than 2 to 3 mL/kg/hour, which, according to guidelines, suggest a reduced risk of methotrexate-induced nephrotoxicity. His creatinine has increased from 0.9 to 1.1 mg/dL (creatinine clearance of 106 mL/minute/1.73 m^2); however, he does not have any signs or symptoms of methotrexate toxicity in spite of his delayed clearance. Leucovorin rescue (15 mg IV every 6 hours beginning at hour 24) is continued. What potential problems could be causing his retention of methotrexate?

Accumulations of protein-containing fluids (called third-spaces), such as pleural effusion and ascites, or GI obstruction, may retain methotrexate and slow the terminal excretion.[55–58] Slow excretion of methotrexate allows more proliferating cells to be exposed to methotrexate during the S phase of the cell cycle, increasing the cytotoxicity and resulting in more mucositis and myelosuppression. Many drugs interact with methotrexate, which can also slow its excretion. Cisplatin reportedly reduces the excretion of methotrexate because of nephrotoxicity, especially at cumulative cisplatin doses greater than 300 mg/m^2.[59] G.C. has received four doses of 120 mg/m^2 (480 mg/m^2 total dose) of cisplatin, which may have contributed to the reduced methotrexate excretion. He has not received concomitant nephrotoxins, such as aminoglycosides or amphotericin B. Weak organic acids, such as salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), penicillins, or trimethoprim–sulfamethoxazole (TMP–SMX), can compete with methotrexate for renal tubular secretion via the organic anion transport system.[59,60] Proton pump inhibitors are thought to more directly inhibit transporter proteins and have been reported to delay methotrexate excretion.[59,61]

Although G.C.'s serum creatinine appears to be the same that it was at diagnosis (1.1 mg/dL), serum creatinine is not always a good indicator of renal function, so it is possible that G.C. has had some renal damage that is not apparent from his serum creatinine concentrations.[29] A measured creatinine clearance was 176 mL/minute/1.73 m^2 at diagnosis, and a repeat at this point is 106 mL/minute/1.73 m^2. Even measured creatinine clearance may not always be accurate when compared with Cr-ethylenediaminetetraacetic acid measurement of glomerular filtration rate.[29] Although the reduced renal clearance may be contributing, it is not clear why G.C. is retaining methotrexate; future courses of methotrexate need close monitoring.

LEUCOVORIN RESCUE

CASE 95-3, QUESTION 4: How long should leucovorin be administered to G.C.?

Leucovorin is a tetrahydrofolate that bypasses methotrexate's block of dihydrofolate reductase and reduces the toxicities of high-dose methotrexate. It, therefore, can be used as a form of methotrexate rescue. Cytotoxic effects of methotrexate depend on concentration and duration of exposure.[62] Many high-dose methotrexate protocols continue leucovorin rescue until serum methotrexate concentrations are 0.1 μM, which would be expected to occur approximately 72 hours after a 12 g/m^2 dose infused over 4 hours. Because G.C. has delayed methotrexate clearance with persistence of methotrexate levels still above 0.1 μM at 72 hours, prevention of GI and bone marrow cytotoxicity may require continuation of leucovorin rescue until methotrexate concentrations are less than 0.05 μM.[62] For G.C., methotrexate concentrations did not fall below 0.1 μM until 108 hours after his dose; thus, leucovorin was continued 24 hours past that time to ensure presence until methotrexate fell below 0.05 μM. Other considerations may also be important in patients receiving leucovorin rescue. Because of the competitive nature of leucovorin rescue, higher leucovorin doses may be needed for patients with excessively high methotrexate concentrations.

Petros and Evans[56] describe in Figure 95-1 that the methotrexate concentrations (those above the blue-shaded area) place patients at high risk for methotrexate toxicity if given the usual low-rescue doses of leucovorin.[56,63–69] Methotrexate doses (12 g/m^2) infused over 4 hours are designed to produce peak methotrexate concentrations in the blood of 1,000 μM, followed by less than 10 μM at 24 hours, 1 μM at 48 hours, and 0.1 μM at 72 hours. Higher concentrations may result in greater toxicity and additional leucovorin doses may be necessary. If G.C.'s methotrexate concentrations had remained more than 1 μM 48 hours after the beginning of the infusion, current COG recommendations are to increase the leucovorin dose to 15 mg/m^2 every 3 hours until methotrexate concentrations fall below 0.5 μM. If concentrations exceed 5 μM 48 hours or more after the methotrexate dose, higher doses of leucovorin are recommended (150 mg/m^2 every 3 hours). Oral leucovorin administration should not be used when the patient has emesis or requires large oral doses (>50 mg), which are often poorly absorbed.[56] If a patient on high-dose methotrexate experiences renal failure and has elevated concentrations of methotrexate, glucarpidase (carboxypeptidase G2) may be used in addition to the leucovorin. Glucarpidase hydrolyzes methotrexate into inactive compounds and is very effective at quickly lowering methotrexate concentrations; however, it generally needs to be administered within the first 96 hours after the methotrexate dose. In spite of rapid reduction of methotrexate concentrations, it is not clear the extent to which it lowers morbidity or mortality from the high levels and delayed clearance.[70]

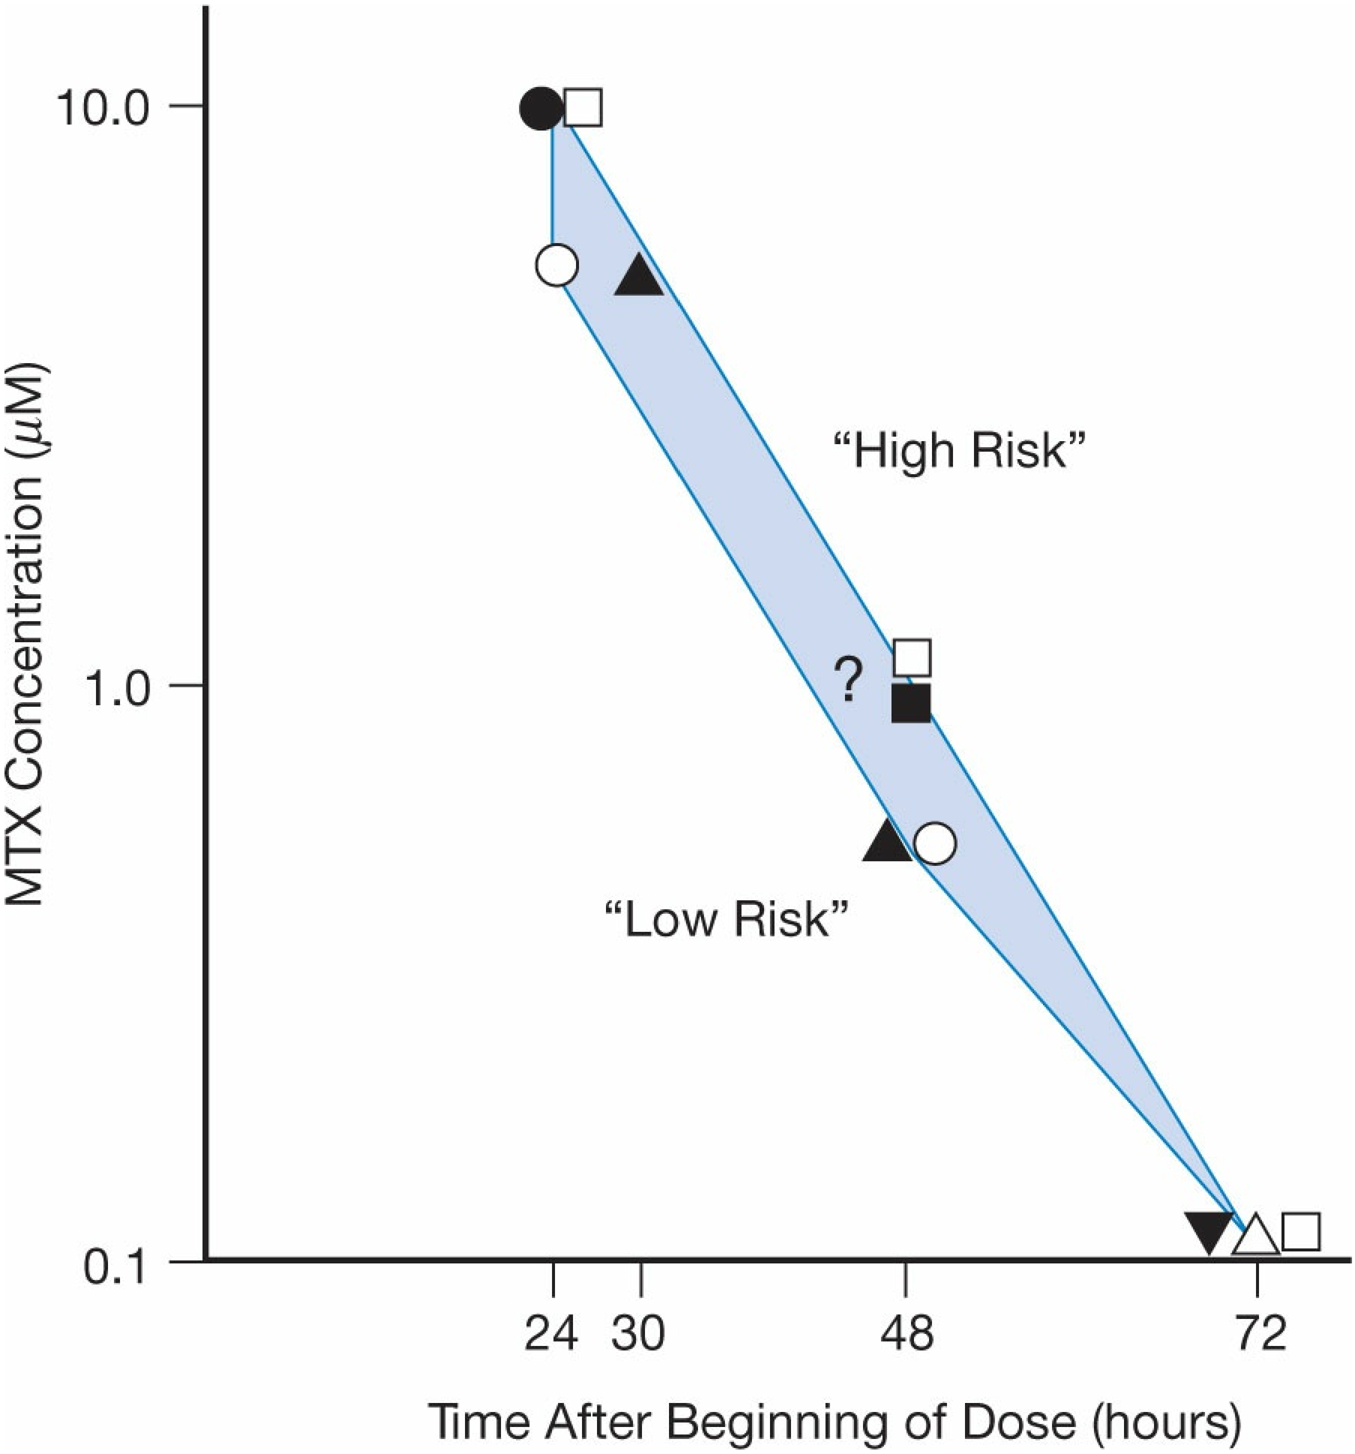

Figure 95-1 Composite semi-logarithmic plot of serum methotrexate (MTX) concentrations versus time. Several research groups have proposed threshold MTX concentrations over time that enable clinicians to identify patients at "high risk" for experiencing toxicity after high-dose MTX plus conventional low-dose leucovorin administration. Data for the figure were obtained from reports of (▲) Evans,[63] (△) Tattersal,[64] (○) Isacoff,[65] (○) Isacoff,[66] (□) Nirenberg,[67] (□) Stoller,[68] and (▼) Rechnitzer.[69] (Source: Petros WP, Evans WE. Anticancer agents. In: Burton ME et al, eds. Applied Pharmacokinetics & Pharmacodynamics. 4th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2006:617.)

Rhabdomyosarcoma

DESCRIPTION, EPIDEMIOLOGY, AND PATHOPHYSIOLOGY

Rhabdomyosarcoma is a soft tissue tumor of skeletal muscle. It is the most common soft tissue sarcoma of childhood, occurring in 3% of all children with cancer.[1] The two most common histologic types in children are embryonal and alveolar.[71]

Embryonal rhabdomyosarcoma cells resemble striated muscle and occur most frequently in young children with involvement in the head and neck or genitourinary tract. Alveolar rhabdomyosarcoma cells resemble lung parenchymal cells and occur more frequently in older children or adolescents with involvement of the trunk or extremities. Generally, patients with alveolar rhabdomyosarcoma have a poorer prognosis than patients with the embryonal type. Recent studies suggest that alveolar-appearing rhabdomyosarcoma cells without the PAX/FOXO1 fusion gene are molecularly and clinically identical to embryonal and may be treated as such, although this is not current practice in protocols.[72,73]

CLINICAL PRESENTATION AND DIAGNOSIS

The clinical presentation of rhabdomyosarcoma varies with its location (head and neck, genitourinary, parameningeal, extremity, orbit, as noted above). Diagnosis involves a biopsy of the tumor, which can be examined for appearance under an electron microscope, and a number of tests are run to identify molecular markers to differentiate it from other small round cell tumors.[71]

TREATMENT OVERVIEW

Treatment combines surgery, radiation, and chemotherapy. Complete surgical removal is often difficult, given the locations and infiltrative characteristics of rhabdomyosarcoma. Because good local control improves the prognosis,[71] radiation is generally administered after the surgery. Combination chemotherapy is necessary because the 5-year survival with local control alone is only 10% to 30%. Vincristine, dactinomycin, and cyclophosphamide (VAC regimen) have been used extensively to treat rhabdomyosarcoma.[71] Other agents producing responses include combinations of vincristine, doxorubicin, and cyclophosphamide; ifosfamide and etoposide; and vincristine and irinotecan.[71] Using the combination of vincristine, dactinomycin, and cyclophosphamide with local control of surgery or radiation in the fourth Intergroup Rhabdomyosarcoma Study (IRS) resulted in a 76% failure-free survival for patients with non-metastatic disease.[74]

CLINICAL PRESENTATION, PROGNOSTIC FACTORS, AND TREATMENT

CASE 95-4

QUESTION 1: F.J. is a 2-year-old girl with a rapidly enlarging mass on the lateral head of the gastrocnemius muscle in the right calf. F.J. has no other complaints. Bone marrow and scans are negative for metastatic disease. The diagnosis is embryonal rhabdomyosarcoma, stage III (unfavorable site and >5 cm mass). Initial expectations were that gross residual tumor would remain after the surgery, consistent with clinical group III. Chemotherapy consists of 3-week cycles of vincristine 0.05 mg/kg (days 1, 8, and 15 of some cycles but day 1 only of some cycles); dactinomycin 0.045 mg/kg on day 1 of each cycle; and cyclophosphamide 73 mg/kg on day 1 of each cycle with mesna to reduce the risk of hemorrhagic cystitis. Because of reports of hepatotoxicity during a prior study, especially in patients younger than 3 years of age, the protocol recommends all three drugs be dosed in milligram/kilogram for children younger than 3 years of age. Prophylactic TMP–SMX is begun at 150 mg/m^2/day (TMP) divided twice daily for three consecutive days/week. After each course of chemotherapy, F.J. is to receive filgrastim 5 mcg/kg/day subcutaneously for 14 days or until the absolute neutrophil count (ANC) is greater than 750 cells/μL. What factors in F.J. are associated with a good prognosis? What chemotherapy treatment would be most appropriate for F.J.?

The embryonal histopathologic classification has a better prognosis than the alveolar one, although evidence indicates that the location of the primary tumor is more important than the histology.[71] The primary site affects resectability, route of spread, and how early the diagnosis is made. Additionally, age between 1 and 9 years is associated with a better prognosis. The IRS have used a clinical grouping system (groups I–IV), which is based on spread of the disease and extent of resection. This system has been useful because of its correlation with prognosis where complete surgical removal and lack of metastases both correlate with good prognosis.[71] The fourth and fifth IRS studies compared the clinical grouping system with a TNM (tumor, lymph node, metastasis) staging system similar to that used in adult cancers. Although the two systems may result in different disease stages for a specific patient, both are considered valuable and current protocols use both systems.

In rhabdomyosarcoma, the tumor site is one important part of the T rating in the staging system. F.J.'s tumor involves an unfavorable site (the calf) and is greater than 5 cm, making it stage III. Although her tumor was expected to be clinical group III, after a good response to neoadjuvant chemotherapy, a complete resection was performed, making it clinical group I. This suggests that she has an 80% to 90% chance of 3-year survival based on the IRS-II, IRS-III, and IRS-IV results.[71,74–76] The IRS-V classified patients as having low-risk, intermediate-risk, or high-risk disease. Patients at low-risk include those with embryonal rhabdomyosarcoma at favorable sites, or at unfavorable sites with no more than microscopic residual tumor.[71] Patients at intermediate risk have the embryonal subtype with gross residual tumor or the alveolar subtype without metastatic disease. Patients at high risk include those with metastatic alveolar or embryonal disease.

Chemotherapy for many patients at low risk is limited to vincristine and dactinomycin.[71] Most at intermediate risk are treated with vincristine, dactinomycin, and cyclophosphamide.

Patients at high risk have not responded well in the past and are candidates for trials with newer drugs added to the vincristine, dactinomycin, and cyclophosphamide. A recent study added courses of vincristine and irinotecan, ifosfamide and etoposide and vincristine, doxorubicin, and cyclophosphamide (COG ARST0431), and 3-year event free survival appears good compared to historical data for patients with 0 to 1 higher-risk features.[77] F.J. would be in the low-risk group; however, her large initial tumor justifies adding cyclophosphamide to the vincristine and dactinomycin as in the intermediate-risk regimen. Because radiation to her leg would stop bone growth and her surgical margins were tumor free, no radiation is being administered.

TRIMETHOPRIM-SULFAMETHOXAZOLE PROPHYLAXIS AND FILGRASTIM FOR MYELOSUPPRESSION

CASE 95-4, QUESTION 2: What are the reasons for treating F.J. with TMP–SMX and filgrastim?

F.J.'s VAC regimen was associated with a high incidence of neutropenic fevers even during the pilot studies. Because of the frequency of severe myelosuppression, TMP–SMX is used until 6 months after chemotherapy for prophylaxis against Pneumocystis jirovecii, an opportunistic pathogen. Filgrastim is used to minimize neutropenia so that the chemotherapy dose intensity can be maintained.

RENAL FANCONI SYNDROME WITH IFOSFAMIDE

CASE 95-4, QUESTION 3: F.J.'s mother read on the Internet about a patient with rhabdomyosarcoma who had received vincristine, ifosfamide, and etoposide and was cured. She wants to know why that regimen is not being used for her daughter. Explain the rationale for F.J.'s regimen.

The IRS-IV results for local or regional disease (intermediate risk) demonstrated no advantages of vincristine, ifosfamide, and etoposide or vincristine, dactinomycin, and ifosfamide over the standard vincristine, dactinomycin, and cyclophosphamide treatment.[74] Additionally, the ifosfamide-containing regimens caused more toxicity. Ifosfamide has been associated with renal Fanconi syndrome, a proximal tubular defect that is characterized by wasting of electrolytes, glucose, and amino acids, as well as renal tubular acidosis and, in a minority of cases, an increased serum creatinine. Data suggest that the risk of Fanconi syndrome is increased in children that are younger than 3 years of age; have received total ifosfamide doses greater than 72 to 100 g/m^2; have hydronephrosis, a single kidney, or an elevated serum creatinine; or have received previous platinum therapy.[78–81] During each course of her chemotherapy, F.J. exhibits ketonuria; however, this is not a toxicity of her chemotherapy. Ketonuria is caused by her mesna therapy, which has been reported to routinely cause false-positive ketone tests.[82]

ACUTE LYMPHOBLASTIC LEUKEMIA OF CHILDHOOD

Acute leukemia is a malignancy of blood-forming cells involving the lymphoid and myeloid cell lines. The two most common types of childhood leukemia are ALL and acute myelogenous leukemia (AML), with the former accounting for 75% of cases and the latter for approximately 15%. Acute lymphoblastic leukemia is the most common childhood cancer, accounting for approximately 26% of all malignancies in children.[83]Approximately 2,600 new cases of childhood ALL occur each year in the United States in children younger than 19 years of age.[83]

A distinct peak incidence occurs at ages 2 to 3 years for ALL (>80 cases/million) and then decreases substantially for 8- to 10-year-olds (20 cases/million). A higher incidence of ALL is seen in white children than in African American children. This racial difference is most apparent in the 2- to 3-year-old age group, with a nearly threefold greater incidence rate for white children.[84]

Before the early 1970s, ALL was a fatal illness with most children succumbing to their disease within 2 to 3 months after diagnosis. Today, more than 80% of children achieve prolonged survival with antileukemic therapy.[83,84] New innovations in therapy for ALL continue to improve survival while decreasing the long-term morbidity associated with current treatment regimens.[85]

Epidemiology and Etiology

The etiology of ALL is unknown; however, several interesting associations have been discovered. A high incidence of leukemia was found among survivors of the atom bomb explosion in Japan during World War II, and those closest to the epicenter of the blast were at greatest risk.[86,87] Leukemia also occurs in children exposed to radiation in utero.[88] Other unproven factors that have been suggested to cause ALL include exposure to electromagnetic fields, pesticides, maternal use of alcohol, contraceptives, and cigarette smoking.[89–92] Viruses have not been proven to cause childhood ALL.[93] In particular, the incidence of childhood ALL has not increased markedly over the past 40 years during a time when electricity use has seen a large increase.[94]

Pathophysiology

The pathophysiology of ALL involves the replacement of normal bone marrow elements with a clone of immature lymphoid cells. The essential lesion in ALL is a stabilization of a malignant cell in the lymphocyte differentiation process. Many factors are involved in the control of normal cellular proliferation. Leukemia may represent a disruption in one or more of the normal relationships within the cell proliferation pathway, such as an abnormal response to lymphoid cell growth factors.[95]

With the availability of classification systems of lymphoblasts based on morphology, immunology, and cytogenetics, it has become clear that ALL is a heterogeneous disease. This is especially true with regard to cytogenetic abnormalities. The immunologic heterogeneity results from leukemic transformation at various stages of lymphocyte differentiation. In addition, an emerging classification involving gene expression profiling may allow for further classification of ALL cytogenetic subtypes, potentially allowing for prediction of response and adverse events.[96] As discussed later in this section, these classifications have important prognostic value.

Clinical Presentation

The signs and symptoms of ALL are nonspecific and many are shared with other childhood diseases such as juvenile rheumatoid arthritis (JRA). This occasionally leads to a child with ALL being mistakenly treated with corticosteroids for JRA. As a general rule, children should not be treated with corticosteroids without first performing a complete blood count (CBC) or a bone marrow aspirate. These signs and symptoms reflect the uncontrolled growth and differentiation of the leukemic clone and the resulting deficiency in normal bone marrow elements, namely neutrophils, red blood cells (RBCs), and platelets. Frequent clinical findings include fever (61%), bleeding (48%), and bone pain (23%).[97] Bone pain is believed to be the result of hypercellular bone marrow and infiltration of leukemic lymphoblasts into pain-sensitive structures such as the periosteum. Although bone pain may be severe, it quickly resolves once chemotherapy is initiated. On physical examination, many patients have lymphadenopathy (50%), splenomegaly (63%), or hepatosplenomegaly (68%).[97]

At diagnosis, at least 59% of patients have a normal or low white blood cell (WBC) count; the remainder have elevated counts.[97] The WBC differential typically shows a low percentage of neutrophils and bands with a marked lymphocytosis. Lymphoblasts may be present in the peripheral blood even with a low WBC count (e.g., 2,000–4,000 cells/µL), but they are more likely when the WBC count is elevated.[98] A normochromic, normocytic anemia, along with thrombocytopenia, is present in most patients.[97]

Diagnosis

A bone marrow aspirate and biopsy are usually necessary to confirm the diagnosis of ALL. In patients with elevated WBC counts, the diagnosis can be confirmed by studies of lymphoblasts in the peripheral blood. The diagnosis of ALL is made when at least 25% of lymphoid cells in the bone marrow are blasts.[99] Most ALL patients have far greater than 25% blasts and many have complete replacement of bone marrow with lymphoblasts. Once a child is diagnosed with ALL, it is important to determine the disease characteristics that influence treatment decisions and prognosis.

Prognostic Variables

CLINICAL VARIABLES

Certain clinical and laboratory findings present at diagnosis are important predictors of prognosis and are used to determine risk stratification. Children with ALL are classified by their risk of relapse into one of the following categories: standard, high, or very high risk. Debate continues over which variables most strongly influences patient outcome. Upon initial presentation, the most important risk-defining features of childhood ALL are age and initial WBC count.[98] Ongoing investigations are likely to further refine what constitutes different ALL risk populations.

White Blood Cell Count

The initial WBC count is considered to be among the most important predictors of outcome in childhood ALL. Its importance as a prognostic feature is often retained after the adjustment for other important prognostic criteria.[99] Children with the highest WBC counts at presentation have the shortest duration of complete remissions.[100–102] There appears to be a linear relationship between the duration of remission and the WBC count at presentation. Although exactly where the demarcation line is for predicting a good or a poor prognosis is unknown, an initial WBC count greater than 50,000 cells/μL is generally associated with a poor prognosis.[98]

Age

Patients younger than 1 year or older than 9.99 years of age at diagnosis tend to have worse prognoses.[98] At least one trial has demonstrated that more intensive therapy may overcome the adverse prognostic factor of adolescent age.[103] These investigators reported that young adults (16–21 years of age) with ALL have an event-free survival of approximately 60% at 6 years, which is similar to that of patients 10 to 15 years of age and superior to that achieved in most trials of older adults.[103] For adolescents 15 to 20 years of age, treatment on intensive pediatric leukemia protocols has demonstrated superiority over that achieved on adult treatment protocols, with one study showing an estimated event-free survival of 67% with the pediatric protocol versus 41% for the adult protocol.[104]

Age is the strongest predictor of prognosis with regard to infants, a group in which survival is exceedingly poor compared with other age groups.[105–107] For infants, even with intensified chemotherapy regimens, long-term, disease-free survival is usually less than 50%, especially when associated with cytogenetic aberrations involving the mixed lineage leukemia (MLL) locus.[108]

Race

Although African Americans have a lower incidence of ALL, several studies have shown that these children appear to have a higher relapse rate than Caucasian children.[84,109–113] Data from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) Program demonstrate a 5-year survival rate of 64% versus 78% for African American and Caucasian children, respectively. The differences in outcome for African Americans appear to be the result of a more severe form of ALL in this patient population.[113] However, intensified therapy showed that 10-year survival rates are equal between African American and Caucasian children.[113] It has also been demonstrated in a SEER update that the incidence rate for Hispanics was greater than for non-Hispanics and was the highest of all racial subgroups.[112] An analysis of racial and ethnic differences in outcome with contemporary therapy also demonstrated a difference in survival among groups, with the greatest survival for Asian children and lowest for African Americans and Hispanics.[113]

IMMUNOLOGIC VARIABLES

Acute lymphoblastic leukemia is classified into different immunologic subsets based on cell surface markers or antigens present on the leukemic lymphoblasts at diagnosis. These can be categorized as cells of B-cell and T-cell origin. The B-cell lineage is further classified into various subtypes through the use of monoclonal antibodies. These subtypes reflect the various stages of differentiation at which leukemia may develop. Approximately 15% to 20% of children with ALL have leukemia with a T-cell lineage,[114,115] and 1% to 2% of patients have leukemia with a mature B-cell origin.[116,117] Using more sophisticated diagnostic techniques, the majority of patients who were previously classified as non–T-cell ALL or non–B-cell ALL (null cell ALL) are now known to have leukemia of a more immature B-cell lineage.[118–120] Most patients with B-cell lineage ALL (80%) have cells that are positive for the common ALL antigen (CALLA, designated CD10) on their surface,[121] this is referred to as common ALL. Additional markers, including CD19 and cytoplasmic immunoglobulin, have been used to further determine the level of differentiation of leukemic cells of the B-cell lineage. Intermediate cells of the B-cell lineage (pre–B cells) possess these markers but more immature cells (early pre–B cells) do not.[121,122] More than 60% of children with ALL have a leukemia of the early pre–B subtype and approximately 20% have a leukemia of pre–B cells.

Mature B-cell ALL (or Burkitt ALL) has traditionally been associated with a poor prognosis, but prognosis has improved greatly with the advent of short-term, very intensive chemotherapy.[117,123,124] Although differences in outcome have been noted among the B-cell subtypes,[123] when other prognostic factors are considered and when effective therapy is used, these differences may no longer be evident.[125] At present, immunologic features that differentiate B-cell precursor, T-cell, and mature B-cell ALL are believed to be clinically important because different types of chemotherapeutic strategies are used for these three immunophenotypes.[85,126]

Patients with T-cell ALL have several distinguishing features, including a greater likelihood of being older males with high initial WBC counts and the presence of a mediastinal mass or initial leukemic involvement of the CNS.[127,128] Patients with T-cell ALL historically have had a decreased survival, although more

---

intensive treatment is improving their outcomes.[125] Studies with more intensified therapy also demonstrate no difference in relapse between T-cell and B-cell lineage ALL, although T-cell ALL patients tend to relapse much earlier.[127,128] T-cell lymphoblasts are less efficient at polyglutamation of methotrexate because these cells have lower concentrations of the methotrexate polyglutamate synthesizing enzyme, folylpolyglutamate synthetase.[129] This has been proposed as a possible explanation for the relative chemotherapy resistance and the need for increased methotrexate dose intensity in patients with T-cell ALL.[85]

CYTOGENETIC VARIABLES

Advances in chromosomal analysis have improved the understanding of ALL biology. Abnormalities in either chromosome number (ploidy) or structure of the leukemic clone have been found in 60% to 75% of ALL cases.[85] Many of these abnormalities appear to have prognostic importance.[85] Ploidy is represented by the DNA index. A value of 1.0 indicates a normal number of chromosomes, and a value greater than 1.0 indicates an increased number of chromosomes by a multiplication factor of the normal chromosome number. Children with leukemia blasts containing more than 52 chromosomes (DNA index >1.16, hyperdiploid) appear to have an increased probability of continuous complete remission versus patients with leukemia blasts containing a diploid chromosome complement or with a DNA index less than 1.16.[130] An in-vitro study of hyperdiploid versus non-hyperdiploid ALL revealed that those cells with a higher DNA index were more sensitive to antimetabolites (e.g., mercaptopurine) and asparaginase.[130,131] Also, B-precursor hyperdiploid ALL cells contain more reduced folate carriers than diploid B-precursor blasts. Hyperdiploid cells have elevated levels of gene expression for these carriers, which may account for the higher levels of methotrexate polyglutamates noted in these cells as compared to patients with B-precursor diploid ALL.[131–134] In contrast, patients with hypodiploidy (<45 chromosomes and, in particular, those with 24–28 chromosomes) have a significantly worse outcome than non-hypodiploid patients.[135]

Translocations are the most common structural abnormalities occurring in leukemic cells[136] and occur in approximately 75% of childhood ALL cases.[137] Certain translocations are associated with treatment failure and relapse.[85] The translocations most commonly associated with treatment failure are the MLL rearrangements [t(4;11), t(11;19), and t(1;11)] and the BCR-ABL fusion transcript [t(9;22), Philadelphia chromosome]. Historically, children with the Philadelphia chromosome rearrangement were considered to represent a population at very high risk of relapse and allogeneic stem cell transplantation was often part of their initial therapy. This translocation occurs in approximately 2% to 5% of childhood ALL cases. A published study added imatinib, a tyrosine kinase inhibitor directed against the Philadelphia chromosome fusion product, to aggressive leukemia therapy. They treated 28 patients with chemotherapy and imatinib and compared them to children receiving a matched sibling transplant (21 patients) or a transplant from an unrelated donor (13 patients). The 5-year event-free survival was similar (70%, 65%, 59%) respectively, and the authors concluded that allogeneic stem cell transplant now provides no role in the upfront treatment of children with Philadelphia chromosome positive ALL.[136–139]

Once a patient achieves complete remission, abnormalities of both ploidy and structure are not evident in the patient's recovered bone marrow by morphologic assessment, although a leukemic cell burden as large as 10^9 may remain. However, newer techniques based on polymerase chain reaction (PCR) assays can detect minimal residual disease (MRD) in many patients. If relapse does occur, the leukemic cell cytogenetic characteristics are usually identical to those observed at diagnosis.[140,141]

EARLY RESPONSE

An additional factor of prognostic importance in childhood ALL is that of early response to therapy. Several investigations have noted that early response, as measured by either clearance of blasts from the peripheral blood or morphologic bone marrow remission (e.g., <5% bone marrow blasts) on day 7 or 14 of therapy, is predictive of long-term disease-free survival. In a review of 15 trials, early response was an independent prognostic factor in each study.[141] Response was most commonly measured based on morphologic evaluation of day 14 bone marrow results, and it appeared that assessment of early response was more sensitive with bone marrow studies. Children who were slow early responders were 2.7 times more likely to have a relapse than those with more rapid clearance of blasts. Interestingly, the rapidity of response maintained its prognostic significance adjusting for the initial

WBC count, providing further evidence that this variable is an important independent marker of prognosis. The rapidity of response is an intuitive marker of treatment sensitivity. However, the use of morphologic criteria to assign responder status still includes patients with a significant disease burden. It is important to note that such tests of bone marrow burden may represent a dilute sample or a decrease in marrow cellularity and may not reflect the total leukemia burden in the body. It is estimated that these measures of early response may detect up to 25% of children at risk for early relapse.[145] Rapid early response has been defined as clearance of bone marrow blasts by day 15 of induction, whereas slow early response refers to the converse. Whether patients are rapid or slow early responders is now being used to determine the type and intensity of further chemotherapy because slow early responders benefit from more intensive post-induction chemotherapy.[133] Other groups have examined response to initial treatment with a 7-day course of prednisone (initiated before the start of systemic induction chemotherapy) in children with high-risk ALL. Prednisone-poor response, defined as patients with greater than 1,000 blast cells/µL in peripheral blood after 7 days, was a predictor of poor outcome and was used to intensify induction therapy with a consequent improvement in event-free survival.[142]

MINIMAL RESIDUAL DISEASE

Several investigators have examined the prognostic value of detecting MRD in bone marrow samples through the use of sophisticated PCR and flow-cytometry. A variety of lymphoblast characteristics, including gene fusion transcripts, immunophenotype, and antigen receptor gene rearrangements, may be relied on for MRD detection in children with ALL. Although specific fusion transcripts can be relied on as PCR targets in only one-third of childhood ALL cases, clonal antigen receptor gene rearrangements occur in virtually all cases.[140] Using various techniques, approximately 50% of children with ALL are MRD positive at the completion of induction therapy, and roughly 45% of these patients will experience a relapse. The association of a negative test for MRD at the completion of induction therapy appears stronger because it has a negative predictive value of 92.5% and a positive predictive value of 44.5%. In patients positive for MRD, there is a continuous decrease in MRD during the months of chemotherapy treatment. Persistence of MRD beyond 4 to 6 months or reemergence of MRD is almost always predictive of future relapse. It is now established that the presence of MRD is an important prognostic factor, regardless of the patient's initial WBC count or age at presentation.[140] A large study of the prognostic value of MRD for day 7 blood samples and for bone marrow samples at both the end of the induction and consolidation phases demonstrated that MRD at the end of the induction phase was the most important predictor of prognosis when compared to other laboratory and clinical factors. Day 7 MRD findings had additional prognostic value. Data from this study for end of induction MRD demonstrated major differences in event-free survival as follows:

88% for MRD negative, 59% for MRD of 0.01% to 0.1%, 49% for MRD of 0.1% to 1%, and 30% for MRD greater than 1%. MRD predicted relapse that occurred early in treatment and late relapses as well. Monitoring of MRD is now established in the management of childhood ALL and is being used to risk-stratify treatment in current front-line leukemia studies.[143,144]

Overview of Treatment

The treatment for pediatric ALL is organized into different phases of chemotherapy. Treatment begins with induction therapy, which typically includes three or four systemic agents in addition to CNS preventive therapy. The intensity of induction therapy is based on the biology of the ALL, and today the main variables used for determining this phase of therapy are the child's age and WBC count at diagnosis. Induction therapy is designed to induce a complete remission and typically lasts 28 days. After induction therapy, the next phase of therapy can be defined as post-induction therapy and consists of a number of different cycles of chemotherapy referred to by such terms as consolidation, delayed intensification, and interim maintenance therapies. This phase of intensive chemotherapy usually uses combination approaches that are somewhat different than induction therapy and that are designed to kill leukemia cells in the cell cycle that were not destroyed by induction therapy. This phase of therapy is continuing to undergo substantial revision as studies determine which therapy components are optimal for various patients. The duration and intensity of the post-induction phase of therapy is tailored based on certain prognostic features of the leukemia as outlined above. The third phase of therapy is termed the maintenance phase, and it represents the longest phase of chemotherapy for these patients, often taking approximately 2 years to complete. Maintenance therapy is typically less intensive than the previous phases and consists mostly of continuous oral chemotherapy with infrequent intravenous and CNS therapy. In general, treatment intensity diminishes from the induction/consolidation phase to the maintenance phase.

REMISSION INDUCTION THERAPY

Goal of Induction

CASE 95-5

QUESTION 1: J.B. is a 4-year-old Hispanic boy presenting with a 2-week history of an upper respiratory tract infection and a 1-week history of otitis media. His symptoms have worsened, and he now presents with a nosebleed and fatigue. Physical examination reveals appreciable pallor and hepatosplenomegaly. A CBC with differential reveals a normochromic, normocytic anemia with the following:

Hematocrit (Hct), 15.7%

Hgb, 5.7 g/dL
WBC count, 4,300 cells/μL
Platelet count, 13,000 cells/μL

A differential on the WBC count reveals 82% lymphocytes (normal, 30%–40%), 7% neutrophils (normal, 50%–60%), and 11% lymphoblasts (normal, 0%). Based on these findings, a bone marrow biopsy is performed which reveals 95% lymphoblasts. A diagnosis of ALL is made. The immunologic class is early pre–B cell based on CD10 and CD19 positivity. Radiography of the chest does not reveal a mediastinal mass and a lumbar puncture shows that there are no leukemic lymphoblasts in the cerebrospinal fluid. J.B. is hydrated, alkalinized, and treated with oral allopurinol 200 $mg/m^2/day$, with a plan to institute induction therapy the next day. Within a few days, J.B. will be treated with several drugs for his leukemia.

What is the goal of the induction therapy that J.B. will receive?

The goal of induction therapy is complete remission (i.e., the inability to detect leukemic cells in the peripheral blood or the bone marrow by morphologic microscopic evaluation). J.B.'s peripheral blood values must be within the normal range and the bone marrow must reveal less than 5% lymphoblasts. This definition also assumes the absence of lymphoblasts in the cerebrospinal fluid (CSF). In addition, based on what is now known regarding MRD, achievement of an MRD measurement of less than 0.01% by the end of induction therapy (i.e., day 29) would now be an additional goal of this first phase of therapy. Although these findings indicate an adequate response to chemotherapy, they do not indicate a cure. Most patients have a total of 10^{12} cells at diagnosis and successful induction regimens reduce this cell load by 99% to 10^9.[145,146] Therefore, continuation of therapy will be required for J.B. to further reduce the leukemic cell population and to increase his chances of long-term survival. Without continuation of therapy, the majority of patients with ALL will relapse within a few months.[147]

Induction Combination Chemotherapy

CASE 95-5, QUESTION 2: Which agents should be used to achieve complete remission?

The agents most commonly used in remission induction therapy are vincristine, prednisone, dexamethasone, asparaginase, pegaspargase, and daunorubicin (Table 95-6). The prednisone or dexamethasone dose is not routinely tapered at the end of induction treatment.[148–151] Dexamethasone has supplanted prednisone as the corticosteroid used during induction therapy or throughout therapy. This is based on earlier work showing that dexamethasone has greater CSF penetration.[152] In patients with standard-risk ALL, a randomized comparison of dexamethasone to prednisone for induction therapy showed a lower CNS relapse rate in the dexamethasone group.[150] However, the use of a 28-day course of dexamethasone during induction for patients with high-risk ALL was also associated with an increased risk of infectious complications and avascular necrosis of the joints in adolescent patients.[153] This has led to removal or alteration of dexamethasone use during induction therapy in high-risk patients. It is plausible that the addition of dexamethasone to a more intensive chemotherapy backbone that is used for induction therapy of high-risk ALL may significantly increase the risk of infection in this more myelosuppressive regimen.

Table 95-6

Systemic Induction Regimens for Childhood Acute Lymphocytic Leukemia

Agent	Route	Dose/Schedule
Three-Drug Induction Regimen		
Prednisone	PO	60 mg/m^2/day × 28 days
Or		
Dexamethasone	PO	6 mg/m^2/day × 14 days
With		
Vincristine	IV	1.5 mg/m^2/week (max 2 mg) × 4 doses
And		
Pegaspargase	IM	2,500 units/m^2 × 1 dose
If Four-Drug Induction		
Daunorubicin	IV	25 mg/m^2/week × 4 doses

IM, intramuscularly; IV, intravenously; PO, orally.

No chemotherapy drug meets the criteria of an ideal agent (i.e., toxic to leukemic cells only and active in all phases of the cell cycle). Corticosteroids, vincristine, and various asparaginase products come closest to this ideal in terms of activity, primarily against lymphoblastic leukemia, because these agents are selectively toxic to the leukemia cells while sparing normal bone marrow elements. To improve the success in attaining complete remission, additional agents have been added to vincristine, prednisone, and asparaginase (Table 95-6). The most frequently used additional agent is an anthracycline, such as daunorubicin or doxorubicin. Use of at least a three-drug induction regimen is the current standard of care for children at low or intermediate risk of relapse and results in improvements in both remission rate and duration versus less intensive therapy.[154–156] Currently, a four-drug regimen, or an even more intensive induction regimen consisting of more than four drugs, and often for a duration of more than 4 weeks, is used for children at high risk of relapse and adult ALL patients.[148,157–159]

If complete remission is not achieved with three agents by the end of induction, patients are treated with additional agents (e.g., an additional 2–4 weeks of daunorubicin and prednisone; initiation of cytarabine with additional asparaginase;

vincristine and prednisone for 1–2 weeks). Because this occurs rarely, there is no consensus about the most effective agents or schedules to use in this situation. Most of these patients have a decreased survival and a higher relapse rate.

Intensive induction treatment has benefits for the majority of children with ALL. This treatment strategy supports the hypothesis of Goldie and Coldman[160] that intensification of early treatment may decrease the chance that drug resistance will develop. This may therefore increase the proportion of long-term relapse-free survivors. Induction therapy is determined based on clinical findings, such as age at diagnosis and initial WBC count. Based on these prognostic variables, J.B. is a patient with a low risk of relapse. A three-drug induction regimen consisting of vincristine, dexamethasone, and pegaspargase is recommended to optimize his chances for long-term disease-free survival.[149,150,161] Additional laboratory testing (e.g., bone marrow analysis for remission and MRD) will be relied on to design his post-induction therapy.

Vincristine Toxicity

CASE 95-5, QUESTION 3: J.B. is discharged from the hospital during the second week of induction chemotherapy. Results of his CBC and differential indicate that he is responding well to his chemotherapy (i.e., WBC count 2,600 cells/μL, neutrophils 69%, lymphocytes 22%, platelets 229,000 cells/μL, Hct 28.6%, and blastocytes 0). However, during the third week of induction chemotherapy, J.B. exhibits severe abdominal pain. It is discovered that he has not had a bowel movement in 6 days. J.B. has also been exhibiting “acting out” behaviors in recent days. How might these symptoms be explained?

The use of vincristine is associated with an autonomic neuropathy, which may substantially reduce GI motility;[162] in severe cases, paralytic ileus may result. Constipation is often accompanied by colicky abdominal pain, which may be quite distressing.[163] These symptoms usually become apparent 3 to 10 days after drug administration and resolve over several days. Prophylactic use of a stool softener (docusate) or laxative (polyethylene glycol) may lessen the severity of J.B.’s constipation and facilitate regular stooling. This regimen should have been instituted soon after the first dose of vincristine.

J.B.’s emotional changes are likely the result of the dexamethasone he is receiving. Emotional lability, sleep disturbances, depressed mood, and listlessness have occurred during corticosteroid therapy in children with ALL.[164] These behavioral changes can be quite disruptive, and parents should be prepared for them in advance. Behavioral disturbances typically resolve within 2 weeks after corticosteroid discontinuation.[164]

INTRATHECAL CHEMOTHERAPY PROPHYLAXIS

CASE 95-5, QUESTION 4: In addition to the aforementioned drugs, J.B. also receives intrathecal (IT) chemotherapy for CNS prophylaxis with methotrexate at the beginning (week 1) and end (week 4) of induction therapy. What is the purpose of IT chemotherapy?

IT or CNS preventive therapy decreases the chance of relapse within the CNS and increases J.B.'s chance of long-term survival. Before CNS preventive therapy was routine, the CNS was the most common site of leukemic relapse and thus predicted bone marrow relapse.[165,166] Patients at greatest risk for CNS relapse include those with very high initial WBC counts, T-cell ALL, and infants.[167,168] However, because all patients with ALL are at risk for CNS relapse, one of the largest incremental improvements in disease-free survival has been the routine use of CNS preventive therapy.[85] Because many antileukemic agents do not distribute well into the CSF, this area becomes a sanctuary site for leukemic lymphoblasts. The aim is to eradicate any CNS leukemic lymphoblasts present at diagnosis and to prevent the emergence of a relapse within the CNS.

Central Nervous System Preventive Therapy Options

CASE 95-5, QUESTION 5: What are the various treatments available for CNS preventive therapy? What factors determine which treatment is selected for J.B.?

All treatment protocols for childhood ALL use some form of CNS preventive therapy, although different regimens are used. The first successful CNS prophylaxis treatments were 2,400 cGy of craniospinal radiation with or without IT methotrexate, which markedly reduced the CNS relapse rate.[169] However, the adverse effects of cranial irradiation were problematic. These included decreased intellectual function, dysfunctions of the neuroendocrine system, and poorer psychosocial functioning.[170–175] As a result, clinicians sought alternative, potentially safer forms of CNS preventive therapy. For example, lower doses (1,800 cGy) of cranial irradiation were combined with IT methotrexate to reduce the CNS effects, which proved to be equivalent to 2,400 cGy in preventing CNS relapse.[168,173] Nevertheless, because concerns regarding the long-term toxicity of cranial radiation remain, especially for younger children, it is currently reserved for patients with detectable CNS disease on presentation, some patients with T-cell ALL, and patients with CNS relapse. Currently, CNS preventive therapy includes IT methotrexate alone, triple IT chemotherapy (methotrexate, cytarabine, and hydrocortisone), or IT methotrexate combined with systemic-dose–intensified methotrexate.[174–176]

Because patients differ in their risk for developing CNS leukemia, CNS preventive therapy should be tailored accordingly. Children with standard ALL have equivalent CNS protection rates with either cranial radiation or IT chemotherapy, as long as adequate intensive systemic therapy is provided.[177–179] These patients are treated with triple IT chemotherapy or IT methotrexate, depending on the institutional protocol.[180]

Intrathecal Chemotherapy: Chronic Adverse Effects

CASE 95-5, QUESTION 6: What are the chronic adverse effects of IT chemotherapy?

The chronic toxicities of IT chemotherapy are now being determined. When examined for effects on growth, triple IT chemotherapy demonstrated no effect on the final height achieved by children in contrast to a reduced final height in patients receiving cranial irradiation.[181] Limited evidence suggests that IT chemotherapy may be associated with some neuropsychologic deficits. At least one study of patients receiving IT chemotherapy without cranial irradiation has demonstrated deficits in higher-order cognitive function tasks and learning disabilities in mathematics.[182] Another study has demonstrated that children who were treated with IT chemotherapy before age 5 years had deficits in the cerebellar-frontal brain subsystem and in neuropsychologic performance.[183] It is unclear whether these deficits translate into significant long-term consequences.

Intrathecal Methotrexate Dose

CASE 95-5, QUESTION 7: J.B. is at a low risk for CNS relapse, and the decision is made to treat him with IT methotrexate. What dose of IT methotrexate should J.B. receive?

High chemotherapy concentrations can be attained within the CSF with relatively low doses because the CSF volume of distribution is small in contrast to the peripheral plasma volume (140 vs. 3,500 mL).[184,185] Drug exposure is also maximized by the longer half-life of most drugs in the CSF.[186] The approach used for IT dosing differs from systemic administration, the latter of which is based on body weight or body surface area. CSF methotrexate concentrations appear to correlate better with patient age than size.[187] The CSF volume in children approaches that of an adult by the age of 3 years. Because CSF volume does not correlate with body surface area, IT doses based on body size result in subtherapeutic concentrations in young children and potentially toxic concentrations in older children and adults. The age-based dosing regimens shown in Table 95-7 are less neurotoxic and are associated with a lower rate of CNS relapse than doses based on size.[187] Using this dosing regimen, J.B.'s dose of IT methotrexate should be 12 mg. If triple IT therapy were used, the doses of IT cytarabine and hydrocortisone would be 24 and 12 mg, respectively. These latter doses are also based on age, but no literature exists to support how they were derived. Nevertheless, empiric evidence supports their efficacy.

Dangers of Intrathecal Vincristine

CASE 95-5, QUESTION 8: J.B.'s IT methotrexate is to be administered on the same day as his vincristine dose. Are there any special precautions that should be taken when these medications are administered in close proximity?

Table 95-7

Dosage Regimen for Intrathecal Chemotherapy Based on Patient Age

Patient Age (years)	Methotrexate (mg)	Hydrocortisone (mg)	Cytarabine (mg)
<1	6	6	12
1	8	8	16
2	10	10	20
3	12	12	24
≥9	15	15	30

Inadvertent administration of vincristine into the IT space is almost uniformly fatal,[188–192] although there is at least one report of a patient in whom death but not serious sequelae was prevented. Despite widespread educational efforts in hospitals and clinics, and numerous precautionary measures, deaths from the inadvertent IT administration of vincristine still occur. The clinical course in patients mistakenly given IT vincristine has typically progressed from backache and headache on day 1, muscle weakness (generalized) on day 2, apnea on day 5, loss of evidence of electroencephalographic activity by days 7 to 9, and death on day 12.[190] To avoid the tragedy of IT vincristine administration, vincristine should be admixed separately or at a different time from IT medications, specially labeled and mixed as a small volume parenteral (i.e., minibag) rather than in a syringe, and preferably delivered to the patient area for IV infusion after the administration of IT medications.

TAILORING OF POST-INDUCTION THERAPY

CASE 95-5, QUESTION 9: An analysis of the chromosomes from J.B.'s bone marrow reveals the TEL-AML1 translocation and a DNA index of 1.0. His MRD findings reveal the following: blood on day 8 is less than 1% of cells and bone marrow on day 29 shows 0.15% of cells. Based on his day 29 (end of induction) bone marrow positive MRD finding, J.B. is scheduled to receive a more aggressive post-induction chemotherapy regimen. This treatment is chosen because MRD findings are more predictive of the chance for relapse than are his cytogenetics. Although J.B. had bone marrow MRD performed at day 8 and at the completion of induction treatment on day 29 that both indicated a complete morphologic remission, his MRD findings at the end of induction take precedence in defining his further therapy. After completion of the induction phase, J.B. was scheduled to receive an intensified phase of post-induction chemotherapy known as augmented interim maintenance. What is the purpose of post-induction treatment and what are some examples of effective regimens for this phase of treatment?

Post-induction chemotherapy consists of a variety of combinations of different agents typically given on a 2 to 6 week treatment cycle. These different phases of post-induction therapy are known as consolidation, interim maintenance, and delayed intensification.

Post-induction treatment has proven to be an important strategy for the prevention of relapse in children with ALL and has helped produce event-free survival of greater than 80% in low-risk childhood ALL.[85,193] To date, the optimum post-induction regimens have yet to be determined. However, a few interesting findings from investigations of consolidation therapy are briefly mentioned. A comparison between high-dose methotrexate 5 g/m² IV every 2 weeks for four doses and escalating "Capizzi" dose methotrexate (every 10 days, increase by 50 mg/m² until toxicity is seen) showed improved 5-year event-free survival (EFS) (82 ±3.5% vs. 75.4 ±3.6% $p = 0.006$) and no increased toxicity. In fact, there was a lower incidence of febrile neutropenia in the high-dose methotrexate group compared to the escalating-dose group; 5.2% versus 8.2% respectively ($p = 0.005$). This advantage was shown in high-risk patients and is currently being studied in standard-risk patients to evaluate if there is a survival advantage in that group as well.[194] Another trial comparing either longer duration or more intensive post-induction regimens for children with high-risk ALL found that a higher intensity treatment regimen improved outcome, whereas the longer duration regimen did not. In this study, the higher intensity post-induction treatment was made up of greater use of pegaspargase, vincristine, and escalating-dose methotrexate (Table 95-8).

Table 95-8

Acute Lymphoblastic Leukemia Post-Induction Regimen Components

Schedule
Vincristine 1.5 mg/m² IV on days 0, 10, 20, 30, and 40
Methotrexate 5000 mg/m² IV over 24 hours, followed by leucovorin rescue. Given every 14 days × 4 doses
Pegaspargase 2,500 units/m² IM on days 1 and 21
Methotrexate IT on days 0 and 30
Cyclophosphamide 1 g/m² IV on days 0 and 28
Cytarabine 75 mg/m² SC or IV on days 1–4, 8–11, 29–32, and 36–39
Mercaptopurine 60 mg/m² PO daily on days 0–13, and 28–41
Methotrexate IT on days 1, 8, 15, and 22
Pegaspargase 2,500 units/m² IM on days 14 and 42
Vincristine 1.5 mg/m² IV on days 14, 21, 42, and 49
Vincristine 1.5 mg/m² IV on weeks 8, 9, 17, and 18
Prednisone 40 mg/m² PO daily × 7 days on weeks 8 and 17
Dexamethasone 10 mg/m² PO daily on days 0–7, 14–20
Vincristine 1.5 mg/m² IV on days 0, 7, and 14
Pegaspargase 2,500 units/m² IM on day 3
Doxorubicin 25 mg/m² IV on days 0, 7, and 14

IV, intravenously; IM, intramuscularly; PO, orally; SC, subcutaneously; IT, intrathecally.

MAINTENANCE CHEMOTHERAPY REGIMENS

CASE 95-5, QUESTION 10: After completion of his induction and post-induction treatments, J.B. is scheduled to receive maintenance (continuation) treatment for a total therapy duration of 2.5 years from the start of his induction therapy. His parents question why treatment will be of such a long duration and ask whether this is necessary because J.B. is already in remission. What is the purpose of J.B.'s maintenance or continuation treatment for ALL? Which agents should be used in J.B. for this phase of therapy?

Maintenance or continuation treatment sustains the complete remission achieved from induction chemotherapy. Early trials have shown that without maintenance treatment, the majority of ALL patients will relapse. Patients who have successfully responded to induction and post-induction therapy may still have a high leukemic cell burden (although undetectable), which must be eradicated by additional treatment. This is supported by the results of bone marrow biopsies from patients who have experienced relapse after several months to years of treatment. The cytogenetic characteristics of the leukemic cells in relapsed patients are identical to those at the time of diagnosis.[195,196] Maintenance therapy is also supported by the results of MRD studies, which demonstrate that some amount of measurable leukemic cells are still present months after the completion of induction therapy.[140–144]

Drugs that are effective during induction therapy cannot, by themselves, sustain remission during maintenance therapy.[9] However, other agents are effective in sustaining a complete remission. Two of the most effective drugs are mercaptopurine and methotrexate. Methotrexate is most effective and least toxic when administered intermittently, usually on a weekly basis in oral doses of 20 mg/m^2/week. Mercaptopurine is effective and well tolerated orally when dosed daily, usually at a dose of 50 to 75 mg/m^2/day.[197–199]

Other agents have been added to standard maintenance therapy with mercaptopurine and methotrexate to improve remission duration and to increase a patient's chances for long-term survival. There is evidence that monthly pulses of vincristine and prednisone offer advantages (lower bone marrow and testicular relapse rates) in standard-risk patients as well. At present, most contemporary treatment regimens for childhood ALL have intensified induction and post-induction phases during approximately the first 6 months. These early intensive treatments typically are followed by a less intensive maintenance therapy consisting of methotrexate and mercaptopurine in combination with periodic IT chemotherapy treatments, either with or without intermittent vincristine/prednisone pulses.[200–206]

The available evidence suggests that a patient like J.B. with standard-risk ALL will benefit from use of daily mercaptopurine 50 to 75 mg/m^2 orally (PO) and weekly methotrexate 20 mg/m^2 PO or IV, along with periodic pulse therapy with vincristine 1.5 mg/m^2 for 1 day and either prednisone 40 mg/m^2 or dexamethasone 6 mg/m^2 PO for 7 days every 4 weeks. In addition, IT methotrexate should be repeated every 8 to

12 weeks.

Dosing of Methotrexate and Mercaptopurine Maintenance

CASE 95-5, QUESTION 11: After 8 weeks of maintenance therapy with the aforementioned regimen, J.B. has had an ANC that has ranged between 2,000 and 3,500 cells/μL for more than 6 weeks. Other hematologic and chemistry findings are also within normal limits. Should any changes in his maintenance therapy be considered at this time? Are there any potential problems with mercaptopurine and methotrexate that could explain his ANC values? Could normal ANCs increase his risk of treatment failure?

Diurnal variation of methotrexate concentration and marked interpatient variability in absorption and metabolism of mercaptopurine have been described, which may explain the varied response among patients to standard doses.[201–207] Most patients are able to tolerate full doses of mercaptopurine, which is inactivated by the enzyme thiopurine-S-methyltransferase (TPMT). It is known that approximately 89% to 94% of patients have high TPMT activity, 6% to 11% have intermediate activity, and 0.3% have deficient activity. Patients with deficient TPMT activity experience severe and even fatal toxicity with standard mercaptopurine doses and require very low doses (approximately 10 mg/m^2 3 times/week) for avoidance of profound myelosuppression.[201,208–210]

Patients receiving half doses of these agents have shorter remission durations;[210] however, even those who tolerate maximal protocol dosages may also be at greater risk of relapse. Patients who are able to tolerate maximal doses without significant myelosuppression may require doses that are higher than protocol initiation doses. Some protocols allow for dosage increases of methotrexate or mercaptopurine every 4 to 6 weeks to maintain a target ANC in the range of 300 to 2,000 cells/μL. This is usually accomplished by alternately increasing the doses of mercaptopurine and methotrexate by 25%. In this situation, dose increases of one of these agents are performed every 4 to 6 weeks.[211]

J.B. has a normal ANC and is tolerating therapy; therefore, it is reasonable to attempt to intensify his chemotherapy dosing. For J.B., this means an increase in mercaptopurine from 50 mg/m^2/day, or an increased methotrexate dose from 20 to 25 mg/m^2/week. Although parenteral administration of methotrexate provides more predictable levels and improved compliance, it does not consistently improve the results of therapy.[212] To assess whether J.B. is receiving an adequate dose, weekly WBC counts are essential. This allows his treatment team to accurately appraise the adequacy of his dose and to follow his disease status to ensure that remission is continuing. If an inadequate degree of myelosuppression is demonstrated, J.B.'s compliance should be investigated because decreased compliance is a frequent problem in the therapy of childhood ALL. At least one investigation has found improved compliance with evening administration of mercaptopurine.[213–215]

Duration of Therapy

CASE 95-5, QUESTION 12: How long should J.B.'s maintenance therapy be continued?

Most centers treat children with ALL until a total therapy duration of approximately 2.5 years for females and 3.5 years for males. Most patients who experience relapse do so during therapy or within the first year of completing therapy. After the second year of therapy and for every year thereafter, relapses become much less common but are occasionally observed. Some centers are exploring whether more intensive treatment protocols could decrease the duration of maintenance treatment because the current duration is based on data from less aggressive protocols. Until there is more conclusive evidence regarding the duration of ALL maintenance therapy, patients with J.B.'s characteristics should receive chemotherapy for approximately 2.5 years.

Asparaginase Preparations

Asparaginase is available from two natural sources, Escherichia coli and Erwinia chrysanthemi. These two preparations are not 100% cross-reactive, so the Erwinia product may be substituted for the E. coli product when hypersensitivity reactions occur. However, one should be aware that cross-reactions occur in 17% to 26% of patients.[216,217] Because of the shorter half-life of the Erwinia product, a dosage increase of Erwinia asparaginase is necessary to equal the activity of the E. coli product. Of note, patients receiving equivalent doses of Erwinia asparaginase have a poorer remission rate and survival than those patients receiving the E. coli asparaginase. In contemporary protocols, the dose of Erwinia asparaginase is typically about 2.5 times greater than the E. coli asparaginase dose. The incidences of rash and silent immune clearance appear to be equivalent for these two preparations.

E. coli–derived asparaginase is available in a long-acting form known as pegaspargase. This agent is formed by covalently linking monomethoxy PEG to E. coli asparaginase. Pegaspargase has a prolonged half-life of 5.8 days compared with 1.2 days for E. coli asparaginase and appears to be safe and effective, even in patients with prior reactions to E. coli and Erwinia asparaginase. The prolonged half-life allows for less frequent (i.e., every 2 weeks) dosing of pegaspargase than for the natural source asparaginase products (i.e., 3 times a week). Asparaginase compounds derived from different E. coli strains may differ in both enzyme activity and half-life. At least one study has reported an unexpected mortality rate in childhood ALL associated with an assumption of equivalence among different E. coli asparaginase preparations.[218–222]

Relapsed Acute Lymphoblastic Leukemia

PROGNOSIS

CASE 95-6

QUESTION 1: N.B. is a 12-year-old boy with T-cell acute lymphoblastic leukemia. Initially he responded to therapy and achieved a complete remission. However, about 17 months after his initial diagnosis, N.B. undergoes a routine lumbar puncture as part of his planned maintenance therapy. Analysis of the CSF indicates the presence of numerous lymphoblasts. A CBC reveals the following:

Hct, 29.5%
Platelet count, 120,000 cells/μL
WBC, 5,300 cells/μL, with 45% lymphocytes, 50% neutrophils, and 5% bands

A bone marrow biopsy confirms relapsed ALL with 53% lymphoblasts. What are N.B.'s chances of achieving a second remission and long-term survival? Are there specific features about N.B.'s relapse which confer a worse prognosis?

N.B. is asymptomatic at the time of relapse, as are most patients experiencing a relapse of ALL. Most of these patients are diagnosed by routine CBCs or lumbar punctures. Although ALL patients typically have excellent responses to treatment after relapse, 20% to 25% of patients will relapse again, and most will not be long-time survivors. Routine bone marrow biopsies may identify bone marrow relapses before they become evident on a CBC, but it has not been demonstrated that earlier identification of bone marrow relapse by morphologic criteria impacts long-term survival.[223–225]

At least 80% of relapsed ALL patients will achieve a second remission with salvage chemotherapy. Unfortunately, bone marrow relapse in childhood ALL is associated with poor long-term survival and most patients will not be cured of their disease. Rates of 5-year disease-free survival vary from 6% to 60% for patients with bone marrow relapse and are dependent on multiple variables. N.B.'s situation has several features which confer a worse prognosis on relapse including male sex, both marrow and CNS relapse, T-cell disease, and relapse less than 18 months from initial diagnosis.[225–229]

TREATMENT OF RELAPSED ACUTE LYMPHOBLASTIC LEUKEMIA

CASE 95-6, QUESTION 2: Which treatments could be used in an attempt to attain a complete remission and improve N.B.'s chances of long-term survival?

Agents used in salvage regimens are similar to those used in high-risk ALL regimens. In general, treatment usually consists of an intensive four-agent induction regimen of vincristine, prednisone, daunorubicin, and asparaginase. This is accompanied by radiation therapy to sites of local relapse (e.g., testis, CNS) and IT chemotherapy.[229–231] After this regimen has been completed, the patient may continue with courses of intensification therapy, continuation therapy, and IT therapy.

Relapsed regimens will include more intensive chemotherapy, including high-dose methotrexate and high-dose cytarabine (HiDAC), as well as etoposide and cyclophosphamide. High-dose methotrexate has excellent penetration into the central nervous system and can be used to treat and prevent CNS leukemia relapses. HiDAC (3 g/m^2 every 12 hours for four doses) in conjunction with standard-dose asparaginase may be used to induce a remission in patients who fail re-induction therapy. This approach has been successful in approximately 40% of patients, although the

median duration of second remission was only 3 months.[232,233] The selection of a salvage regimen will depend on how intensive the patient's initial therapy was, whether or not the relapse occurred while on therapy and sites of relapse. In N.B.'s case, his regimen should include intensive therapy, preferably with chemotherapy drugs and regimens to which he has not been previously exposed, because his relapse occurred while he was on therapy. Additionally, he will have CNS radiation and IT chemotherapy aimed at treating his specific sites of relapse.

CASE 95-6, QUESTION 3: N.B.'s family is quite concerned about the poor prognosis associated with his relapse and inquire about the role of hematopoietic cell transplantation (HCT) in his relapse treatment. Should he be considered for HCT at this point? Knowing the potential morbidity and mortality associated with allogeneic transplantation, would autologous transplant be a more appropriate option for N.B?

Allogeneic HCT is emerging as a superior treatment option for children with relapsed ALL who have high-risk and intermediate-risk features. In patients who receive a matched sibling HCT during their second complete remission for relapsed ALL, event-free survival rates of 52% at 5 years have been reported versus chemotherapy alone producing 5% event-free survival at 5 years.[234–237] Autologous HCT does not appear to be superior to standard chemotherapy for children with ALL in second remission and should not be offered.[236] N.B.'s family should be offered the option of allogeneic HCT, and his family should be tested for an appropriate sibling match as this offers lower morbidity than an unrelated donor. Because his outcome in transplant improves if performed during a second complete remission, he should begin re-induction chemotherapy, while HCT is being arranged. If HCT does not prove to be a feasible option for N.B., novel therapies may be considered. Nelarabine is a purine analog approved for the treatment of relapsed T-cell leukemias and lymphomas, and it has shown response rates (complete and partial remission) as high as 55% in pediatric populations.[237,238]

PEDIATRIC NON-HODGKIN LYMPHOMA

Lymphomas are a collection of diseases originating in cells and organs of the immune system. Lymphomas account for approximately 10% to 15% of all childhood malignancies, but they are less common in children than in adults. Children younger than 16 years account for only 3% of all lymphoma cases. The malignancy can occur in any lymphoid cell at any level of differentiation and appears to be a consequence of a genetic alteration. Non-Hodgkin lymphoma (NHL) is the most common form of lymphoma in children younger than 10 years of age, whereas Hodgkin lymphoma is most common in children 15 to 19 years of age. This section will focus on NHL. Considerable progress has been made in the treatment of children with NHL and currently approximately 80% are cured.[239]

Classification

Numerous classification systems for NHL exist, and there is considerable variation in terminology among these systems.[239] Pediatric NHLs are best classified using histopathology, which divides them into three different categories: B-cell lymphomas, lymphoblastic lymphomas, and anaplastic large-cell lymphomas.[240–243] This is a narrower range of histologic types than in adults.

Lymphoblastic lymphomas account for approximately 30% of childhood NHLs, B-cell lymphomas for about 50%, and large-cell lymphomas for the remainder[1] The lymphoblastic lymphomas are usually immature T-cells that are histologically identical to the cells of ALL. The distinction between lymphoblastic lymphoma and ALL is made on the basis of bone marrow involvement, with ALL being diagnosed if there is greater than 25% bone marrow infiltration. B-cell lymphomas may be further divided into Burkitt, Burkitt-like, and large B-cell lymphomas. Anaplastic large-cell lymphomas may be T-cell or null cell in origin.[240–243]

Clinical Presentation

Pediatric patients with NHL may present with a number of different symptoms, many of which are related to the type of NHL. In general, these symptoms differ from those in adults because of the propensity of pediatric NHLs to be extranodal in origin in contrast to the common nodal presentation of adult NHL. Patients with lymphoblastic lymphoma commonly present with a mediastinal mass or pleural effusions. They also may have pain, dyspnea, or swelling of the face and upper arms if superior vena cava obstruction is present. Lymphoblastic lymphoma also has a predilection for the bone marrow and the CNS.[244,245] Lymphadenopathy in patients with lymphoblastic lymphoma tends to be supradiaphragmatic. Patients with B-cell NHL typically present with an abdominal tumor, abdominal pain, an alteration in bowel function, and possibly nausea and vomiting. In addition, many patients with B-cell NHL present with bone marrow involvement. Lymphadenopathy in these patients typically occurs below the diaphragm in the inguinal or iliac area. Anaplastic large-cell lymphomas may involve the gut or unusual sites such as the lung, skin, face, or CNS.[246,247]

Staging

Several staging systems for pediatric NHLs are used. A commonly used staging system for pediatric NHL is the St. Jude staging system.[244] This staging system includes four stages, with stage I being a single tumor or a single nodal area, and higher stages including cases with regional involvement or more than one anatomical site involved. The highest stage (stage IV) refers to patients with bone marrow or CNS involvement. The main predictor of outcome in pediatric patients with NHL has historically been determined by tumor burden at presentation.[247] However, with modern chemotherapy regimens that are tailored to the extent of disease, patients with higher-stage disease may achieve a similar event-free survival to that achieved in patients with lower-stage disease. A higher LDH is correlated with greater tumor burden, and it has been demonstrated that serum LDH greater than or equal to 500 to 1,000 units/L is a significant predictor of poorer outcome.[247]

Overview of Treatment

LYMPHOBLASTIC (T-CELL) LYMPHOMAS

The primary treatment for all stages and histologic types of pediatric NHL is combination chemotherapy because it is a generalized disease at the time of diagnosis.[248,249] A wide variety of chemotherapy agents have activity in childhood NHL. At present, the best results to date are reported by the Berlin–Frankfurt–Muenster (BFM) group, with an estimated 5-year event-free survival of approximately 92% (Table 95-9). This regimen uses an intensive scheme of multi-agent chemotherapy administered over 24 months. Patients with lymphoblastic lymphoma require longer treatment duration than patients with B-cell or anaplastic large-cell lymphoma. This chemotherapy plan is similar to that used in the treatment of ALL, and it is designed to deliver continuous or weekly therapy. All patients with lymphoblastic lymphoma are given CNS preventive therapy, regardless of stage. Few patients with lymphoblastic lymphoma present with limited disease (stages I and II), thus making it difficult to conduct adequate studies in this patient population. Attempts to shorten the duration of therapy for patients with limited-stage disease have been unsuccessful, although less-intensive therapy is administered to patients with early-stage disease on some protocols.

Table 95-9

Berlin–Frankfurt–Muenster (BFM) Group Treatment Protocols for T-Cell Lymphoblastic Lymphoma

Drug	Dose	Days of Administration
Induction Protocol I (All Stages)		
Prednisone (PO)	60 mg/m^2	1–28, then taper
Vincristine (IV)	1.5 mg/m^2 (max 2 mg)	8, 15, 22, 29
Daunorubicin (IV over 1 hour)	30 mg/m^2	8, 15, 22, 29
L-asparaginase (IV[a] over 1 hour)	10,000 IU/m^2	12, 15, 18, 21, 24, 27, 30, 33
Cyclophosphamide[b] (IV over 1 hour)	1,000 mg/m^2	36, 64
Cytarabine (IV)	75 mg/m^2	38–41, 45–48, 52–55, 59–62
6-Mercaptopurine (PO)	60 mg/m^2	36–63
Methotrexate (IT)[c]	12 mg	1, 15, 29, 45, 59
Protocol M (Typically Stages I and II)		
Mercaptopurine (PO)	25 mg/m^2	1–56
Methotrexate (IV)	5 g/m^2	8, 22, 36, 50
Methotrexate (IT)	12 mg	8, 22, 36, 50
Re-induction Protocol II (Stages III and IV Only)		
Dexamethasone (PO)	10 mg/m^2	1–21, then taper
Vincristine (IV)	1.5 mg/m^2 (max 2 mg)	8, 15, 22, 29
Doxorubicin (IV over 1 hour)	30 mg/m^2	8, 15, 22, 29
L-asparaginase (IV[a] over 1 hour)	10,000 IU/m^2	8, 11, 15, 18
Cyclophosphamide[b] (IV over 1 hour)	1,000 mg/m^2	36
Cytarabine (IV)	75 mg/m^2	38–41, 45–48
Thioguanine (PO)	60 mg/m^2	36–49
Methotrexate (IT)	12 mg	38, 45
Maintenance (All Stages)		
Mercaptopurine (PO)	50 mg/m^2	Daily until month 24 of therapy
Methotrexate (PO)	20 mg/m^2	Weekly until month 24 of therapy

Note: IT methotrexate doses were adjusted for children younger than 3 years. Ten percent (of the 5 g/m^2 methotrexate dose in Protocol M was given for 30 minutes, and 90% was given as a 23.5-hour continuous IV infusion. Leucovorin rescue: 30 mg/m^2 IV at hour 42; 15 mg/m^2 IV at hours 48 and 54.

[a] This agent is typically administered intramuscularly in most treatment protocols in the United States.

[b] With mesna.

[c] Additional intrathecal chemotherapy doses are given on days 8 and 22 for CNS-positive patients.

CNS, central nervous system; IT, intrathecally; IV, intravenously; PO, orally.

B-CELL LYMPHOMAS

The main differences between the treatment of lymphoblastic and B-cell lymphoma are the use of more agents and longer treatment duration in the former. The trend in the treatment of B-cell lymphomas has been toward short-duration, intensive therapy with alkylating agents in conjunction with high-dose antimetabolite therapy (e.g., methotrexate, cytarabine). Chemotherapy is administered in rapid succession with limited recovery from neutropenia (i.e., ANC 500 cells/μL) between cycles. Patients with localized B-cell lymphomas respond as adequately to a four-drug regimen (consisting of cyclophosphamide, vincristine, methotrexate, and prednisone) as they do to more aggressive regimens.[249,250]

Evidence suggests that a 6-month course is as efficacious as an 18-month course for patients with localized B-cell lymphomas. Studies indicate that even 6 months of chemotherapy may be unnecessary for patients with limited-stage disease because it has been demonstrated that maintenance treatment offered no additional benefit after 9 weeks of combination chemotherapy. Contemporary chemotherapy regimens include varying degrees of treatment intensity from three to seven cycles, depending on whether the tumor is completely resected, on bone marrow and CNS involvement, and the serum LDH.[250]

With the addition of high-dose methotrexate, ifosfamide, etoposide, and HiDAC to the standard regimen, patients with stage III disease are now achieving survival rates comparable to those of patients with limited-stage disease. Patients with bone marrow disease also benefit from these intensive therapeutic strategies and have achieved impressive survival rates of approximately 80%.[1] Currently, patients with advanced-stage disease are treated with a total of six to eight cycles of chemotherapy, and these treatment protocols achieve superior results to those of a much longer duration (e.g., 1–2 years) used previously. Although rituximab is now a standard therapy component for B-cell lymphomas in adults, it has yet to be

---

routinely used in front-line treatment in the pediatric arena. Case reports demonstrate the utility of this agent when added to a standard chemotherapy backbone for children with relapsed disease.[250–252]

LARGE-CELL LYMPHOMAS

Large-cell lymphomas have responded well to both types of regimens.[253,254] Thus, the use of shorter, less complicated, B-cell protocols is appropriate. Patients who fail to respond may be treated with additional courses of their prescribed protocol in hopes of eventually inducing a response. Patients who relapse may be re-induced with intensive chemotherapy, but their prognosis for long-term survival is unfavorable.

Lymphoblastic Lymphoma

ACUTE TREATMENT

CASE 95-7

QUESTION 1: D.B., a 16-year-old girl, presents with a history of shortness of breath and chest pain for 3 weeks before admission. A mediastinal mass is found, and a biopsy confirms a lymphoblastic (T-cell) lymphoma. Radiography of the chest reveals a right pleural effusion. Laboratory values show the following results:

Erythrocyte sedimentation rate, 35
WBC count, 22,000 cells/μL
Uric acid, 7 mg/dL
LDH, 1,259 units/L

The bone marrow, CNS, and abdomen are negative for lymphoma. How should D.B. be managed acutely? Besides chemotherapy, what types of adjunctive therapies should be initiated to minimize the acute effects of treatment?

Given D.B.'s shortness of breath and chest pain, it is likely that her mediastinal mass may be obstructing the superior vena cava. To alleviate this obstruction, the most appropriate course of action is to decrease the tumor mass by initiating chemotherapy as soon as possible. Radiation therapy offers no additional benefit in patients such as D.B. with a tumor such as NHL, which is highly responsive to chemotherapy.[255] Because of the high cell kill that will result from the initial chemotherapy treatment, tumor lysis syndrome and uric acid nephropathy are possible. However, the risk of this complication is probably greater in patients with B-cell NHL in whom the fraction of cells in S phase is higher.[256,257]

Alkaline diuresis and allopurinol should be instituted before chemotherapy to prevent tumor lysis syndrome. Because D.B. has a pleural effusion, fluids may collect in this third space, resulting in weight gain and decreased urine output. Thus, in addition to placement of a chest tube with suction, D.B. should be given diuretics to maintain an adequate urine output. To minimize intravascular volume depletion and maintain electrolyte balances, fluid input and output, body weight, and electrolyte panels should be monitored daily. These values should be used to make appropriate adjustments in D.B.'s electrolyte and fluid balance. See Chapter 96, Hematologic Malignancies, for a complete discussion of tumor lysis syndrome.

Adverse Effects

CASE 95-7, QUESTION 2: D.B. is treated with the BFM combination chemotherapy regimen. Because of her intrathoracic mass, her disease is characterized as stage III. She is to receive induction therapy (Induction Protocol I) for 8 weeks, as outlined in Table 95-9. Which acute adverse effects is D.B. likely to experience with these agents? How can they be monitored, minimized, and treated?

Several toxicities are expected with these chemotherapy agents. For vincristine, both constipation and neuropathy are likely to appear during or after the 4 weeks of therapy.[163] Constipation can be prevented or minimized by use of stool softeners with or without a laxative. Neuropathy may be painful (especially when jaw pain occurs) but can be managed with mild analgesic regimens consisting of NSAIDs or acetaminophen with codeine. Both toxicities are self-limiting and are not reasons to discontinue or decrease the dosage of vincristine unless neuromuscular toxicity, as evidenced by motor weakness, develops. The incidence of jaw pain and foot drop is higher in pediatric populations as compared to adults. Asparaginase can cause several types of toxicities (e.g., hypersensitivity reaction, coagulation disorders, pancreatitis), most of which are not thought to be preventable.

Prednisone is likely to increase D.B.'s appetite and may cause gastritis, although divided doses will help decrease stomach upset. In addition, prednisone-induced behavioral disturbances, such as hyperactivity, are common in children.[164] Unlike prednisone and vincristine, daunorubicin, cyclophosphamide, cytarabine, and mercaptopurine produce significant myelosuppression. Leukopenia is common with the nadir occurring in approximately 8 to 14 days, and recovery occurring by approximately day 21 after administration. Because the goal of induction therapy is achievement of remission, doses of daunorubicin will not be held for uncomplicated myelosuppression during the first 4 weeks of induction therapy, although during the latter 4 weeks, the combination of cyclophosphamide, cytarabine, and mercaptopurine are typically held until hematologic recovery occurs.

Hemorrhagic cystitis may occur with cyclophosphamide, but it is usually associated with high-dose therapy or with prolonged administration, which D.B. is not receiving. Vigorous IV hydration to maintain urine output of approximately 50 to 100 mL/m^2/hour should reduce the risk of this toxicity at this dose. In addition, this chemotherapy protocol also includes mesna, which will bind to urotoxic metabolites of cyclophosphamide and also reduce the risk of hemorrhagic cystitis. Because most of the induction regimen will be administered on an outpatient basis, patients or parents should be instructed to report signs or symptoms of infection (e.g., febrile episodes) immediately so that proper treatment may be instituted as soon as possible. To decrease the risk of hemorrhagic cystitis, parents should be instructed to report whether patients are urinating regularly after cyclophosphamide. See Chapter 94, Adverse Effects and their Treatment, for further discussion of these adverse effects.

Nausea and vomiting are likely to be induced by both daunorubicin and cyclophosphamide/cytarabine. D.B.'s chemotherapy regimen includes a corticosteroid (prednisone), which may provide some antiemetic activity during the initial 4 weeks.[258] However, to maximize tolerance to her chemotherapy, D.B. should receive a 5-HT_3 serotonin antagonist. D.B. is unlikely to require additional corticosteroids during the first 4 weeks of induction therapy. However, during the second portion of induction, D.B. will benefit from a few doses of dexamethasone at the time of cyclophosphamide administration.[259] See Chapter 22, Nausea and Vomiting, for further discussion of chemotherapy-induced nausea and vomiting.

Central Nervous System Prophylaxis

CASE 95-7, QUESTION 3: What is the importance of CNS prophylaxis for D.B. and what type of treatment regimen is typically used?

All pediatric patients with lymphoblastic lymphoma should receive some form of CNS prophylaxis. Although lymphoblastic lymphoma rarely presents with CNS involvement, as illustrated by D.B., it was a common site of relapse before CNS prophylaxis was included as a routine part of the chemotherapy regimen.[250,251] Recurrence of NHL within the CNS is rare when IT methotrexate or cytarabine is given.[245] D.B. will be treated with IT methotrexate periodically, as outlined in Table 95-9.

Myelosuppression and Hematopoietic Recovery

CASE 95-7, QUESTION 4: After completion of induction therapy, the chemotherapy plan for D.B. consists of protocol M and re-induction protocol II, as outlined in Table 95-9. How should D.B.'s hematopoietic recovery be managed, and what guidelines may be used to determine when it is appropriate for her to receive the next sequence of the treatment cycle? Would D.B. benefit from a colony-stimulating factor to aid with hematopoietic recovery?

Protocol M will likely not produce significant myelosuppression because leucovorin rescue will reduce the myelosuppression from the high-dose methotrexate. The most challenging problems with this phase of treatment will be to confirm that the methotrexate has been properly eliminated and to continue aggressive hydration, alkalinization, and leucovorin dosing until the methotrexate level is nontoxic. Owing to D.B.'s pleural effusion at the time of diagnosis, it should be confirmed that this has resolved before administration of high-dose methotrexate to avoid significantly delayed clearance because the pleural effusion could allow for third spacing of high doses of methotrexate. Pleural effusions are a relative contraindication to high-dose methotrexate. Methotrexate elimination has high interpatient and intrapatient variability, and necessitates close monitoring of methotrexate concentrations and renal function after each dose. Refer to the discussion of high-dose methotrexate earlier in this chapter.

Protocol II will result in significant myelosuppression. However, as with protocol

I, dosing of doxorubicin will not be held for uncomplicated myelosuppression. Similarly, during the second phase of this protocol, dosing of cytarabine and thioguanine will also not be held for uncomplicated myelosuppression. However, before initiating the second phase on day 36, clinicians will assure adequate hematologic recovery, typically defined as an ANC greater than 750 cells/ μL and platelets greater than 100,000 cells/μL. It is unlikely that D.B. will benefit from a colony-stimulating factor during these phases of therapy. When myelosuppressive chemotherapy is given fairly continuously, as is the case with protocol II, there is little room for inserting doses of colony-stimulating factors on days where myelosuppressive chemotherapy is not being administered.

Rachel Elsey, and Katie A. Won

CORE PRINCIPLES

ACUTE MYELOID LEUKEMIA

		CHAPTER CASES
1	Acute myeloid leukemia (AML) generally appears suddenly and progresses rapidly. Death as a result of infection or bleeding occurs within weeks to months if the patient is not effectively treated.	**Case 96-1 (Questions 1, 2)**
2	Although more than 60% of patients treated for AML achieve complete remission after induction therapy, the median duration of the remission is only about 12 to 18 months, and only 20%–40% of patients have a disease-free survival (DFS) exceeding 5 years. Short remissions have been attributed to proliferation of clinically undetectable leukemic cells. Thus, the rationale for administering chemotherapy after remission is to eradicate these residual cells.	**Case 96-1 (Questions 6, 7)**
3	The incidence of AML increases with advancing age. At age 40 years, there is only 1 case of AML per 100,000, but the annual incidence increases to 15% at age greater than 75 years. The prognosis of patients with AML is directly related to age.	**Case 96-1 (Question 8)**
4	Elderly patients do not tolerate intensive induction and postremission chemotherapy as well as younger patients. Older patients often have comorbid medical conditions and a poor performance status, which are associated with worse outcomes with conventional therapy.	**Case 96-1 (Question 8)**
5	In younger patients, failure to achieve remission or disease relapse remains the major cause of treatment failure. This reflects both the failure of current salvage regimens and the absence of effective strategies to secure long-term DFS in those patients who achieve a second hematologic remission. A wide range of salvage options have been studied, but with less than 50% of patients achieving a second remission and median survival ranging from 3 to 12 months, there remains considerable room for improvement.	**Case 96-2 (Question 1)**

CHRONIC MYELOGENOUS LEUKEMIA

1	Many patients are asymptomatic at presentation but are evaluated because of an abnormally high leukocyte count. The cytogenetic hallmark of chronic myelogenous leukemia (CML) is the Philadelphia chromosome. The chromosomal translocation generates a fusion gene	**Case 96-3 (Question 1)**

	called BCR-ABL that becomes inappropriately expressed, leading to CML. Identifying the Philadelphia chromosome is important in confirming the diagnosis of CML.	
②	Hematopoietic stem cell transplantation is the only curative therapy for CML, but it is seldom recommended as first-line therapy for patients in chronic-phase CML. Imatinib, nilotinib, and dasatinib are all small-molecule tyrosine kinase (TK) inhibitors of the BCR-ABL protein and are all approved as initial first-line treatment.	**Case 96-3 (Question 3)**

p. 2023

p. 2024

CHRONIC LYMPHOCYTIC LEUKEMIA

①	Common treatment regimens for chronic lymphocytic leukemia (CLL) in patients without significant comorbidities include combinations of rituximab with fludarabine, cyclophosphamide, or bendamustine. Patients unable to tolerate a purine analog are treated with a monoclonal antibody in combination with chlorambucil.	**Case 96-4 (Question 3)**
②	Infectious complications are common in patients with CLL. For recurrent infections, immune globulin treatment may be indicated. Vaccinations to prevent influenza and pneumococcus are indicated. Live vaccines, including varicella zoster virus, must be avoided.	**Case 96-4 (Question 5)**

MULTIPLE MYELOMA

①	Multiple myeloma (MM) generally begins as a benign condition known as monoclonal gammopathy of undetermined significance (MGUS). This condition may precede MM by years before transforming into a malignant disorder with clinical manifestations.	**Case 96-5 (Question 1)**
②	Induction therapy followed by hematopoietic cell transplantation (HCT) in eligible patients is the standard of care and has increased overall survival (OS) in those with MM.	**Case 96-5 (Question 2)**
③	Supportive care of patients with MM includes the prevention and treatment of skeletal disease and should be considered in conjunction with induction therapy.	**Case 96-5 (Question 3)**
④	Multiple myeloma is not generally curable, even with maintenance therapy. Therefore, relapse usually occurs, and salvage therapies are commonly used.	**Case 96-5 (Questions 4, 5)**

LYMPHOMA

①	The lymphomas are a diverse collection of hematologic malignancies originating from lymphoid tissues. Lymphomas are classified as either Hodgkin lymphoma (HL) or non-Hodgkin lymphoma (NHL). The NHLs can be further divided into aggressive or indolent subgroups. Symptoms include painless lymphadenopathy along with nonspecific findings of generalized malaise and fatigue. Advanced complications arise from the	**Case 96-6 (Questions 1)**

	infiltration of the disease into extramedullary tissues including the lungs, central nervous system (CNS), and bone marrow.	
2	Hodgkin lymphoma (HL) is B-cell neoplasm and is highly responsive to chemotherapy and often curable with modern treatments. A combination of doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) is the most frequently used chemotherapy regimen. Delayed consequences of therapy have a heightened importance in management of this disease due to the expected long-term survival for most patients.	**Case 96-7 (Questions 1, 2)**
3	Aggressive NHLs such as diffuse large B-cell lymphoma (DLBCL) progress rapidly and are treated with intensive combination chemotherapy regimens administered with a curative intent. Chemoimmunotherapy with rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) is conventional therapy for DLBCL.	**Case 96-8 (Questions 1, 2)**
4	Although indolent NHLs including follicular lymphoma (FL) are generally incurable, these diseases develop slowly and are initially responsive to numerous therapies. Treatment is aimed at reducing disease burden and prolonging survival and is often reserved until the patient is symptomatic. A combination of bendamustine and rituximab (BR) is commonly used in the management of these neoplasms.	**Case 96-9 (Questions 1, 2)**

ACUTE MYELOID LEUKEMIA

Epidemiology

Acute myeloid leukemia (AML) consists of a group of relatively well-defined hematopoietic neoplasms involving precursor cells committed to the myeloid line of cellular development.

In the United States and Europe, the incidence has been stable at 3 to 5 cases per 100,000. AML is the most common acute leukemia in adults and accounts for approximately 80% of cases in this group of neoplasms. In contrast, AML accounts for less than 10% of acute leukemias in children younger than 10 years of age. In adults, the median age at diagnosis is approximately 67 years. The incidence increases with age with approximately 1.3 and 12.2 cases per 100,000 for those younger than or older than 65 years, respectively. The male-to-female ratio is approximately 5:3.[1,2]

Pathophysiology

AML is characterized by a clonal proliferation of myeloid precursors with a reduced capacity to differentiate into mature myeloid cells. As a result, there is an accumulation of leukemic blasts in the bone marrow, peripheral blood, and occasionally in other tissues, with a variable reduction in the production of normal red blood cells, platelets, and mature granulocytes. The proliferation of malignant cells, along with a reduction in normal hematopoietic cells, results in a variety of systemic consequences including anemia, bleeding, and an increased risk of infection.

Table 96-1

Pretreatment Molecular Entities Shown to Predict Disease Outcome in Adults with Acute Myeloid Leukemia and a Normal Karyotype

Gene	Mutation Frequency (%)	Prognosis
NPM1	45–63	Favorable
FLT3	23–33	Poor
C/EBPa	8–19	Favorable
MLL	5–30	Poor

Source: Baldus CD et al. Clinical outcome of de novo acute myeloid leukemia patients with normal cytogenetics is affected by molecular genetic alterations: a concise review. Br J Haematol. 2007;137:387.

Based on karyotype status (characterization of the chromosome such as shape, type, or number), two major groups of AML can be identified: (a) those with an abnormal karyotype, which accounts for approximately 50% to 60% of patients, and (b) those that demonstrate a normal karyotype by conventional cytogenetic testing, which accounts for the remainder of AML patients.[3,4]

The outcomes of patients with an abnormal karyotype are generally poor regardless of the molecular findings. However, the prognosis of patients with normal karyotype in the presence of each of these mutations is different as shown in Table 96-1.

Clinical Presentation and Diagnosis

Patients with AML generally present with symptoms related to complications of pancytopenia (e.g., anemia, neutropenia, and thrombocytopenia), including weakness and easy fatigability, infections of variable severity, and hemorrhagic findings such as gingival bleeding, ecchymosis, epistaxis, or menorrhagia. Combinations of these symptoms are common. It is often difficult to date the onset of AML precisely, at least in part because individuals have different symptomatic thresholds for seeking medical attention. It is likely that most patients have had more subtle evidence of bone marrow involvement for weeks, or perhaps months, before diagnosis. Although a presumptive diagnosis of AML can be made by examination of the peripheral blood smear when there are circulating leukemic blasts, a definitive diagnosis usually requires a bone marrow aspiration and biopsy. Morphologic, immunophenotypic, cytogenetic, and molecular studies must be performed in every case. The information derived from these studies is critical for making the correct diagnosis as well as determining prognosis.

Overview of Treatment

Once the diagnosis of AML is established, induction chemotherapy is given with the goal of rapidly restoring normal bone marrow function. Treatment regimens and outcomes differ between younger and older adults. Although there is no clear dividing line between younger and older adults when dealing with AML, in most studies "older adults" are defined as older than 60 years of age.

The objective of induction therapy is to reduce the total body leukemia cell population from approximately 10^{12} to less than the cytologically detectable level of about 10^9 cells. It is generally assumed, however, that a substantial burden of leukemia cells persists undetected (i.e., presence of "minimal residual disease"), leading to relapse within a few weeks or months if no further therapy was administered. The traditional goal of treatment of AML is to produce and maintain a complete remission. Criteria for this are platelet count higher than 100,000 cells/μL, neutrophil count higher than 1,000 cells/μL, and bone marrow specimen with less than 5% blasts.[5]

The most commonly used induction regimens for AML are the "7+3" regimens, which combine a 7-day continuous intravenous (IV) infusion of cytarabine (100 or 200 mg/m^2/day) with a short infusion or bolus of an anthracycline given on days 1 through 3. The most commonly used anthracycline in this regimen is daunorubicin, but idarubicin may be used instead.

Sixty to 80% of adult patients with newly diagnosed AML will attain a complete remission with intensive induction chemotherapy. However, without additional cytotoxic therapy, virtually all of these patients will relapse within a median of 4 to 8 months. In contrast, patients who receive postremission therapy may expect 4-year survival rates as high as 40% in young and middle-aged adults with good-risk disease.[6] High-dose cytarabine (HiDAC) has been the consolidation chemotherapy of choice for more than a decade for younger patients with good- or intermediate-risk disease. Attempts to improve on survival rates attained with HiDAC by substituting other agents with different mechanisms of action have not been successful.[7] For patients with an abnormal karyotype or with adverse molecular mutations, consolidation with HiDAC followed by an allogeneic hematopoietic cell transplantation (HCT) with a suitably matched donor is the treatment of choice whenever possible. For patients older than 75 years of age, there is no specific standard of care except to enroll in a clinical trial when available. For the large number of patients who are 60 to 75 years of age, most clinicians will base induction and consolidation therapy recommendations on a patient's performance status, patient’s wishes, and prognostic factors such as cytogenetics and mutation analysis.[8]

Twenty to 30% of young adult patients and 50% of older adult patients with newly diagnosed AML will fail to attain a complete response (CR) with intensive induction chemotherapy as a result of drug resistance or death. In addition, a large percentage of patients who initially attain a CR will relapse. The therapy that provides the best chance to cure a patient with relapsed or refractory AML is an allogeneic HCT. The best outcomes appear to be with a myeloablative preparative regimen administered after attaining a CR. However, some patients may be cured with myeloablative HCT even without attaining a CR although their chance of long-term survival is reduced. Nonmyeloablative preparative regimens are considered for patients who are not candidates for myeloablative HCT but have attained a CR.[9] See Chapter 101, Hematopoietic Cell Transplantation, for a complete discussion of HCT for leukemia. Please refer to the following online reference for more details about the treatment and prognosis of AML: http://www.cancer.gov/cancertopics/pdq/treatment/adultAML/healthprofessiona

Signs and Symptoms

CASE 96-1

QUESTION 1: J.V., a 57-year-old man, presented to the emergency department with increasing fatigue and fever and an inability to eat. This past week, a peripheral blood smear (complete blood count [CBC]) revealed a white blood cell (WBC) count of 180,000 cells/µL with a differential of more than 90% leukemic blasts (normal, 0%), a hemoglobin (Hgb) of 7.8 g/dL, and a platelet count of 46,000 cells/µL. A bone marrow aspirate and biopsy confirmed the diagnosis of AML (FAB-M2, myeloid with maturation; 60% blasts, myeloperoxidase positive; CD13 and CD33 positive). All serum chemistry values were within normal limits, with the exception of potassium (K), 3.2 mEq/L; phosphorus, 5.5 mg/dL; and lactate dehydrogenase (LDH), 3,500 units/mL. Physical examination was remarkable for oral leukoplakia from oral candidiasis and poor dentition. Which signs and symptoms exhibited by J.V. are consistent with AML?

J.V.’s symptoms of increasing fatigue and fever of 1 week’s duration are consistent with a rapid reduction in red blood cells leading to anemia (Hgb, 7.8 g/dL) and a low neutrophil count leading to infection (oral candidiasis). Although his WBC count is high, the differential reveals that more than 90% are blasts, which are immature, nonfunctional cells of myeloid or lymphoid origin. Circulating blast cells are typically not present in early chronic leukemias or mild-to-moderate infections. However, blasts may be observed on the peripheral blood smear in patients with anemia associated with primary bone marrow dysfunction (myelodysplastic syndromes). Blasts are also present in patients with severe infection, stress, or trauma, and in those with chronic myelogenous leukemia (CML) in transformation to acute leukemia. J.V.'s platelet count is also low, which may lead to bleeding or bruising. Collectively, these are presenting signs and symptoms of acute leukemia.

J.V.'s symptoms are consistent with either AML or acute lymphocytic leukemia (ALL). However, patients with ALL also commonly present with lymphadenopathy and hepatosplenomegaly, which J.V. does not have. It is important to distinguish between these two disorders because treatment regimens differ greatly. AML is more common in adults than in children. For additional information on ALL, see Acute Lymphoblastic Leukemia of Childhood section in Chapter 95, Pediatric Malignancies.

Classification and Diagnosis

For a definitive diagnosis of AML, the bone marrow aspirate must contain more than 20% leukemic blast cells. A normal bone marrow aspirate would typically contain less than 5% blasts. Eight major variants of AML are defined by the French–American–British (FAB) classification system based on morphologic characteristics. More recently, the World Health Organization (WHO) has developed a classification system that expands the number of AML subtypes and better incorporates genotypic information, which is important in determining prognosis.[10]

Cells of myeloid origin commonly contain myeloperoxidase enzymes and express surface markers CD13, CD33, CD14, and CD15. Specific clonal chromosomal abnormalities are associated with several AML subtypes. These aberrations include gains or losses of whole chromosomes on the long (q) or short (p) arms, as well as a variety of structural rearrangements (e.g., translocations, inversions, insertions). A number of cytogenetic abnormalities in AML are associated with molecular-clinical syndromes, which are now under investigation at the genetic level. The translocation t(15;17) is the cytogenetic hallmark of acute promyelocytic leukemia (APL or AML-M3). This translocation splits the retinoic acid receptor gene on chromosome 17 and blocks expression of retinoic acid-controlled genes required for cell differentiation. Treating patients who have APL with all- trans retinoic acid (ATRA, tretinoin) has resulted in complete morphologic responses. This example shows how defining cytogenetic or chromosomal abnormalities in acute leukemia can be critical to understanding its pathophysiology and identifying optimal treatments. Currently, three chromosomal abnormalities are recognized as being associated with a better prognosis: t(8;21), t(15;17), and inversion (inv) 16.[11,12] In contrast, several chromosomal abnormalities have been associated with a relatively poor prognosis, including inv 3, deletion (del) 5, del(5q), del(7), and del(7q); trisomy 8; and complex (three or more unrelated cytogenetic abnormalities) cytogenetics. Additionally, molecular abnormalities such as FLT3, which is generally unfavorable, and NPM1 and C/EBPa, which are generally favorable, are central in the evaluation of AML patients.[13] These findings are increasingly being used to guide treatment decisions. For example, patients with cytogenetic and molecular findings associated with a poor prognosis may be considered for more aggressive postremission therapy such as high-dose chemotherapy with HCT. Other poor prognostic signs in AML include age older than 60 years at the time of diagnosis, a preexisting hematologic disorder (e.g., myelodysplastic syndrome), prior exposure to a chemotherapy agent (e.g., a secondary leukemia), and poor baseline performance status.[14]

J.V. has FAB-M2 (myelomonocytic) AML. Approximately 10% to 20% of patients with FAB-M2 acute leukemia have a translocation of t(8;21)(q22;q22).[11] This translocation is usually seen in young patients such as J.V. and is associated with a better response to therapy. J.V.'s bone marrow has been sent for cytogenetic and molecular analysis; however, results will not be available for approximately a week. Although neither the cytogenetic nor the molecular analysis will alter the planned induction therapy for J.V., these findings in combination with other prognostic features, as discussed previously, will influence postremission therapy recommendations.

Treatment

GOAL OF THERAPY

CASE 96-1, QUESTION 2: What is the goal of treatment and what type of therapy is indicated for J.V. at this time?

The leukemic cells populating J.V.'s blood are abnormal and incapable of fighting infection. Their rapid proliferation is suppressing red blood cell and megakaryocyte production in the bone marrow. J.V. is at substantial risk for life-threatening infections and bleeding complications. The goal of the initial chemotherapy is to clear the bone marrow and peripheral blood of all blast cells in the hope that normal blood cell components can regenerate.

INDUCTION THERAPY

Standard induction chemotherapy for AML includes an anthracycline (either daunorubicin or idarubicin) and cytarabine, an antimetabolite. One commonly used regimen includes idarubicin 12 mg/m^2/day on days 1 to 3 as an IV bolus injection, plus cytarabine 100 mg/m^2/day as a continuous IV infusion on days 1 to 7.[15–17] This combination (7 + 3) is one of the most effective chemotherapy regimens used to treat adult AML, with CR rates of 60% to 80%.[11] Continuous infusions of cytarabine are preferred because these regimens produce higher response rates than bolus injections during induction therapy.[18,19]

If a patient presents with a very high WBC count, he or she may experience complications associated with hyperviscosity of the blood (e.g., ringing ears, stroke, blindness, or headache as a result of impaired oxygen delivery to the central nervous system

---

[CNS], pulmonary infarction). Because it may take several days for cytarabine and idarubicin to substantially decrease the WBC count, the patient may receive hydroxyurea 2 to 4 grams orally or undergo leukapheresis to rapidly reduce the WBC count. Leukapheresis is not routinely done unless the patient is experiencing symptoms of hyperviscosity or has a WBC 100,000 cells/μL or greater on diagnosis.

Because J.V.'s initial WBC was 180,000 cells/ μL, leukapheresis was initiated together with concomitant hydroxyurea 2 grams twice daily. Approximately 12 hours after initiating leukapheresis, J.V.'s WBC had decreased to 85,000 cells/ μL and he was stable enough to proceed to induction therapy with idarubicin and cytarabine. The leukapheresis and hydroxyurea were subsequently discontinued.

Tretinoin and Arsenic Trioxide for Acute Promyelocytic Leukemia

CASE 96-1, QUESTION 3: Would induction therapy for other subtypes of AML differ from that described previously?

Induction therapy with 7 + 3 is standard for all types of AML, with one exception: APL (also called AML-M3). APL is uniquely characterized by the t(15;17) translocation that fuses the PML gene on chromosome 15 to the retinoic acid receptor-alpha (RAR-α) gene on chromosome 17. In clinical trials, tretinoin has induced complete remission in approximately 90% of patients with APL.[20] Serial bone marrow aspirations after initiation of tretinoin therapy demonstrate progressive differentiation without hypoplasia.[20,21] Unfortunately, tretinoin typically induces brief remissions. A number of trials have investigated combination treatment with chemotherapy and tretinoin.[22,23] Current evidence supports the use of concurrent tretinoin with arsenic trioxide[24–26] or an anthracycline with or without cytarabine for induction in the treatment of low-risk APL. For high-risk APL, conventional chemotherapy remains the standard of care.[24] In addition, postremission therapy should include at least two cycles of an anthracycline-based regimen. Maintenance therapy with intermittent tretinoin has been shown to decrease the relapse rate.[22,27]

Tretinoin therapy, although avoiding life-threatening myelosuppression, can produce significant toxicities, including the differentiation syndrome (formerly called retinoic acid syndrome), which manifests as fever, weight gain, respiratory distress, lung infiltrates, pleural or pericardial effusion, hypotension, and acute renal failure.[28,29] If this syndrome develops, corticosteroid therapy (dexamethasone 10 mg twice a day for 3 to 5 days with a taper over 2 weeks) should be initiated.[24,30] Tretinoin also causes dryness of the lining of the mouth, rectum, and skin; hair loss; skin rash; blepharoconjunctivitis; corneal erosions; muscle weakness; nail changes;

depression; elevated liver enzymes; and high cholesterol. Despite the risk of serious complications and death during induction therapy, the long-term disease-free survival (DFS) rate of patients with APL is superior compared with other AML subtypes. Approximately 75% of patients who receive tretinoin-based induction and maintenance therapy are alive 3 to 5 years after diagnosis.[27]

Complications of Induction Therapy

Tumor Lysis Syndrome

CASE 96-1, QUESTION 4: Twenty-four hours after J.V.'s induction chemotherapy was initiated, the following laboratory values were obtained:

WBC count, 78,000 cells/µL
K, 5.3 mEq/L
Phosphorus, 6.0 mg/dL
Uric acid, 9.8 mg/dL
Calcium, 6.0 mg/dL
Creatinine, 1.6 mg/dL

Why have these laboratory values changed so suddenly? Could this have been minimized or prevented? How should these metabolic disturbances be managed?

J.V. presented with a very high number of peripheral blood blasts. On administration of chemotherapy, patients with a hypercellular bone marrow and high number of blast cells can have a rapid lysis of the blast cells and the release of cellular contents. This can result in tumor lysis syndrome (TLS), which is associated with metabolic abnormalities such as hyperuricemia, hyperphosphatemia, hypocalcemia, and uremia. These disturbances may lead to arrhythmias and acute renal failure. In most cases, TLS occurs 12 to 24 hours after chemotherapy is initiated. TLS may occur after therapy for other malignancies, particularly in those with a high tumor burden, such as high-grade lymphomas and ALL; it rarely occurs after therapy for solid tumors.

Patients should receive IV hydration (3–4 L/day) beginning 24 to 48 hours before chemotherapy to maintain renal perfusion, optimize the solubility of tumor lysis products, and compensate for fluid losses caused by fever or vomiting. Alkalinization of the urine with the addition of sodium bicarbonate to the IV fluids may also reduce or prevent uric acid from precipitating in the renal tubules and collection ducts by maintaining the urate in its ionized state, but is not currently recommended for all patients. This is because the increased pH may increase the risk of precipitating calcium phosphate in both soft tissue and kidney tubules, and it may aggravate hypocalcemia.[31,32]

Allopurinol, a xanthine oxidase inhibitor that blocks the production of uric acid, should be started before chemotherapy to prevent or minimize the complications of TLS. The recommended adult dosage is 300 to 600 mg/day. J.V.'s serum uric acid and electrolytes should be monitored at least 2 to 3 times a day for 24 to 48 hours after initiating chemotherapy. If severe abnormalities occur, more aggressive measures should be initiated. Allopurinol may be discontinued if the serum uric acid is within normal limits, the LDH has normalized, and the WBC count is low. Rasburicase, a recombinant urate oxidase product, can also be used as prophylaxis in patients who are at high risk of developing TLS or for the treatment of patients who present with or develop TLS. Rasburicase acts as a catalyst in the enzymatic oxidation of uric acid to allantoin, which is 5 to 10 times more soluble than uric acid and undergoes rapid renal excretion. The recommended dose of rasburicase for both prevention and treatment of TLS is 0.2 mg/kg/dose IV. Rasburicase results in a rapid reduction in serum uric acid (within 4 hours of administration) and is generally well tolerated.[33] In many adult centers, doses of 3 or 6 mg are commonly used.[34–38] Although rasburicase has demonstrated excellent efficacy and tolerability, its optimal role in the prevention and management of hyperuricemia in adults remains to be defined because of its high cost and lack of a randomized trial comparing its effect with other interventions.

Although J.V.'s serum potassium was low on admission, it has increased significantly as a result of TLS. For this reason, replacement potassium therapy by any method is not recommended before chemotherapy in patients in whom TLS is highly likely. In extreme circumstances, dialysis may be required to correct severe metabolic and electrolyte disturbances associated with TLS. J.V.'s kidneys continued to function throughout. Even though J.V.'s creatinine was above the normal range, his urine output did not decline substantially and he was able to proceed without further intervention.

Myelosuppression

CASE 96-1, QUESTION 5: J.V. received allopurinol therapy and aggressive hydration throughout his induction chemotherapy. The metabolic abnormalities gradually resolved as his WBC count declined and tumor lysis diminished. What other complications may occur during induction therapy and can they be treated?

Patients receiving cytarabine and idarubicin induction therapy develop profound anemia, granulocytopenia (e.g., WBC count <100 cells/µL), and thrombocytopenia (<20,000 platelets/µL) shortly after therapy is initiated, which usually persist for approximately 21 to 28 days. Additionally, all infectious complications must be considered life-threatening in severely immunocompromised patients such as J.V.

Filgrastim (granulocyte colony-stimulating factor [G-CSF]) and sargramostim (granulocyte-macrophage colony-stimulating factor [GM-CSF]) stimulate leukemic cells as well as normal granulocyte precursors in vitro; however, several studies have demonstrated that these agents, when used as an adjunct to AML chemotherapy, are safe and do not adversely affect disease outcome.[39,40] Most studies have demonstrated that colony-stimulating factors (CSFs) can modestly decrease the length of profound neutropenia and sometimes reduce the incidence of infection-related morbidity, the duration of systemic antibiotic and antifungal therapy, and the number of hospitalization days. Despite the reduction in short-term neutropenia-related complications, administration of CSFs after induction chemotherapy does not appear to have an impact on the rate of CR or the long-term outcomes of the disease. Refer to Chapter 94, Adverse Effects of Chemotherapy and Targeted Agents, for additional information about CSFs.

Severe thrombocytopenia may result in bleeding episodes that range in severity from oozing gums to massive hemorrhage. Serious bleeding complications can usually be avoided if patients receive platelet transfusions when their platelet counts decrease to less than 10,000 cells/μL or when patients experience bleeding.

Other common drug-induced complications that may occur during induction therapy include nausea and vomiting, mucositis, fever, and skin rash (see Chapter 22, Nausea and Vomiting, Chapter 55, Pain and Its Management, and Chapter 94, Adverse Effects of Chemotherapy and Targeted Therapy, for additional information and their management).

Postremission Therapy

CASE 96-1, QUESTION 6: After completion of his induction chemotherapy, J.V.'s WBC count fell to less than 100 cells/μL and his platelet count fell to 5,000 cells/μL. He received platelet transfusions approximately every 2 to 3 days to prevent bleeding complications. On day 9, he developed a fever of 38.8°C. He was started immediately on empiric, broad-spectrum antibiotic therapy for fever and neutropenia, and it subsequently resolved. On day 29, his WBC count was 5,600 cells/μL with a normal differential, and his platelet count was 168,000 cells/μL. He received packed red blood cell transfusions on two separate occasions when his Hgb fell to less than 7 mg/dL. A repeat bone marrow aspirate showed no evidence of persistent leukemia, and J.V. was told that his leukemia was in remission. Nevertheless, his hematologist recommended additional chemotherapy, and J.V. questions why this is necessary. Is postremission therapy necessary, and if so, what therapeutic options are available to J.V.?

RATIONALE

Although greater than 60% of patients treated for AML achieve CR after induction therapy, the median duration of the remission is only about 12 to 18 months, and only 20% to 40% of patients have a DFS exceeding 5 years.[41] Short remissions have been attributed to proliferation of clinically undetectable leukemic cells. Thus, the rationale for administering chemotherapy after remission is to eradicate these residual cells.

In adult AML, postremission therapy (also referred to as consolidation therapy) includes three to four cycles of chemotherapy. Clinical trials have shown that high-dose postremission therapy results in a higher percentage (30%–40%) of long-term (>2–5 years) disease-free survivors than either no or low-dose postremission chemotherapy in patients generally younger than 60 years of age.[42,43] Postremission therapy regimens usually include HiDAC alone or in combination with one or more agents such as an anthracycline or etoposide. Patients 60 years of age and older or those with comorbid disease may not be able to tolerate this intensive postremission therapy. In these circumstances, the risk of life-threatening toxicity may outweigh the potential benefits of postremission chemotherapy. Allogeneic HCT has also been studied in the postremission treatment of AML and is addressed in Chapter 101, Hematopoietic Cell Transplantation.

In conclusion, J.V. should receive consolidation therapy after HiDAC induction because this has been shown to give him the best chance of long-term survival. Additionally, because J.V. was fortunate enough to be diagnosed with good-risk disease, he will not require an allogeneic HCT. He will be followed closely with at least bimonthly CBCs and a bone marrow biopsy at least every year for 5 years after consolidation. This close follow-up is vital for catching relapse as early as possible with the intent of going immediately to an allogeneic HCT and minimizing additional reinduction therapy if relapse occurs.

HIGH-DOSE CYTARABINE

CASE 96-1, QUESTION 7: Because J.V. does not require an allogeneic HCT at this time, his hematologist recommends three courses of HiDAC as postremission therapy. One week after he was declared to be in remission, J.V. is readmitted to the hospital to receive HiDAC 3 grams/m^2 every 12 hours, over 3 hours, on days 1, 3, and 5. What are the potential acute and delayed toxicities associated with HiDAC, and how can these effects be prevented?

At conventional dosages of 100 to 200 mg/m^2/day, adverse effects associated with cytarabine include myelosuppression, fever, and skin rashes. Occasionally, liver enzymes rise transiently. The side effect profile for HiDAC (>1 g/m^2/day) by contrast is very different and can produce major cerebellar, ocular, and skin toxicities that present as rash or palmar-plantar erythrodysesthesia (PPE).[44,45]

Cerebellar and Ocular Toxicity

Cerebellar toxicity is a significant problem in patients receiving HiDAC therapy. See Chapter 94, Adverse Effects of Chemotherapy and Targeted Agents, for details regarding cerebellar toxicity. Ocular toxicity results from damage to the corneal epithelium, occurring when cytarabine penetrates the epithelium through the anterior chamber of the eye or tears. Symptoms include conjunctivitis, excessive lacrimation, “burning” ocular pain, photophobia, and blurred vision. Artificial tears (two drops every 4–6 hours) administered concurrently with HiDAC generally prevent these symptoms. Corticosteroid eye drops can be used as an alternative to artificial tears or if symptoms of conjunctivitis occur.[46]

ACUTE MYELOID LEUKEMIA IN THE ELDERLY

CASE 96-1, QUESTION 8: Would recommendations for induction and postremission therapy differ if J.V. were elderly (60 years of age or older)?

As mentioned earlier, the incidence of AML increases with advancing age. At age 40 years, there is only 1 case of AML per 100,000, but the annual incidence increases to 15% at ages older than 75 years. The prognosis of patients with AML is also directly related to age. Older patients are generally less able to tolerate intensive induction and postremission chemotherapy. Older patients often have comorbid medical conditions and a poor performance status, which are directly associated with worse outcomes with conventional AML therapy.[47,48]

Many single-institution and cooperative group studies exclude elderly patients with AML or treat them on a separate, less-intensive protocol. Elderly patients are often judged to be poor-risk candidates for intensive chemotherapy without objective review of available criteria. Because the median age of patients with AML and myelodysplastic syndrome is 67 years, the results of regimens studied in younger patients may not be applicable to the elderly. Some hematologists believe that it is most appropriate to offer older patients supportive care only, low-intensity therapy, or investigational treatment. Others believe that moderately intensive chemotherapy is beneficial in some candidates. However, most physicians feel uncomfortable offering intensive chemotherapy to elderly patients because of the high risk of induction mortality. Several studies have addressed the outcome of elderly patients.[49–56]

The selection of postremission therapy is difficult in elderly patients because they have a higher risk of morbidity and mortality, and more important, no clinical trials have demonstrated the benefit of postremission therapy specifically in the elderly. The intensity of the regimens must often be attenuated because there is risk of serious toxicities. This is particularly true with HiDAC therapy because of the increased risk of cerebellar toxicity in the elderly. Studies have shown that postremission therapy with low-dose cytarabine (100 mg/m^2 by continuous infusion for 5 days) is as effective as HiDAC and better tolerated in elderly patients.[42]

Refractory or Resistant Acute Myeloid Leukemia

CASE 96-2

QUESTION 1: A.W., a 55-year-old man, is approximately 40 days after induction therapy with 7 + 3. Initially, his counts recovered on day 25, and a bone marrow biopsy on day 28 revealed less than 5% blasts; therefore, he was in remission. Thereafter, a recent CBC showed a significant drop in his platelet count from 150,000 cells/μL on day 30 to 90,000 cells/μL 10 days later. A subsequent bone marrow biopsy reveals 60% blasts, confirming the diagnosis of relapsed AML. What are treatment options for A.W. at this time?

In younger patients, failure to achieve remission or disease relapse remains the major cause of treatment failure. This reflects both the failure of current salvage regimens and the absence of effective strategies to secure long-term DFS in those patients who achieve a second hematologic remission. A wide range of salvage options have been studied, but with less than 50% of patients achieving a second remission and median survival figures ranging from 3 to 12 months, there remains considerable room for improvement.[57]

The treatment of relapse in a patient younger than 75 years of age with a good performance status generally comprises one of several salvage options, including clofarabine, intermediate-dose cytarabine to HiDAC, or combination regimens such as fludarabine, cytarabine, and filgrastim (FLAG), or cladribine, cytarabine, and filgrastim (CLAG), followed by allogeneic HCT.

Future Chemotherapy in Acute Myeloid Leukemia: Targeted Therapies?

CASE 96-2, QUESTION 2: The results of A.W.'s cytogenetic and molecular analysis show that his leukemia is FLT3 positive. What would be the next step for A.W.?

Whereas some clinical factors have an impact on response to treatment, it is the cytogenetic and molecular heterogeneity of AML that is the major determinant of treatment success or failure. For A.W., the finding that his AML has a mutation in the FLT3 gene portends a poor likelihood of long-term survival without new therapies. The estimated 5-year survival is approximately 10% to 15% among patients with a FLT3 internal tandem duplication mutation.[58] Therefore, it is an attractive molecular target for the development of new therapeutics. Although several molecules have been reported to have inhibitory activity against FLT3,[59,60] only a few have clinical trials to assess their efficacy in AML patients: lestaurtinib,[60–62] midostaurin,[63–65] quizartinib,[60] sorafenib,[66–68] and sunitinib.[69]

To date, FLT3 inhibitors have shown only modest efficacy as monotherapy in patients with relapsed or refractory disease. However, in vitro studies suggest synergism between FLT3 inhibitors and conventional chemotherapy. As a result, clinical trials are being conducted to investigate the combination of FLT3 inhibitors in combination with conventional chemotherapy like daunorubicin and cytarabine along with hypomethylating agents such as decitabine and azacitidine with the hope of improving the outcomes of patients with FLT3 mutations in both the initial and relapse setting.[70] Some trials have been shown that there may be an increased risk for toxicity and infectious complications with combination therapy and further research will be necessary to find improved combinations that can maximize efficacy and minimize adverse effects of treatment.[67,68]

For A.W., the best option would be to enroll in an investigational trial that incorporates one of the available FLT3 inhibitors with chemotherapy. If a trial is not available, then HiDAC or a combination regimen containing clofarabine or fludarabine followed by an allogeneic HCT would be his best option.

CHRONIC MYELOGENOUS LEUKEMIA

Epidemiology and Pathophysiology

Chronic myeloid leukemia is a myeloproliferative disorder characterized by unregulated stem cell proliferation in the bone marrow and an increase in mature granulocytes in the peripheral blood. The disease is relatively rare, representing only 0.4% of all cancer cases and 12% of new leukemia cases.[71,72] The median age of diagnosis is 64 years and the current estimated 10-year survival rate is 80% to 90%.[71,73]

Clinical Presentation and Diagnosis

Approximately 30% to 50% of patients are asymptomatic at presentation with the most common physical finding of splenomegaly occurring in 50% to 60% of patients.[73] Additional symptoms may include fatigue, abdominal fullness, fever, anorexia, and weight loss. For many patients, the suspicion for CML is based solely on an abnormal CBC with a confirmatory bone marrow biopsy revealing the hallmark of CML, the Philadelphia (Ph) chromosome. Cytogenetic analysis reveals the presence of the Ph chromosome which is a translocation of chromosomes 9 and 22 t(9;22)(q34;q11).[74] This translocation creates a new protein (BCR-ABL) that has unregulated tyrosine kinase (TK) activity. The three major mechanisms that have been implicated in the malignant transformation by unregulated TK include abnormal cell cycling, inhibition of apoptosis, and increased proliferation of cells.[74] The natural history of CML can be divided into three distinct phases: chronic phase, accelerated phase, and blast phase. The greatest number of patients is diagnosed in chronic phase, which is the earliest phase of the disease.

Treatment

Hematopoietic stem cell transplant (HCT) remains the only curative therapy for CML. However, due to its substantial risks of morbidity and mortality, TK inhibitors have become first-line therapy in most patients. Patients in accelerated or blast phase at presentation or those progressing during TK inhibitor therapy are generally referred for HCT.[75] Though the exact timing of HCT remains controversial, patient outcomes are dependent on disease stage with patients having better 3-year survival rates if transplanted in chronic phase (91%) as compared to accelerated (59%) or blast phase.[76] Use of HCT for CML has declined since 2001 when the FDA approved the first TK inhibitor but the indication has remained for patients who fail these therapies or for those who obtain suboptimal response. Additional information regarding HCT for CML can be found in Chapter 101, Hematopoietic Cell Transplantation.

The primary goals of the TK inhibitors are to prevent progression from chronic phase to accelerated or blast phase while achieving a complete cytogenetic response (CCyR) within 12 to 18 months of therapy initiation.[74] Assessment of response to TK inhibitors is based on hematologic, cytogenetic, and molecular responses. Hematologic response (Table 96-2) is defined by normalization of peripheral blood, platelet count, and splenomegaly whereas cytogenetic response (Table 96-3) is determined by the amount of Ph chromosomes within the bone marrow. Complete molecular response is defined quantitatively by polymerase chain reaction assay with no detectable BCR-ABL mRNA identified to 4.5 logs below the standard baseline.[74]

Table 96-2

Definition of Hematologic Response in Chronic Myelogenous Leukemia

	Partial Response	**Complete Response (CR)**
Peripheral leukocyte count	$<10 \times 10^9$/L	$<10 \times 10^9$/L
Platelet count	<50% pretreatment count (but $>450 \times 10^9$/L)	$<450 \times 10^9$/L
Immature cells	Present	Absent
Splenomegaly	Present (but <50% pretreatment extent)	Absent

Table 96-3

Definition of Cytogenetic Response in Chronic Myelogenous Leukemia

Cytogenetic Response	**Philadelphia (Ph) Chromosome-Positive Metaphase Cells (%)**
Complete	0
Partial	1–35
Major (includes complete and partial responses)	0–35
Minor	>35

Adapted with permission from NCCN Clinical Practice Guidelines in Oncology (NCCN Guidelines). Chronic myelogenous leukemia. 2015; V1.2015. Available at: http://www.nccn.org/professionals/physician_gls/f_guidelines.asp. Accessed May 17, 2015.

Cytogenetic monitoring is an evaluation of the reduction in Ph-positive (Ph+) metaphases within the bone marrow and is the most widely used technique for monitoring patient response to TK inhibitor therapy.[74] Quantitative polymerase chain reaction (QPCR) assay is widely used at three-month intervals to monitor BCR-ABL transcript levels for failure of treatment or recurrence of CML disease.[73,74] BCR-ABL transcript levels >10% signify medication failure and more than one measurement is needed to support a change to an alternative therapy.[77,78]

Signs and Symptoms

CASE 96-3

QUESTION 1: S.E., a 66-year-old white woman, recently had a routine CBC drawn during her annual checkup. Her CBC showed a WBC count of 152,000 cells/μL with 15% basophils, a hematocrit of 32%, and a platelet count of 300,000 cells/μL. The only pertinent physical finding was splenomegaly. On further workup, a bone marrow aspirate revealed a hypercellular marrow with less than 10% blasts. Cytogenetic analysis confirmed a diagnosis of Ph+ CML in chronic phase. S.E. was asymptomatic at diagnosis even though her WBC count was very high. What are the possible clinical consequences of this abnormally high value?

S.E.'s labs indicate hyperleukocytosis, which would be a white blood count (WBC) greater than 100,000 cells/μL. A major consequence of hyperleukocytosis can be leukostasis which may manifest as dizziness, dyspnea, priapism, headaches, tinnitus, and cerebrovascular accidents.[79] Interestingly, S.E. is asymptomatic except for splenomegaly, which occurs in 50% to 60% of newly diagnosed CML patients. The presence of Ph chromosomes within S.E.'s bone marrow established her diagnosis as CML and the percentage of blasts and basophils confirm her stage. Less than 10% of blasts in the bone marrow and less than 20% of basophils in the peripheral blood space place S.E. in chronic phase using the WHO Criteria for CML Staging.[74] Please see Table 96-4 for these criteria.

Clinical Course and Prognosis

CASE 96-3, QUESTION 2: What is the prognosis for S.E. and others with newly diagnosed CML?

S.E. has been diagnosed with chronic-phase CML, which may range in duration from a few months to many years. Because symptoms can be nonspecific and relatively minor, CML may remain undiagnosed until patients progress into more advanced stages. S.E.'s prognosis is good and her projected 10-year overall survival (OS) is 80% to 90% if treated with a TK inhibitor.[73]

Table 96-4

World Health Organization Criteria for CML staging

Chronic phase	■ None of the criteria for blast or accelerated phase
Accelerated phase	■ Blasts 10%–19% of peripheral white blood cells or nucleated bone marrow cells ■ Peripheral blood basophils >20% ■ Persistent thrombocytopenia (<100 × 10^9/L) not related to therapy or persistent thrombocytosis (>1,000 × 10^9/L) unresponsive to therapy ■ Increasing spleen size and increasing WBC count, unresponsive to therapy ■ Cytogenetic evidence of clonal evolution
Blast phase	■ Blasts >20% of peripheral white blood cells or nucleated bone marrow cells. ■ Extramedullary blast proliferation ■ Large foci or clusters of blasts in the bone marrow biopsy

Adapted from Vardiman JW et al. The World Health Organization (WHO) classification of myeloid neoplasms. Blood. 2002;100:2292.; Cortes J, Kantarjian H. How I treat newly diagnosed chronic-phase CML. Blood. 2012;120:1390.

If S.E.'s leukocytosis progresses despite therapy, an increased number of immature leukocytes (blasts) would appear in the peripheral blood signaling the second phase of the disease, the accelerated phase. The accelerated phase can progress quickly to blast phase if left untreated. The estimated 4-year OS is 40% to 55% for those patient with accelerated phase CML who are started on a TK inhibitor.[73] The final phase of the disease (blast phase or blast crisis) is defined as 20% or more blasts in the peripheral blood or bone marrow by the WHO or 30% or more blasts in the blood or bone marrow by the European Leukemia Net.[79] During this phase, CML is indistinguishable from AML with the exception of cytogenetics and is often refractory to conventional induction chemotherapy regimens for AML when treated. The median survival for patients in this phase is approximately 9 to 12 months with allogeneic HCT considered a good first-line treatment option.[73]

Treatment

CASE 96-3, QUESTION 3: What therapy is appropriate for S.E.'s chronic-phase disease?

With the approval of the TK inhibitors, treatment of CML has shifted towards disease management. Because S.E. was asymptomatic upon presentation, she will receive one of the TK inhibitors approved for first-line management of chronic-phase CML.

TYROSINE KINASE INHIBITORS

Imatinib, a first-generation TK inhibitor, inhibits BCR-ABL kinase, which prevents phosphorylation of substrates that are involved in regulating the cell cycle.[73] Approval was based on the pivotal International Randomized Study of Interferon and STI571 (IRIS) trial, which compared imatinib with the combination of interferon (IFN)-α plus low-dose cytarabine in patients with newly diagnosed CML in the chronic phase. A total of 1,106 patients were randomized to either imatinib (400 mg orally daily) or IFN/cytarabine.[80] All primary and secondary end points of the trial demonstrated superiority of imatinib versus IFN/cytarabine. Based on the results of this trial, TK inhibitors became standard of care as first-line therapy for patients with newly diagnosed CML in chronic phase. At the 8-year follow-up of the IRIS trial, 55% of the patients were still taking imatinib, and the estimated OS was 85%.[81] The most common toxicities reported with imatinib are superficial edema, nausea, muscle cramps, and rashes.

Dasatinib is a second-generation TK inhibitor that binds the BCR-ABL protein in the active confirmation, making it 325 times more potent than imatinib.[82] Approval was based on the international DASISION (Dasatinib versus imatinib study in treatment-naïve CML patients) trial, which compared dasatinib with imatinib in 519 patients with chronic-phase CML.[83] The primary objective of CCyR at 12 months and the secondary objective of a major molecular response by 12 months were statistically superior for dasatinib versus imatinib. Dasatinib demonstrates a similar safety profile compared with imatinib but with a higher incidence of pleural effusion, pulmonary hypertension, and thrombocytopenia as well as a lower incidence of rash and diarrhea.[82,84]

Nilotinib is a second-generation TK inhibitor which is structurally similar to imatinib but 30 times more potent as a result of an improved structural fit in the receptor pocket.[82] Approval was based on the international ENESTnd (Evaluating Nilotinib Efficacy And Safety In Clinical Trials—Newly Diagnosed Patients) trial, which randomly assigned 846 patients with chronic-phase CML to either imatinib or two strengths of nilotinib. At 12 months, both doses of nilotinib were statistically superior for molecular response and CCyR compared with imatinib.[85] Upon follow-up, molecular remission rates between the nilotinib arms and the imatinib arm increased from 6% to 10% at 1 year to approximately 21% to 23% by 5 years.[86] Nilotinib demonstrates a similar safety profile compared with the other TK inhibitors, with a higher incidence of rash, headache, pruritus, and alopecia and a lower incidence of nausea, diarrhea, vomiting, edema, and muscle spasm.[85]

Clinicians and patients must carefully evaluate the potential risks and benefits of each treatment modality to make the best therapeutic decision for each individual situation. The following online video discusses the current treatment strategies for CML: https://www.youtube.com/watch?v=Lvz-C6QRNQc. Because S.E. presented in chronic-phase CML, initiation of either imatinib, nilotinib, or dasatinib is an appropriate choice but S.E.'s physician chose to start her on imatinib 400 mg once daily.

Relapsed and Refractory Disease

CASE 96-3, QUESTION 4: On routine follow-up at 3 months, S.E. is found to have an 11% BCR-ABL transcript level. Her side effects and compliance were evaluated, where she was found to be 90% compliant due to nausea. She was counseled on medication adherence as well as what she can take for nausea and then re-evaluated at 6 months. The BCR-ABL level was measured at 15% and her bone marrow revealed 36% Ph+ metaphases. Because S.E.'s compliance had improved, the disease appeared to be resistant to imatinib. Imatinib was discontinued and dasatinib was initiated at 100 mg once a day. S.E. maintained low BCR-ABL assay levels until 12 months when her level was measured at 12%. Cytogenetic analysis revealed that S.E. had become resistant to dasatinib. What treatment options are available for S.E. at this time?

Primary cytogenetic resistance is defined as failure of the patient to achieve any level of cytogenetic response at 6 months, major cytogenetic response at 12 months, or CCyR at 18 months.[74] Just like 15% to 25% of all patients who start on imatinib therapy, S.E. appeared

to have primary cytogenetic resistance at 6 months which prompted therapy discontinuation.[74] Medication adherence can affect resistance rates as well as outcomes.[87] In the ADAGIO study, one-third of patients were noted to be nonadherent to imatinib therapy with suboptimal response occurring in those with higher rates of nonadherence.[88] In S.E.'s case, adherence improved but nausea was problematic, so a dose escalation of imatinib from 400 mg daily to 400 mg twice daily did not seem prudent, given her symptoms and cytogenetics.

Although S.E. has relapsed, she has multiple options for treatment: dasatinib, nilotinib, bosutinib, ponatinib, and omacetaxine. Both nilotinib and bosutinib can be used for second-line treatment while ponatinib and omacetaxineare generally reserved for patients with resistance or intolerance to at least two TK inhibitor therapies. Bosutinib is a TK inhibitor that has shown effectiveness in patients with resistant CML. Of the 118 patients pretreated with imatinib, dasatinib, and/or nilotinib, 24% achieved CCyR with bosutinib, thus estimating the 2-year OS to be 83%.[89] Ponatinib is a TK inhibitor which can be used in patients who have exhausted other TK inhibitor options or in patients with a particular gene mutation (T315I).[74] In the PACE study, which evaluated heavily pretreated patients, major cytogenetic response was achieved and maintained for 2 years in 89% of patients and OS was 86% at 2 years.[90] Omacetaxine is a protein synthesis inhibitor which can be used in patients who have failed at least two TK inhibitors.[74] An average cytogenetic response of 20.5% was found in one study of TK inhibitor-resistant patients who were given omacetaxine.[91] S.E.'s next treatment would likely be based on her tolerability of the first two therapies, her genetic mutations, her concomitant medications, and her comorbidities.

CHRONIC LYMPHOCYTIC LEUKEMIA

Epidemiology and Pathophysiology

Chronic lymphocytic leukemia (CLL) is a disorder of mature but functionally incompetent lymphocytes. Lymphomas are also disorders of lymphocytes; therefore, some molecular abnormalities are shared between the diseases. CLL is the most common type of leukemia in adults, with approximately 15,000 new cases annually and 4,700 deaths.[92] It is a disease of the older population, and the median age at diagnosis is 65 years, with 90% of patients older than age 50 at diagnosis.[93,94] This disease is characterized by overproduction of functionally incompetent B-cell lymphocytes derived from a single stem cell clone in the bone marrow. These lymphocytes accumulate in the blood, bone marrow, lymph nodes, and spleen.

Presentation, Diagnosis, and Overview of Treatment

Chronic leukemias follow a relatively insidious onset and course compared with acute leukemias. Approximately 40% of patients are asymptomatic at presentation and are diagnosed by routine CBC (lymphocytosis, anemia, or thrombocytopenia).[95] Symptomatic patients commonly experience night sweats, fatigue, weight loss, fever, and painful lymphadenopathy. Patients often seek medical attention for infection caused by immune suppression or bleeding caused by thrombocytopenia.

Predicting the clinical course of CLL remains a challenge because some patients experience an indolent course and maintain a good quality of life, whereas others experience more aggressive disease and debilitation. Therefore, survival is variable and depends on the stage of disease at diagnosis. CLL is staged based on peripheral lymphocyte counts; enlargement of lymph nodes, liver, and spleen; and the presence of anemia or thrombocytopenia. The two most commonly used staging systems in clinical practice are the Rai classification and the Binet system. The Rai classification is used in national treatment guidelines and is shown in Table 96-5. The Rai classification is the most clinically useful because it contains prognostic information. Low-risk patients (Rai Stage 0) have survival similar to that of age-matched control subjects. Intermediate-risk patients (Stages I and II) have shorter survival, and high-risk patients (Stages III and IV) have poor prognosis.

Selection of therapy is in part determined by the presence or absence of cytogenetic abnormalities such as del(11q) or del(17p) which are unfavorable, comorbidities, and age. Common first-line therapies include targeted monoclonal antibodies in combination with chlorambucil, bendamustine, fludarabine, or cyclophosphamide. Relapsed disease is often treated with combinations of the same drugs used for initial treatment. Although patients with CLL may survive for years with suppressive therapies, these disorders are curable in only a fraction of patients who are candidates for immune-based approaches using chemotherapy and HCT.

Signs and Symptoms

CASE 96-4

QUESTION 1: G.R., a 66-year-old man, presents to his physician with a persistent semiproductive cough and increased fatigue. A routine CBC revealed an Hgb of 13.0 g/dL, a WBC count of 34,000 cells/μL (80% lymphocytes), and a platelet count of 175,000 cells/μL.

Blood pressure was 120/70 mm Hg, heart rate 64 beats/minute, and respiratory rate 23 breaths/minute. He was afebrile. Physical examination was unremarkable. He was prescribed azithromycin for possible community-acquired pneumonia and scheduled for a return visit in 3 weeks. At that time, his CBC results were Hgb 13.2 g/dL, WBC count 32,000 cells/μL (82% lymphocytes), and platelets 168,000 cells/μL. Physical examination was unchanged, the chest radiograph was clear, and his cough had resolved. G.R. was referred to a hematologist for evaluation of his persistent lymphocytosis. What is the most likely cause of persistent lymphocytosis in G.R.?

Table 96-5

Modified Rai Classification

Risk	Stage	Lymphocytosis[a]	Anemia[b]	Thrombocytopenia[c]	Lymphadenopathy	Hepatomeg or Splenomeg
Low	0	+	–	–	–	–
Intermediate	I	+	–	–	+	–
	II	+	–	–	±	+
High	III	+	+	–	±	±
	IV	+	±	+	±	±

[a] Lymphocytes >5,000/μL in peripheral blood and >30% of total cells in the bone marrow.

[b] Hemoglobin <11 g/dL excluding immune-mediated etiology.

[c] Platelets <100,000/μ/L.

Source: Rai KR et al. Clinical staging of chronic lymphocytic leukemia. Blood. 1975;46:219.

CLL is usually included in the differential diagnosis of any adult with persistent lymphocytosis (>5,000 lymphocytes/μL in peripheral blood). Additional causes of lymphocytosis include transient reactions to acute infections such as influenza or mononucleosis, as well as other hematologic malignancies.

To differentiate between benign and malignant lymphocytosis, examination of the peripheral blood or bone marrow morphology may be required. Patients with CLL commonly have lymphocytosis in both the peripheral blood and bone marrow, whereas patients with other disorders have a high percentage of atypical lymphocytes in the peripheral blood alone. The absence of fever or additional signs of infection without significant diagnostic or physical examination findings, together with the presence of mature peripheral blood lymphocytes, make CLL the most likely diagnosis for G.R. Immunophenotyping and cytogenetics of involved cells are required to establish the diagnosis, to provide prognostic information, and to determine therapy. Bone marrow biopsy with aspirate may be useful to determine the definitive diagnosis.[95]

Staging and Prognosis

CASE 96-4, QUESTION 2: G.R.'s bone marrow examination reveals normal cellularity with greater than 40% of nucleated cells lymphocytes. The immunophenotype indicates that peripheral blood lymphocytes are predominately B cells and are positive for CD5, CD19, and CD20. A diagnosis of CLL is confirmed. Is G.R.'s presentation consistent with CLL? What is the prognosis for G.R.'s disease? What treatment is indicated at this time? G.R.'s cells were sent for routine cytogenetic analysis, which revealed a chromosome abnormality (deletion 11q). How does this affect his management?

G.R. has fatigue, infection, and lymphocytosis without lymphadenopathy, and these are consistent with low-risk CLL based on his modified Rai stage. Given his stage, G.R. has an expected survival of at least 10 years.[93,96]

An accepted treatment modality for early-stage disease includes a conservative, watchful waiting approach. No clear advantage has been demonstrated in treating asymptomatic patients in early-stage disease with alkylator-based chemotherapy as compared with deferred treatment.[97] The survival of patients with smoldering CLL is similar to an age- and sex-matched normal population.[98,99]

There is significant heterogeneity in the clinical course of CLL that is in part attributable to the biologic differences between tumors. Scientific advances have led to the discovery of chromosomal abnormalities (deletions 11q or 17p), gene mutations (unmutated immunoglobulin variable region and p53), and serum or cell surface markers (increased β_2 microglobulin, zeta-associated protein-70, and CD38 expression) that may confer poor prognosis.[100–102] The deletion 13q is the most common cytogenetic abnormality, occurring in 55% of patients, and it has a favorable prognosis (survival >10 years). The deletion 11q and deletion 17p occur in 18% and 7%, respectively, with shorter survival times of approximately 7 and 3 years, respectively. Current national guidelines take into account some of these factors in their treatment recommendations.

Despite his early stage by the modified Rai classification, G.R. had an 11q deletion, conferring a worse prognosis; he would be encouraged to start treatment. However, as a result of having minimal symptoms, G.R. chooses to delay treatment until he becomes symptomatic.

Treatment

CASE 96-4, QUESTION 3: G.R. returns to the hematologist every 3 months and has no new symptoms or infectious complications for about 2 years. At that time, physical examination reveals enlargement of cervical, inguinal, and axillary lymph nodes; hepatomegaly; and splenomegaly. His WBC has increased from 34,000 cells/μL 6 months ago to 68,000 cells/μL today (85% lymphocytes). His Hgb is 11.7 g/dL, and his platelet count is 140,000 cells/μL. What treatment is now indicated?

Indications for treatment initiation in CLL include significant anemia or thrombocytopenia, progressive disease demonstrated by lymphadenopathy, hepatomegaly, splenomegaly, a lymphocyte doubling time of less than 6 months, persistent B symptoms (fever, night sweats, and weight loss), threatened end-organ function, and recurrent infection. Patient performance status, comorbid conditions, pharmacoeconomic variables, and social support should all be taken into consideration when selecting treatment. Cytogenetic results will also be considered. Because G.R. has experienced significant lymphadenopathy and hepatosplenomegaly, he should initiate treatment at this time to prevent further deterioration of his hematologic and immune function.

INITIAL THERAPY

Chlorambucil

Therapy for CLL has historically included use of an alkylating agent, most often oral chlorambucil or cyclophosphamide, with or without prednisone. A variety of daily and intermittent dosing schedules have been reported. The overall response (OR) rate to chlorambucil was approximately 40% to 60%, but only 3% to 5% achieved a CR.[94] Chlorambucil use has diminished, and the use of purine analogs, such as fludarabine, is more common in clinical practice; however, chlorambucil is recommended for patients older than or equal to 70 years, or in younger patients if they have significant comorbidities.[101] Chlorambucil is often used in combination with monoclonal antibodies.[101]

Fludarabine

Fludarabine is an active agent in the treatment of CLL. Fludarabine monotherapy at a dose range of 25 to 30 mg/m^2/dose IV × 5 days has shown a 70% to 80% OR rate, and CR rates of 20% to 30% with increased progression-free survival (PFS).[103–107] Fludarabine may have improved OS compared with chlorambucil, but results are inconsistent across studies.[107,108] Toxicities associated with fludarabine are typically mild and include fever and immunosuppression. Increased incidence of infection and autoimmune hemolytic anemia are also associated with fludarabine therapy. Infection prophylaxis should be considered in elderly patients and patients with advanced disease or renal dysfunction.

Fludarabine has been combined with other chemotherapy and monoclonal antibodies, including cyclophosphamide and rituximab, in an effort to prevent multidrug resistance and increase response. Although combination regimens including fludarabine have demonstrated higher response rates and PFS, no difference in OS has been consistently demonstrated.[109–110] Additional toxicities of the combination regimens include higher rates of leukopenia, thrombocytopenia, nausea, vomiting, and alopecia.

Bendamustine

Bendamustine, a nitrogen mustard/alkylating agent, was approved in 2008 for the treatment of CLL. In clinical studies, it has been shown to be superior to chlorambucil with OR and CR rates of 68% and 31%, respectively.[111] A typical dose and schedule is 100 mg/m^2 IV on days 1 and 2. Toxicities include infusion reactions and myelosuppression. It is often used in combination with rituximab and primarily in patients older than or equal to 70 years or those with comorbidities.[101]

Rituximab

Rituximab is a chimeric human–murine anti-CD20 monoclonal antibody. The CD20 surface antigen is expressed on a high percentage of CLL cells. Rituximab monotherapy as initial therapy for untreated patients at a dose of 375 mg/m^2 weekly for four doses yielded OR rates of 58% and CR rates of 9%; these are lower than those seen with cytotoxic therapy, with a disappointing duration of response.[112] Therefore, rituximab monotherapy is reserved for patients with significant comorbidity. Generally, it is used in combination therapy with cytotoxic agents.

Combination Regimens

A regimen for initial treatment is the combination of FCR. In a study of first-line treatment of CLL, patients were treated with fludarabine 25 mg/m^2 IV on days 1 to 3, cyclophosphamide 250 mg/m^2 IV on days 1 to 3, and rituximab 375 mg/m^2 IV on day 1 of cycle 1, escalated to 500 mg/m^2 in subsequent cycles. OR rate was 96%. Toxicity of this regimen included infusion-related reactions, nausea, vomiting, and myelosuppression. Grade 3 or 4 neutropenia was frequently noted with an infection rate of 20%.[113] The FCR regimen is recommended in patients younger than 70 years without significant comorbidities or older patients without comorbidities, and in any patient with the unfavorable del(17p) cytogenetic abnormality.[93]

Results for a bendamustine plus rituximab (BR) combination regimen have recently been reported. In a study of 117 patients with previously untreated CLL, patients were given bendamustine 90 mg/m^2 IV on days 1 and 2, and rituximab 375 mg/m^2 IV on day 1 of cycle 1, escalated to 500 mg/m^2 in subsequent cycles for up to 6 cycles. OR was 90% and CR 33%.[114] Trials are ongoing to compare this combination with FCR as first-line therapy for CLL patients who are able to tolerate combination chemotherapy. A published interim analysis showed an ORR that was identical in both groups at 98%. However, the adverse effect profile favored BR with a higher rate of toxicity in the FCR group (91% for FCR vs. 79% for BR).[115] The BR regimen, like chlorambucil with or without prednisone, is commonly used in patients older than or equal to 70 years or in younger patients with comorbidities.[101]

In summary, first-line therapy for patients older than or equal to 70 years old or with significant comorbidities generally includes BR or chlorambucil. For younger patients without comorbidities, three-drug combinations such as FCR may be offered. G.R. is now 68 years old with no significant comorbidities and is likely to tolerate treatment with FCR.

RELAPSED OR REFRACTORY THERAPY

CASE 96-4, QUESTION 4: G.R. receives FCR as initial CLL therapy. After the third cycle, he has complete regression of his lymphadenopathy and hepatosplenomegaly, and his WBC count decreases to 9,000 cells/μL. He finishes six cycles in total. G.R. comes to clinic 1.5 years after completion of therapy. A CBC is obtained that reveals a WBC count of 55,000 cells/μL (70% lymphocytes), Hgb of 10 g/dL, and platelet count of 90,000 cells/μL. On physical examination, G.R. is found to have cervical, inguinal, and axillary lymphadenopathy with no palpable splenomegaly. He complains of excessive fatigue and fever. Therefore, G.R. has recurrent disease. What therapies may be helpful to him at this point?

Second-line therapy should be selected based on criteria similar to those used for initial management. Relapsed patients are classified as treatment-sensitive if the disease relapses more than 3 years after FCR treatment.[101] G.R.'s relapse occurred less than 2 years from completion of FCR therapy. He is classified as refractory to his first-line regimen. He is still younger than 70 years old with minimal comorbidities and is a candidate for aggressive second-line treatment.

TREATMENT SENSITIVE

Treatment-sensitive patients are retreated with the same regimen given for first-line therapy as long as they are expected to tolerate treatment. For patients who are older than 70 years or those who have comorbidities, the regimen may be changed to one with less toxicity. These less toxic regimens include dose-reduced FCR, obinituzumab, chlorambucil, ibrutinib, BR, single-agent rituximab, or cyclophosphamide–prednisone–rituximab.[101]

TREATMENT REFRACTORY

Treatment-refractory patients will be offered a regimen containing at least one anticancer agent not previously given. For patients older than 70 years with comorbidities, options include chemoimmunotherapy combinations: dose-reduced FCR, dose-reduced pentostatin–cyclophosphamide–rituximab, rituximab–chlorambucil, BR, and high-dose methylprednisolone–rituximab. Other options are ofatumumab, obinutuzumab, and ibrutinib. Patients younger than 70 years old without significant comorbidities have several options, including combination chemotherapy, chemoimmunotherapy, ibrutinib, and monoclonal antibodies and consideration of allogeneic HCT.[101]

In conclusion, G.R.'s disease relapsed within 18 months of completing initial therapy and is treatment refractory; therefore, he should receive a second-line regimen, which includes an agent to which he has not been previously exposed. G.R. received FCR as his initial treatment; therefore, the BR regimen is a good choice for him now. In addition, he is younger than 70, in relatively good health, and should tolerate combination therapy.

Infectious Complications

CASE 96-4, QUESTION 5: Six weeks after the initiation of BR, G.R. complains of progressive shortness of breath and fever. On questioning, he reveals that he quit taking his trimethoprim–sulfamethoxazole and valacyclovir because "I felt fine." Radiography of the chest reveals bilateral infiltrates. G.R. is admitted to the hospital for further evaluation and treatment. A CBC reveals a WBC count of 22,000 cells/μL (80% lymphocytes) and an absolute neutrophil count of 800 cells/μL, Hgb of 11 g/dL, and platelet count of 70,000 cells/μL. Quantification of serum immunoglobulins reveals profound hypogammaglobulinemia. What are the possible causes of G.R.'s pneumonia, and what treatment is indicated?

Infections contribute significantly to morbidity and mortality in patients with CLL. The immune compromise of CLL is attributable to immunoglobulin deficiency, abnormal T-cell function, neutropenia, and chemotherapy, which contribute to the increased rate of both common and opportunistic infections.[116] Up to 80% of patients will develop an infectious complication; therefore, the use of IV immune globulin, antibacterials (trimethoprim–sulfamethoxazole), and antivirals (acyclovir for herpes simplex virus), and vaccinations (influenza, pneumococcal) are common. Opportunistic infections are particularly common in patients receiving a purine analog. The use of supplemental IV immune globulin for prophylaxis of future infection is often used in patients with low immunoglobulin levels (IgG <500 mg/dL) and recurrent infections requiring hospitalization.[117]

Hospitalization is warranted for G.R. so he can receive broad-spectrum antimicrobials for neutropenic fever and a thorough workup for opportunistic etiologies. Because G.R. has a significant pulmonary infection requiring hospitalization with a documented hypogammaglobulinemia, prophylactic IV immune globulin therapy should be considered to prevent future infections.

MULTIPLE MYELOMA

Incidence and Epidemiology

Multiple myeloma (MM) is defined as a malignancy of “plasma cells,” terminally differentiated B lymphocytes responsible for the production of antibodies and for the rapid immune response to antigen exposure.[118,119] In the United States, an estimated 26,850 new cases of MM will be diagnosed in 2015, accounting for 1% of all cancers.[120] MM occurs nearly twice as often in African-Americans compared to whites, is slightly more common in males than in females, and is diagnosed at a median age of 65 years.[118,121]

Pathophysiology

Although MM may present as a de novo diagnosis, most cases are believed to arise from a benign precursor condition known as monoclonal gammopathy of undetermined significance (MGUS). It is characterized by the accumulation of abnormal clonal plasma cells and may be differentiated from MM by the serum concentration of M-protein (<3 g/dL) and the lack of clinical manifestations typically associated with MM (osteolytic bone lesions, hypercalcemia, renal dysfunction, etc.).[122,123] By way of a complex multistep process involving a variety of genetic events and changes in the plasma cell’s microenvironment, a transformation from MGUS to smoldering MM or symptomatic MM occurs at a rate of approximately 1% of patients/year.[124,125] Cellular events promoting the growth of malignant plasma cells, i.e., induction of angiogenesis, suppression of immunity, and the production of osteoclast-activating factors (e.g., IL-6, tumor necrosis factor, parathyroid hormone-related peptide), occur during the conversion of benign plasma cells to their malignant counterparts.[126,127]

Smoldering myeloma represents an indolent form of the disease in which patients produce M-protein ≥3 g/dL and/or have 10% to 60% plasma cells in the bone marrow, but remain asymptomatic.[122,126] Smoldering myeloma progresses to MM at a rate of 10%/year for the first 5 years after diagnosis, 3%/year for the next 5 years, and 1%/year for the next 10 years.[126]

Clinical Presentation

Patients presenting initially with symptomatic MM frequently complain of bone pain, fatigue, and recurrent infections. Patients may also have end-organ damage, including hypercalcemia, renal dysfunction, anemia, and bone lesions (which may be remembered using the mnemonic CRAB). Because MM is not generally considered to be a curable malignancy, the goal of treatment is to achieve and maintain a clinical response through the combination of induction therapy, hematopoietic stem cell transplant (HCT), and maintenance therapy. See the following video for more general information on MM: http://www.youtube.com/watch?v=uxdgFn1ZMRk.

CASE 96-5

QUESTION 1: B.B. is a 62-year-old, otherwise healthy man who presents with acute back pain after performing light maintenance work. He was initially prescribed nonsteroidal anti-inflammatory drugs (NSAIDs) but has achieved little relief. Computed tomography (CT) scan of the spine reveals osteolytic bone lesions from T6 to T11. Further workup reveals an Hgb of 7 g/dL, serum calcium of 11.8 mg/dL, and serum creatinine of 1.9 mg/dL. Serum and urine protein electrophoresis reveals M-protein typed as IgG-kappa of 5.3 g/dL. A serum β_2 microglobulin was 4.4 mg/L. Bone marrow biopsy reveals 90% plasma cells, and cytogenetics reveal that he has a t(4;14) translocation. Skeletal survey shows additional lesions in the ribs. A diagnosis of MM Stage II is made. Is this presentation consistent with the diagnosis of MM?

B.B. presents with a number of the classic features of MM. Bone pain and skeletal disease are common and occur when plasma cells infiltrate the bone marrow and secrete osteoclast-activating factors. Plain radiographic films will reveal osteopenia or multiple osteolytic bone lesions. Patients with smoldering MM should have more extensive imaging scans done with magnetic resonance imaging (MRI), positron emission tomography (PET), and/or CT, to help determine the presence of MM bone lesions.[122] Hypercalcemia and pathologic fractures often accompany the osteolytic lesions. When plasma cells infiltrate the bone marrow, they can also lead to a normocytic normochromic anemia in up to 70% of patients, although neutropenia and thrombocytopenia are relatively rare. Renal dysfunction is generally attributable to deposition of kappa or lambda light chains of immunoglobulin in the distal tubule, and up to 40% of patients have or will develop renal insufficiency with the disease.[128] Renal dysfunction can be further complicated by dehydration secondary to hypercalcemia, the use of NSAIDs, and the use of contrast dyes in radiographic evaluation. B.B. should receive hydration to restore euvolemia and reduce his calcium; he should avoid NSAIDs and other nephrotoxic therapies. Excessive immunoglobulin production may also cause hyperviscosity syndrome, which may lead to CNS, renal, cardiac, or pulmonary symptoms. Plasmapheresis may be used to alleviate life-threatening cases. Patients may experience recurrent infections as a result of depressed production of other immunoglobulin classes, leading to an inability to opsonize bacteria.

Diagnosis, Staging, and Risk Stratification

Diagnostic criteria for plasma cell disorders are shown in Table 96-6. B.B. clearly meets the criteria for MM. Two staging systems have been used for patients with MM: the older Durie–Salmon system, developed in 1975, and the newer international staging system (ISS).[122,129] The ISS was validated in a large international study demonstrating that prognosis can be predicted reliably from serum β_2 microglobulin (a light chain protein expressed on all nucleated cells) and albumin (Table 96-7). Based on the ISS, B.B. has Stage II MM. Further classifying patients as having standard or high-risk disease based on cytogenetic markers can also help determine a patient's prognosis and help guide treatment decisions.[130]

Treatment

INITIAL THERAPY

Patients with MM are candidates for systemic chemotherapy (Table 96-8). The most effective treatment is induction followed by autologous HCT; therefore, eligibility for HCT helps determine the most appropriate treatment option.[131] Determination of HCT eligibility includes consideration of patient age (typically 65 years of age or younger) and comorbidities. In the case of B.B., his age (62 years) and relative good health make him a candidate for further consideration of HCT as a component of his MM management. Those who are eligible for HCT should not be treated with agents such as melphalan, which may compromise the ability to collect a sufficient number of hematopoietic stem cells necessary to perform the autologous HCT. More aggressive 3 drug combination regimens may be advantageous in high-risk patients to help increase the chance of developing a CR.[130]

Table 96-6

Diagnostic Criteria for Plasma Cell Disorders

Multiple Myeloma
Biopsy-proven plasmacytoma or bone marrow clonal plasmacytosis ≥10%, plus 1 or more of the following: 1. End-organ damage (CRAB features) related to plasma cell proliferation, including the following: Elevated calcium (1 mg/dL above the upper limit of the normal range, or >11 mg/dL) Renal insufficiency (creatinine >2 mg/dL or creatinine clearance <40 mL/minute) Anemia (2 g/dL below the lower limit of normal range, or <10 g/dL) Bone lesions (lytic lesions or osteoporosis with compression fractures) 2. Presence of any one of the following biomarkers: Bone marrow clonal plasmacytosis ≥60% Serum free light chain ratio ≥100 (involved: uninvolved) MRI studies with >1 lesion of ≥5 mm in size
Asymptomatic (Smoldering) Multiple Myeloma
1. Serum monoclonal immunoglobulin ≥3 g/dL or urine monoclonal protein ≥500 mg/24 hours and/or clonal bone marrow plasmacytosis 10%–60% 2. No end-organ damage related to plasma cell proliferation
Monoclonal Gammopathy of Undetermined Significance (MGUS)
1. Serum monoclonal immunoglobulin <3 g/dL 2. Bone marrow plasma cells <10%

3. No end-organ damage related to plasma cell proliferation

CASE 96-5, QUESTION 2: The decision is made to begin B.B. on treatment with a regimen including bortezomib, lenalidomide, and dexamethasone. What advantages and disadvantages does this regimen have compared with others?

The proteasome inhibitor bortezomib acts by inhibiting the 26S proteasome, a multienzyme complex responsible for regulation of proteins that promote cell survival, stimulate growth, and reduce susceptibility to programmed cell death.[146] Bortezomib is commonly used in combination with thalidomide, lenalidomide, cyclophosphamide, and/or dexamethasone. Patients should be monitored for common adverse events, including fatigue, diarrhea, mild nausea, thrombocytopenia, and peripheral neuropathy (the most common cause of discontinuation of bortezomib in clinical trials).[133] Subcutaneous administration significantly reduces the incidence of neuropathy and may be a preferred route for many patients.[147,148] Reactivation of herpes zoster has been observed in greater than 10% of patients treated with bortezomib; therefore, concomitant antiviral prophylaxis should be utilized.[149,150] An additional benefit of bortezomib is the ability to induce responses in patients with del(13) and t(4;14).[151,152] B.B. has the t(4;14) and would benefit from the use of bortezomib.

Thalidomide and lenalidomide are immunomodulatory drugs (IMiDs) commonly used in the initial treatment of MM. They possess complex antiangiogenic, anti-inflammatory, and immunomodulatory properties that make them active in MM.[153] Common adverse effects of lenalidomide include hematologic toxicities, muscle weakness, fatigue, and rash.[154] Several studies have also revealed a small but concerning risk of secondary malignancies, which may be associated with combined oral melphalan use.[155] Although this concern should not prohibit the use of lenalidomide, patients should be made aware of this risk. In comparison with lenalidomide, thalidomide is less potent and has a less favorable toxicity profile with sedation and peripheral neuropathy being common in addition to constipation. Both thalidomide and lenalidomide have a risk of thromboembolism, and venous thrombotic embolism prophylaxis is recommended.[156] Thalidomide and lenalidomide are only available via a restricted access prescription programs due to the risk of teratogenicity.

Table 96-7

International Staging System for Multiple Myeloma

Stage I—β_2 microglobulin <3.5 mg/L and serum albumin ≥3.5 g/dL
Stage II—neither Stage I nor Stage III
Stage III—β_2 microglobulin ≥5.5 mg/L

Source: Greipp PR et al. International staging system for multiple myeloma. J Clin Oncol. 2005;23:3412.[129]

Dexamethasone is an active treatment option for MM, mostly used in combination regimens. It does have significant adverse effects, including hyperglycemia, insomnia, and increased infection risk. Although response rates are increased with higher doses, lower doses are often more beneficial. When combined with lenalidomide, low-dose dexamethasone (120 mg/cycle) improved 1-year OS compared to high-dose dexamethasone (480 mg/cycle) (96% vs. 87%, $p = 0.0002$).[131]

Several 2 or 3 drug combination regimens are effective and appropriate for the initial treatment of MM. The combination of lenalidomide, bortezomib, and dexamethasone (RVD) has demonstrated response rates up to 100% in patients with newly diagnosed MM and is well tolerated with sensory neuropathy, fatigue, and hematologic toxicities being the most commonly reported.[134] The most current National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines In Oncology (NCCN Guidelines) recommend RVD as a preferred initial induction therapy option along with several other regimens, some of which are outlined in Table 96-8.[157] Independent of the choice of induction regimen, patients commonly receive 3 to 6 cycles of treatment before HCT.[158]

In patients ineligible for autologous HCT, melphalan-based regimens are appropriate for induction therapy. Melphalan and prednisone (MP), combined with either bortezomib (MPB), thalidomide (MPT), or lenalidomide (MPR), have all been proven to be more effective than MP alone.[137–139] The MPT regimen may have limited utility due to the increased risk of toxicities compared to MP, including thromboembolism, neuropathy, constipation, and infection. In addition to melphalan-based regimens, lenalidomide plus low-dose dexamethasone or bortezomib plus dexamethasone are also considered preferred initial induction therapy options for transplant ineligible MM.[157]

HEMATOPOIETIC CELL TRANSPLANTATION

Efforts to improve the outcome of MM treatment have led to the investigation of high-dose chemotherapy (e.g., melphalan 200 mg/m^2) with autologous HCT. Randomized comparisons of autologous HCT and conventional chemotherapy in previously untreated patients demonstrated higher response rates and improved survival in patients assigned to receive autologous HCT.[159–162] Younger age, chemosensitive disease, and fewer pretransplant therapies have emerged as important predictive factors for response to autologous HCT.[131] Currently, autologous HCT is considered an integral component of the overall treatment of MM and should be performed in conjunction with induction therapy in eligible patients.[163] The use of allogeneic HCT in MM is a potentially curative option, although it has shown mixed results and is often associated with excessive morbidity and mortality (see Chapter 101, Hematopoietic Cell Transplantation).[164–166] B.B. will receive three cycles of RVD and will be evaluated for HCT.

Table 96-8

Multiple Myeloma Treatment Regimens

Regimen[a]	Agents
Induction Therapy	
Eligible for High-Dose Chemotherapy with Autologous HCT	
Rd[b,c,132]	Lenalidomide 25mg PO daily, days 1–21 Dexamethasone 40mg PO daily, days 1, 8, 15, and 22 Repeat cycle every 28 days
BD[d,130,133]	Bortezomib 1.3 mg/m^2 IV days 1, 4, 8, and 11 Dexamethasone 20 mg PO daily, days 1–2, 4–5, 8–9, 11–12 Repeat cycle every 21 days
RVD[b,c,d,134]	Lenalidomide 25 mg PO daily, days 1–14 Bortezomib 1.3 mg/m^2 IV days 1, 4, 8 and 11 Dexamethasone 20 mg PO daily, days 1–2, 4–5, 8–9, 11–12 Repeat cycle every 21 days
VTD[b,d,135]	Bortezomib 1.3 mg/m^2 IV days 1, 4, 8, and 11 Thalidomide 200 mg PO daily, days 1–21 Dexamethasone 40 mg PO daily, days 1–4 and 9–12 Repeat cycle every 21 days
CyBorD[d,130,136]	Cyclophosphamide 300 mg/m^2 PO daily, days 1, 8, 15, and 22 Bortezomib 1.3 mg/m^2 IV days 1, 8, 15, and 22 Dexamethasone 40 mg PO daily, days 1, 8, 15, and 22 Repeat cycle every 28 days
Ineligible for High-Dose Chemotherapy with Autologous HCT	
MPB[d,137]	Melphalan 9 mg/m^2 PO daily, days 1–4 Prednisone 60 mg/m^2 PO daily, days 1–4 Bortezomib 1.3 mg/m^2 IV days 1, 4, 8, 11, 22, 25, 29, 32 for the first 4 cycles, then days 1, 8, 22, 29 in subsequent cycles Repeat cycle every 42 days
MPR[b,c,138]	Melphalan 0.18 mg/m^2 PO daily, days 1–4 Prednisone 2 mg/kg PO daily, days 1–4 Lenalidomide 10 mg PO daily, days 1–21 Repeat cycle every 28 days
MPT[b,139]	Melphalan 4 mg/m^2 PO daily, days 1–7 Prednisone 40 mg/m^2 PO daily, days 1–7 Thalidomide 100 mg PO daily, days 1–28 Repeat cycle every 28 days
Rd[b,c] and BD[d] are also appropriate treatment options for patients ineligible for HCT	
Salvage Therapy	

Carfilzomib + dexamethasone ± lenalidomide[b],[d,140,141]	Carfilzomib 20 mg/m^2 (days 1 and 2 of cycle 1) or 27 mg/m^2 (doses thereafter) IV days 1, 2, 8, 9, 15, and 16 Dexamethasone 40mg PO daily, days 1, 8, 15, and 22 Lenalidomide 25 mg PO daily, days 1–21 Repeat cycle every 28 days
Pomalidomide + dexamethasone[b,142,143]	Pomalidomide 4 mg PO daily, days 1–21 Dexamethasone 40 mg PO daily, days 1, 8, 15, and 22 Repeat cycle every 28 days
Panobinostat + bortezomib + dexamethasone[d,144]	Panobinostat 20 mg PO daily, days 1, 3, 5, 8, 10, and 12 Bortezomib 1.3 mg/m^2 IV days 1, 4, 8, and 11 Dexamethasone 20 mg PO daily, days 1, 2, 4, 5, 8, 9, 11, and 12 Repeat cycle every 21 days
Bortezomib + liposomal doxorubicin[d,145]	Bortezomib 1.3 mg/m^2 IV days 1, 4, 8, and 11 Liposomal doxorubicin 30 mg/m^2 IV once on day 4 Repeat cycle every 21 days
Additional single or combination regimens, including several utilized as induction treatments, can also be appropriate salvage therapy options	

[a] List of regimens is not all inclusive. Additional combination regimens exist that may be appropriate for the treatment of MM.

[b] Antithrombotic prophylaxis is recommended when on lenalidomide, pomalidomide, or thalidomide, especially when combined with glucocorticosteroids.

[c] Lenalidomide dose adjustments are recommended if creatinine clearance is <50 mL/minute.

[d] Antiviral prophylaxis against herpes virus is recommended while on bortezomib or carfilzomib.

HCT, hematopoietic cell transplantation; IV, intravenously; PO, orally.

BISPHOSPHONATES

CASE 96-5, QUESTION 3: Zoledronic acid 4 mg IV over 15 minutes every 28 days is ordered for B.B. What is the rationale for bisphosphonate therapy in the presence of normal serum calcium? What benefits and toxicities are associated with bisphosphonate therapy?

Osteolytic bone lesions or osteopenia occurs in nearly 80% of all patients with MM and represents one of the most significant challenges to quality of life in this patient population.[124] Although the bone manifestations of MM may occur throughout the body, they are most commonly identified in the vertebral column, where they may lead to clinically significant issues, including fracture.[118]

The efficacy of pamidronate and zoledronic acid for the prevention of skeletal-related events and improvement in OS has been established in MM patients, irrespective of the presence of osteolytic bone lesions.[167,168] Equivalent efficacy with monthly infusions has been shown with pamidronate and zoledronic acid. Because bisphosphonates can negatively affect kidney function, serum creatinine should be monitored monthly and treatment should be held if creatinine increases by more than

0.5 mg/dL above baseline. Higher doses and shorter infusion times have been associated with renal damage. Patients with creatinine clearances between 30 and 60 mL/minute should receive reduced doses of zoledronic acid and pamidronate over 4 to 6 hours is recommended if the creatinine is more than 3 mg/dL. Osteonecrosis of the jaw (ONJ) is a rare but serious complication of bisphosphonate therapy. Zoledronic acid is associated with a 9.5-fold increased risk of ONJ compared with pamidronate.[169] Baseline dental examinations and avoidance of invasive dental procedures during therapy are recommended. All patients with responsive or stable disease should be strongly considered for bisphosphonate discontinuation after 2 years of treatment.

Denosumab is a monoclonal antibody that binds to RANK ligand, which results in decreased osteoclast function and a reduction in bone resorption and bone destruction. Although the efficacy and side effect profile of denosumab are appealing, it cannot be recommended at this time to replace bisphosphonates in the management of MM patients because of an increased risk of mortality observed in a planned subgroup analysis.[170]

B.B. is a candidate for bisphosphonate therapy because he has symptomatic MM and osteolytic disease in the spine and ribs.

MAINTENANCE THERAPY

CASE 96-5, QUESTION 4: B.B. receives three cycles of RVD, followed by autologous HCT. He returns to clinic today 8 weeks after HCT. Should he receive any additional treatment at this time?

Given the near certainty that MM will progress after autologous HCT, maintenance therapies are utilized to extend the duration of response. Two Phase III studies have evaluated the benefit of lenalidomide in this setting. In the CALGB 100104 and IFM 2005-02 studies, lenalidomide 10 to 15 mg/day significantly improved PFS with the CALGB study also demonstrating an OS advantage.[171,172] Although thalidomide has also demonstrated some efficacy as maintenance therapy, its side effect profile limits its use long term. Therefore, lenalidomide may be preferred as a result of its improved toxicity profile although the risk of secondary malignancies should be discussed with patients. Bortezomib has also shown efficacy in the maintenance setting. Compared with thalidomide, bortezomib, at a dose of 1.3 mg/m^2 every 2 weeks, significantly improved PFS and OS.[173] Although neuropathy is a long-term toxicity that may limit its use in some patients, bortezomib may be considered a treatment option in the maintenance setting as well.

The decision was made that B.B. would receive maintenance therapy with lenalidomide 10 mg daily until disease progression was documented.

Relapsed and Refractory Disease

CASE 96-5, QUESTION 5: Four years after autologous HCT, B.B. is found to have relapsed disease. What other therapies may offer benefit for his myeloma?

The number of treatment options for relapsed or refractory MM is continuing to grow. When deciding on treatment, many factors need to be taken into consideration such as chromosomal abnormalities, prior regimen exposure and toxicities, response to prior regimens, and comorbidities.[174] For patients presenting with relapsed MM more than 6 months after initial induction therapy, it is reasonable to re-treat using the same regimen. For those patients with early relapse or refractory MM, bortezomib- or lenalidomide-containing regimens are acceptable options. When either of these agents was studied in combination with dexamethasone, they demonstrated significantly improved time to progression and OS compared to dexamethasone alone.[175,176] Bortezomib may also be combined with pegylated liposomal doxorubicin as an effective salvage regimen with cytopenias, diarrhea, and fatigue being common toxicities.[145]

Carfilzomib and pomalidomide are 2 newer agents, both approved in the relapsed or refractory setting with ongoing studies as initial therapy options. Carfilzomib is a proteasome inhibitor that binds irreversibly and more selectively than bortezomib, leading to decreased neuropathy and activity in some bortezomib-resistant patients. Common adverse effects include fatigue, anemia, nausea, and thrombocytopenia. Peripheral neuropathy occurs in 12.4% of patient with only 1.1% being grade 3 or higher.[140] Carfilzomib also has significant efficacy when combined with lenalidomide and dexamethasone, as demonstrated in the Phase III ASPIRE trial.[141] Dexamethasone premedication is recommended with each dose during cycle 1 and with any dose increase due to the risk of infusion reactions. Hydration is also recommended with each dose during cycle 1 to decrease the risk of TLS. Pomalidomide is the new IMiD structurally similar to thalidomide and lenalidomide.[153] Phase II and III trials have demonstrated significant activity and a manageable toxicity profile when used with or without dexamethasone in the relapsed/refractory setting.[142,143] Pomalidomide is dosed at 4 mg daily for 21 days of each 28 day cycle, although lower doses may be effective. Myelosuppression is the most common toxicity.

The histone deacetylase inhibitor, panobinostat, has also been approved for use in the relapsed and refractory setting in combination with bortezomib and dexamethasone based on the favorable result of the Phase III PANORAMA-1 trial.[144] Side effects, including cytopenias, diarrhea, and peripheral neuropathy, may limit the use of panobinostat. The NCCN considers a variety

---

of combinations as preferred regimens for the management of patients with relapsed or refractory MM, some of which are listed in Table 96-8.[157]

LYMPHOMA

The lymphomas represent a dramatically diverse collection of hematologic malignancies originating from lymphoid tissues. The heterogeneity among these lymphoproliferative disorders is manifest by variations in pathophysiologic features, disease course, and therapeutic approach. Disease may present within the lymph nodes or in extranodal sites such as gastrointestinal tract, skin, bone marrow, sinus or CNS. Lymphomas are classified as either Hodgkin lymphoma (HL) or non-Hodgkin lymphoma (NHL). The NHLs are further divided into more than 20 subtypes according to factors such as cell of origin, histology, and natural history. A review of lymphoma classifications is presented in Table 96-9. Refer to Chapter 95, Pediatric Malignancies, for further discussion of pediatric lymphomas.

Epidemiology, Pathophysiology, and Etiology

The lymphomas impact pediatric through elderly populations with prevalence differing not only according to disease type but also additional factors such as geographic region, ethnicity, and socioeconomic status.[72,177] Causality is often not established; however, certain viral infections including Epstein–Barr virus and human immunodeficiency virus as well as immunosuppression, autoimmune disease, and family history contribute to an increased risk.[178–182]

Table 96-9

Simplified Classification of Lymphomas

	Cell of Origin
Hodgkin Lymphomas	
Classical Hodgkin lymphoma	B cell
Nodular lymphocyte predominant	B cell
Aggressive Non-Hodgkin Lymphomas	
Diffuse large B-cell lymphoma	B cell
Burkitt lymphoma	B cell
Mantle cell lymphoma	B cell
AIDS-related B-cell lymphoma	B cell
Primary central nervous systemlymphoma	B cell
Precursor lymphoblastic leukemia/lymphoma	B or T cell
Peripheral T-cell lymphomas	T cell
Anaplastic large-cell lymphoma	T cell
Adult T-cell leukemia/lymphoma	T cell
Extranodal NK/T-cell lymphoma	NK/T cell
Indolent Non-Hodgkin Lymphoma	

Follicular lymphoma	B cell
Cutaneous T-cell lymphomas	T cell
Marginal zone lymphoma	B cell

Clinical Presentation and Diagnosis

CASE 96-6

QUESTION 1: E.A. is a 35-year-old female with a two-week history of fevers, lymphadenopathy, malaise, and shortness of breath that was initially treated with antibiotics for suspected pneumonia. Progressive symptoms resulted in a hospital admission where radiologic evaluation revealed diffuse lymph node enlargement. Are E.A.'s symptoms consistent with aggressive or indolent lymphoma?

E.A.'s presenting symptoms of fevers, lymphadenopathy, and malaise are all generalized signs of lymphoma with the respiratory symptoms being consistent with pulmonary infiltration of malignant cells. The rapid onset and extensive disease involvement at presentation is suggestive of aggressive lymphoma. A biopsy of an involved node is essential to establish a definitive diagnosis and determine the subtype of lymphoma.

CASE 96-6, QUESTION 2: What diagnostic evaluation is necessary to establish the diagnosis of lymphoma for E.A.?

Suspicion of lymphoma requires a confirmatory biopsy of the lymph node or involved tissues. Morphology, immunophenotyping, flow cytometry, and cytogenetic techniques are utilized to refine the diagnosis. Additional patient assessment should include a complete history and physical examination with a focus on lymph node bearing areas along with laboratory analysis including CBC, comprehensive metabolic panel, and human immunodeficiency virus serology. Radiologic evaluation includes computerized tomography or PET to evaluate the extent of disease. Staging is based on the Ann Arbor system for HL or the Lugano modifications for NHL.[183] A simplified version of these schema is shown in Table 96-10. A bone marrow biopsy or lumbar puncture may be advisable under certain clinical circumstances. Assessment of baseline cardiac and pulmonary function is necessary for all patients expected to be treated with anthracyclines or bleomycin, respectively.

Treatment

Chemotherapy, immunotherapy, radiation, and bone marrow transplant are used in various combinations and sequences in lymphoma therapy. Selection of treatment is guided according to each specific classification of disease. Aggressive lymphomas, such as diffuse large B-cell lymphoma (DLBCL) and Hodgkin lymphoma, are treated with intensive combination chemotherapy regimens administered with a curative intent. In contrast, indolent lymphomas such as follicular lymphoma (FL) are essentially incurable and are regularly managed with an approach aimed at reducing disease burden and prolonging survival. Individual patient characteristics, including comorbid conditions and performance status, must be carefully considered in order to optimize outcomes. An overview of chemotherapy regimens is presented in Tables 96-11 and 96-12.

A biopsy of a supraclavicular lymph node confirms the diagnosis of aggressive NHL for E.A.

CASE 96-6, QUESTION 3: What are some important supportive care considerations with lymphoma therapy?

Beyond selecting the optimal chemotherapy regimen, care for E.A. will require proper supportive care focused on addressing both treatment- and disease-related complications. Prophylaxis and treatment of TLS is vital upon therapy initiation particularly for cases like this involving aggressive and bulky disease. Adequate antiemetics must accompany all chemotherapy. While common to virtually all lymphoma therapies, regimens designed for aggressive lymphoma are associated with significant hematologic toxicity and risk for infectious complications. As such, appropriate support with granulocyte colony-stimulating factors, antibiotics, and blood product transfusions is imperative. Although the urgent need for treatment may preclude opportunities, fertility counseling for a patient of childbearing age like E.A. should be offered. Delayed effects of both chemotherapy and radiation may develop more than a decade after conclusion of therapy and include secondary malignancy, cardiovascular disease, and pulmonary dysfunction. Subsequently, survivorship programs designed to monitor for delayed complications of treatment are increasingly valuable when treating theoretically curative diseases.

Table 96-10

Simplified Staging of Lymphoma

Stage		Description
Early	I	Disease limited to a single lymph node region
	II	Multiple lymph node regions involved on the same side of the diaphragm
Advanced	III	Lymph node regions involved on both sides of the diaphragm
	IV	Diffuse disease involving one or more extranodal organs

A: absence of any of the B symptoms; B: unexplained fever, drenching night sweats, or unexplained weight loss >10% of body weight during the previous 6 months

Adapted from Cheson BD et al. Recommendations for initial evaluation, staging, and response assessment of Hodgkin and non-Hodgkin lymphoma: the Lugano classification. J Clin Oncol. 2014;32:3059.

Table 96-11

Summary of Essential Initial Chemotherapy Regimens for Lymphoma Therapy

Regimen	**Medication**	**Dose**	**Days**	**Cycle Length (days)**
ABVD	Doxorubicin	25 mg/m^2 IV	1, 15	28
	Bleomycin	10 units/m^2 IV	1, 15	
	Vinblastine	6 mg/m^2 IV	1, 15	
	Dacarbazine	375 mg/m^2 IV	1, 15	
R-CHOP	Rituximab	375 mg/m^2 IV	1	21
	Cyclophosphamide	750 mg/m^2 IV	1	
	Doxorubicin	50 mg/m^2 IV	1	
	Vincristine[a]	1.4 mg/m^2 IV	1	
	Prednisone	100 mg PO	1–5	
EPOCH-R	Etoposide[b]	50 mg/m^2 IV	1–4	21
	Prednisone	60 mg/m^2 PO	1–5	
	Vincristine[b]	0.4 mg/m^2 IV	1–4	
	Cyclophosphamide	750 mg/m^2 IV	5	
	Doxorubicin[b]	10 mg/m^2 IV	1–4	
	Rituximab	375 mg/m^2 IV	1	
BR	Bendamustine	90 mg/m^2 IV	1, 2	28
	Rituximab	375 mg/m^2 IV	1	

[a] Maximum dose is 2 mg

[b] Etoposide, vincristine, and doxorubicin are infused over 24 hours

Table 96-12

Summary of Select Alternative Initial or Relapsed/Refractory Regimens for Lymphoma Therapy

Regimen	Chemotherapy
Stanford V	Mechlorethamine, doxorubicin, vinblastine, prednisone, Vincristine, bleomycin, and etoposide
BEACOPP	Bleomycin, etoposide, doxorubicin, cyclophosphamide, Vincristine, procarbazine, and prednisone
ESHAP ± R	Etoposide, methylprednisolone, cytarabine, cisplatin
DHAP ± R	Dexamethasone, cytarabine, cisplatin

ICE ± R	Ifosfamide, carboplatin, etoposide
CVP ± R	Cyclophosphamide, vincristine, prednisone
Hyper-CVAD ± R	Cyclophosphamide, vincristine, doxorubicin, and dexamethasone (Part A) alternating with methotrexate and cytarabine (Part B)
McGrath Protocol ± R	Cyclophosphamide, vincristine, doxorubicin, methotrexate (CODOX-M) alternating with ifosfamide, etoposide, cytarabine (IVAC)

R, rituximab

Hodgkin Lymphoma

CASE 96-7

QUESTION 1: L.G. is a 26-year-old woman with a month-long history of painless swelling around her collarbone and drenching night sweats. She reports increased fatigue and “feeling unwell” over the past 6 months. Radiography revealed a cervical, mediastinal, and inguinal lymph node enlargement. Excisional biopsy of the cervical lymph node revealed nodular sclerosing HL. Because of anemia and thrombocytopenia on presentation, a bone marrow biopsy was performed and found to be positive for lymphoma cells. All other laboratory values are normal and she is otherwise in very good health. What is the goal of therapy for L.G.?

Hodgkin lymphoma, formerly referred to as Hodgkin disease, is a B-cell neoplasm consisting of characteristic Reed–Sternberg cells within an inflammatory background. HL represents approximately 10% of lymphomas and will account for an estimated 9,050 new diagnoses in 2015 in the United States.[71,72] Occurrence of HL displays a bimodal age distribution primarily occurring in young adults with a second peak at approximately age 65.[184] Although once a uniformly fatal disease, improvements in treatment over the last 50 years represent a remarkable success story as now three out of every four new cases can be cured.[185] Given that long-term survival is expected for most patients, delayed consequences of therapy have a heightened importance in management of this disease.[186,187]

Hodgkin lymphoma is categorized as either classical HL or nodular lymphocyte predominant according to the appearance of tumor cells and the composition of the tumor microenvironment.[188] Classical HL is further subdivided, in order of prevalence, as nodular sclerosing, mixed cellularity, lymphocyte rich, and lymphocyte depleted.[189] Nodular lymphocyte-predominant HL accounts for only 5% of all HL and has a unique immunophenotypic profile and therapeutic approach. The remainder of this section will focus on classical HL.

Prognosis is multifactorial and incorporates systemic symptoms, stage of disease, and the size of the mass. The International Prognostic Score (IPS) for HL describes hypoalbuminemia (albumin < 4 g/dL), anemia (Hgb < 10.5 g/dL), male gender, age > 45, Stage IV disease, leukocytosis (WBC > 15,000/mm^3), and lymphocytosis (lymphocyte count <8%) as adverse indicators.[190] According to the IPS for HL, L.G. has two adverse indicators—anemia and Stage IV disease. This suggests that, while she presented with advanced disease, she maintains favorable long-term prognosis.

INITIAL THERAPY

CASE 96-7, QUESTION 2: What is appropriate initial therapy for L.G.?

The objective of initial therapy in HL is to maximize the potential for disease eradication while simultaneously limiting the risk of late effects. This requires stratifying patients according to prognostic factors. European Organization for the Research and Treatment of Cancer (EORTC) criterion is commonly employed to divide patients into one of three groups—early-stage favorable, early-stage unfavorable, and advanced disease. Early-stage favorable patients have Stage I or II disease and have no large mediastinal adenopathy, an erythrocyte sedimentation rate <50 mm/hour, ≤ 3 involved nodes, and are age ≤50. Patients with Stage I or II disease not meeting this criterion are classified as early-stage unfavorable; patients with Stage III or IV HL are considered to have advanced disease.

Radiation alone was the standard of care for decades in early-stage disease. Although effective, the utility of this approach is limited by substantial long-term toxicity.[191,192] The incorporation of combination chemotherapy into HL protocols has both improved long-term disease control and enhanced tolerability. Consequently, radiation therapy alone is no longer an acceptable approach. The regimen ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) is the most commonly used regimen in modern practice and supplanted the previous standard, MOPP (mechlorethamine, vincristine, procarbazine, and prednisone), by demonstrating superior efficacy with reduced incidence both of acute toxicities and long-term complications such as secondary leukemia and sterility.[193,194] In early-stage favorable HL, chemotherapy with ABVD can either be given for four to six cycles alone or for two to four cycles followed by sequential radiation therapy.[195–197] Neither approach is considered superior because OS appears to be equivalent. Comparative studies suggest that chemotherapy alone portends a reduced risk of latent adverse events whereas dual therapy provides a lower rate of disease recurrence.[198–200] Patients with early unfavorable disease require a longer duration of therapy (four to six cycles), and incorporation of radiation therapy becomes essential.[201] For patients with advanced disease, chemotherapy becomes the mainstay of treatment and the duration of ABVD is increased to six to eight cycles.[202–204] Radiation is conventionally reserved to augment therapy for poor responders or patients requiring rapid debulking.[205] A distinctive feature of ABVD is the general avoidance of dose reductions or delays secondary to leukopenia due to the heightened importance of maintaining dose intensity in this disease.[206,207]

The Stanford V regimen incorporates a shorter duration of chemotherapy with an increased reliance on radiation.[208] While less commonly utilized, it represents a suitable alternative to ABVD and can be utilized in both early and advanced HL.[203,209,210] Advantages to the regimen include reduced cumulative doses of doxorubicin and bleomycin and thereby a reduced incidence of late effects of these antineoplastics.[211,212]

Select patients may benefit from escalating therapy to the BEACOPP regimen. This intensive chemotherapy regimen appears to improve tumor control, although a definitive survival advantage has yet to be elucidated.[204,213,214] Individuals with four or more adverse IPS factors and the physical capacity to tolerate the markedly increased toxicity of the combination are likely to derive the greatest potential advantage from this approach.

Given the multiple nodal sites on both sides of the diaphragm and the involvement of the bone marrow, L.G. has Stage IV HL and should be treated with six to eight cycles of ABVD. Although she has advanced disease, she has a favorable prognosis and long-term remission would be anticipated.

RELAPSED AND REFRACTORY DISEASE

CASE 96-7, QUESTION 3: On routine follow-up 9 months after completion of therapy, L.G. is found to have an extensive recurrence of nodal enlargement which is confirmed to be relapsed disease. What are appropriate treatment options for L.G.?

Unlike numerous malignant diseases, patients with HL maintain a reasonable likelihood of attaining cure in the setting of relapsed or refractory disease. Relapses consisting of minimal disease occurring more than 12 months after documented remission suggest a better prognosis. Salvage chemotherapy alone or with radiation is often sufficient therapy.[215,216] Patients with an early or extensive relapse or primary refractory disease generally require second-line chemotherapy followed by autologous bone marrow transplant. Selection of therapy is dependent on individual patient characteristics and provider preference because there is currently no standard of care. Effective regimens in this setting mimic those used in relapsed NHL, and include DHAP, ESHAP, and ICE.[217] Repetition of initial therapy or use of an alternative first-line regimen may be reasonable in a minority of patients.[218,219] Brentuximab vedotin is a CD30-targeted monoclonal antibody linked to an antitubulin antineoplastic agent that has demonstrated activity in heavily pretreated patients failing bone marrow transplant and/or two prior lines of chemotherapy.[220]

L.G. should likely receive a salvage regimen such as ESHAP followed by autologous stem cell transplant given her early and extensive relapse. The aim of her therapy should remain curative.

Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma (NHL) is a spectrum of lymphoid malignancies distinguished by variations in clinical features and responsiveness to treatment. These diseases combined will account for an estimated 71,850 new cases and 19,790 deaths in the United States in 2015.[71] Although various histopathologic classification schemes for NHL have been developed and modified as the cellular understanding of NHL has improved, NHLs can essentially be classified as either aggressive or indolent. Approximately 90% of all lymphomas arise from B lymphocytes with the remaining cases developing from T-lymphocytes or, rarely, natural killer (NK) cells. DLBCL and FL are the two most frequently occurring subtypes of NHL and, as such, will be the focus of this section.

AGGRESSIVE LYMPHOMA

Aggressive lymphomas include DLBCL and Burkitt lymphoma. Although these diseases are rapidly fatal if untreated and require intensive treatments, the prospect of attaining cure is reasonable for many patients receiving modern therapy.

CASE 96-8

QUESTION 1: P.A., a 64-year-old male, presents with complaints of swollen lymph nodes and occasional fevers and night sweats during the past month. Physical examination reveals marked cervical, supraclavicular, and inguinal lymphadenopathy. Laboratory values are normal with the exception of a mild anemia and an elevated LDH. Excisional biopsy of a supraclavicular lymph node confirms a diagnosis of DLBCL. Flow cytometry is positive for CD10, CD19, and CD20 surface markers. He does not have any identifiable extranodal disease. Is P.A.'s disease considered curable?

DLBCL represents about 25% to 30% of all cases of NHL and is the most common type of lymphoma.[10,189,221] Incidence of DLBCL increases with age with the median age at diagnosis occurring in the sixth decade of life.[222] Anticipated 5-year survival rates range from 21% to 76% depending on various prognostic indicators. Adverse indicators include age >60, elevated LDH, multiple extranodal sites, advanced clinical stage, and poor performance status.[223,224] Although the potential for relapse is relatively high given his numerous adverse indicators, the goal of therapy for P.A. is, nonetheless, curative.

Initial Therapy

CASE 96-8, QUESTION 2: Given this information, what is generally considered the standard of care for P.A.?

A combination of chemotherapy and immunotherapy with or without radiation is the foundation of therapy for DLBCL. The cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) protocol has been the prevailing chemotherapy backbone in DLBCL for decades owing to its activity, tolerability, and simplicity in comparison with previously utilized regimens.[225] The inclusion of rituximab, a CD20-targeted monoclonal antibody, with CHOP therapy (R-CHOP) increases survival by approximately 10 to 15% with only a nominal increase in adverse effects.[226–228] Likewise, immunotherapy with rituximab is integrated into virtually all therapy for DLBCL. For patients with Stage I or II disease, a treatment course consists of three cycles of R-CHOP followed by involved field radiation.[229,230] If relative contraindications or aversions to radiotherapy are present, adequate results can typically be obtained by omitting radiation and extending chemotherapy duration. The large size and/or extent of disease limit the utility of radiation in patients with advanced disease (Stage III/IV or bulky tumors). As such, administration of R-CHOP for a total of six to eight cycles is the predominant practice in this setting.

Chemotherapy with CHOP plus rituximab (because his lymphoma is CD20 positive) for six to eight cycles would be ideal for P.A. The addition of radiation treatment is not beneficial in this setting because P.A. has Stage III disease.

Unique Circumstances

CASE 96-8, QUESTION 3: During completion of pretreatment assessment, P.A. is found to have a past medical history significant for cardiac disease. His ejection fraction is revealed to be 45% following an echocardiogram. Final cytogenetic analysis reveals his lymphoma is positive for c-Myc and BCL-2. Do any of these findings change the therapeutic approach for P.A? If so, how?

Notwithstanding its proven reliability, therapy with R-CHOP is not applicable to all patients with DLBCL. Anthracyclines, such as doxorubicin, are a cornerstone of numerous lymphoma regimens. This presents a significant clinical challenge for patients with underlying cardiovascular disease. Replacing the doxorubicin in CHOP with either liposomal doxorubicin or mitoxantrone may be reasonable options to limit cardiovascular toxicity although efficacy is compromised.[231,232] The EPOCH regimen has substantial efficacy in DLBCL and employs infusional doxorubicin which is thought to minimize cardiac effects.[233] If the anthracyclines and related compounds must be avoided entirely, the CEPP regimen (cyclophosphamide, etoposide, prednisone, procarbazine) is feasible.[234] Alternatively, etoposide or gemcitabine serves as acceptable replacements for doxorubicin in the CHOP regimen.[235,236] Treatment of very frail or elderly patients with DLBCL represents a similar challenge to those with cardiac disease. Maintaining dose intensity is ideal given the curative intent of therapy; however, this is not attainable for all patients and use of reduced intensity therapy may be required.[237,238]

The presence of c-Myc and BCL-2 typically appears in NHL with features intermediate between DLBCL and Burkitt lymphoma. These findings, often referred to as "double-hit" lymphomas, are indicative of a poorer prognosis and reduced responsiveness to conventional therapy.[239,240] Escalation from CHOP to EPOCH, a protocol with known activity in Burkitt lymphoma, appears to increase response rates with acceptable tolerability in this subset of DLBCL patients.[241,242]

A change from R-CHOP to EPOCH plus rituximab might be advantageous for P.A. because this treatment is potentially superior given his cytogenetic abnormalities and may be associated with reduced cardiac complications.

Relapsed and Refractory Disease

CASE 96-8, QUESTION 4: Four years after completing therapy, P.A. experiences a relapse of disease. In addition to his lymphoma recurrence, his physical condition has significantly deteriorated since his first therapy due to worsening of comorbid disease unrelated to his cancer.

What is the goal of additional therapy for P.A. now that his disease has recurred?

Eligibility for bone marrow transplant is a critical component in decision-making for the management of relapsed or refractory disease. The aim of therapy for appropriate candidates is administration of aggressive chemotherapy to induce maximal response followed promptly by autologous transplant.[243,244] Comparatively, the approach to patients that are not transplant appropriate, fail to respond to therapy, or relapse following transplant is largely palliative. Numerous intensive regimens have been successfully used to induce remission prior to autologous transplant (Table 96-11).[245–247] No option has proven superior to another, and all are associated with significant hematologic and nonhematologic toxicity. Although efficacy data are limited, rituximab is frequently included into these salvage regimens. Treatment with less-intensive therapy such as gemcitabine plus oxaliplatin (GemOx) or BR is ideal for patients not pursuing stem cell transplant.[248,249] Low doses of single-agent chemotherapy may be a useful approach to palliate symptoms caused by large masses.

Now at age 68 and in suboptimal physical condition, P.A. is not likely a candidate for aggressive salvage therapy followed by bone marrow transplant. A reduced intensity treatment such as BR may be beneficial at controlling disease, though the aim of therapy in this setting would be palliative.

Other Aggressive NHL Subtypes

Burkitt lymphoma is a quintessential aggressive malignancy that demonstrates an exceptionally rapid proliferation rate. Urgent therapy is crucial and must be more vigorous than conventional DLBCL protocols.[250] Active regimens include the McGrath protocol, Hyper-CVAD, or various Cancer and Leukemia Group B (CALGB) protocols.[251–254] Although many of these regimens were developed in the pre-rituximab era, the monoclonal antibody is generally included given the limited impact on toxicity and evidence suggesting improved responses. The EPOCH regimen is a viable therapeutic option with improved tolerability and comparative efficacy to other commonly used regimens.[255] Given the predilection of the disease to involve the CNS, prophylaxis with either intrathecal chemotherapy or high-dose methotrexate and cytarabine is an imperative component to Burkitt lymphoma treatment.[256] While treatment-related complications can be severe, durable remission is attained in 60% to 90% of pediatric and young adult cases.[257] This favorable prognosis dissipates when the disease occurs in older populations.[258]

Mantle cell lymphoma harbors the incurable nature of indolent lymphoma while displaying the capability for rapid proliferation of aggressive disease.[259] Therapy for the disease reflects this dual nature because therapy ranges from low-intensity indolent regimens to high-intensity aggressive regimens. While there is no current standard of care, conventional practice is to administer intensive regimens such as Hyper-CVAD with rituximab to young and medically fit patients based on the perceived advantage in disease response.[260] Protocols such as BR or R-CHOP are ideal for elderly patients or those with significant comorbid disease.[261–263] Various combinations of antineoplastics or single-agent therapy with ibrutinib, a Bruton TK inhibitor, have shown efficacy in the relapsed/refractory setting.[264–266] Autologous or allogeneic bone marrow transplant may be considered for carefully selected individuals.[267]

INDOLENT LYMPHOMA

In contrast to the aggressive lymphomas, indolent varieties are subject to slow growth and typically do not require treatment until the patient is symptomatic.[268] Although numerous effective treatments are available, indolent lymphomas are frequently incurable and prone to recurrent relapses. Treatment is aimed at prolonging survival and palliating symptoms by reducing disease burden until the malignancy either becomes resistant to therapy and/or transforms to a more aggressive lymphoma.[269]

CASE 96-9

QUESTION 1: T.M. is a 61-year-old male in generally good health who is presenting with a three month history of painless axillary lymphadenopathy that seems to "come and go." He is otherwise asymptomatic. An excisional biopsy and pathologic examination revealed follicular B-cell lymphoma, a type of indolent lymphoma. A CT scans showed axillary, mediastinal, and iliac lymphadenopathy. Laboratory values are normal. What is the goal of therapy for T.M.?

FL is the second most common form of NHL and comprises approximately 70% of all indolent lymphomas.[270] The condition predominantly appears in patients over 50 years of age though pediatric variants have been described. A reasonable percentage of patients will survive a decade or longer with disease. The Follicular Lymphoma International Prognostic Index (FLIPI) identifies age >60, elevated LDH, Stage III or

IV disease, Hgb <12, and more than four involved nodes as adverse indicators.[271]

Initial Therapy

Myriad treatment options are available for FL though no absolute standard of care has been established. For a small subset of patients presenting with early disease, treatment may consist of radiation therapy alone which is potentially curative in rare instances.[272–275] Under most circumstances, however, initial treatment of FL involves chemoimmunotherapy. Similar to B-cell-related aggressive NHL, the availability of rituximab has dramatically shaped therapy for FL in the modern era.[276,277] Preferred initial treatment regimens are BR, R-CHOP, or R-CVP (rituximab, cyclophosphamide, vincristine, prednisone). Bendamustine, an alkylating agent with additional properties similar to purine analogs, in combination with rituximab is perhaps the most commonly applied regimen for FL today. In comparison with alternatives such as R-CHOP, BR provides improved PFS and has a lower incidence of myelosuppression, infections, and alopecia.[263,278] Although BR is currently favored by many practitioners, R-CHOP is supported by extensive experience and remains a reasonable therapy particularly for patients with advanced presentations.[279] For patients unable to tolerate anthracyclines, R-CVP has favorable tolerability compared to R-CHOP but compromised efficacy secondary to the removal of doxorubicin.[276] Single-agent rituximab elicits significant response rates with minimal toxicity and is an ideal treatment for patients unable to tolerate the rigors of cytotoxic therapy.[280,281] Administration of maintenance rituximab in various schedules following completion of initial therapy shows an increase in PFS.[282,283]

CASE 96-9, QUESTION 2: When should treatment be initiated for T.M.?

Distinct from aggressive lymphoma therapy, active treatment of FL can be withheld until the development of disease-related symptoms without compromising outcomes.[268,284] Advantages to the “watchful waiting” approach include cost avoidance, minimizing treatment complications, and theoretically limiting future drug resistance. Localized symptoms due to nodal disease, compromised organ function secondary to lymphoma infiltration, B symptoms, cytopenias from bone marrow involvement, or an aggressive tempo are generally considered indications to initiate therapy.

Because his disease is presently asymptomatic, a “watchful waiting” approach is reasonable for T.M. Once criteria for treatment are met, therapy can be initiated with the goal being to reduce disease-related symptoms and to prolong survival.

Relapsed and Refractory Disease

CASE 96-9, QUESTION 3: T.M. eventually requires treatment for his FL and maintains a durable remission after therapy with the BR regimen. Three years later, he has a rapid onset of recurrent disease in multiple nodal regions accompanied by unintentional weight loss and night sweats. Laboratory evaluation reveals thrombocytopenia and neutropenia. Given the characteristics of his relapse, what additional diagnostic tests must be considered prior to providing therapy for T.M?

Nearly one in three FLs will transform into an aggressive lymphoma at the time of relapse.[285] In the event of aggressive presentation, a repeat biopsy is required to determine conversion to alternate histology.[286] If transformation is documented, treatment must be intensified to a protocol consistent with aggressive lymphoma therapy.

CASE 96-9, QUESTION 4: What treatment options are available for T.M.?

For simple relapses of FL, rituximab maintains a pivotal role in relapsed disease and is effective both as a single agent or in combination with chemotherapy.[287,288] Rechallenge with a previously administered regimen is reasonable for patients attaining a durable remission with minimal symptoms. Alternative first-line regimens may also be effectively used in the relapsed setting. Treatment regimens containing bortezomib, mitoxantrone, and fludarabine have additionally demonstrated activity in patients with prior chemotherapy.[289–292] Hematopoietic stem cell transplant is an important treatment option for young and medically fit patients.

The rapid nature of disease relapse in T.M. is an important finding and concerning for transformation to a more aggressive lymphoma. A repeat lymph node biopsy is indicated in this case. If disease has not transformed, a regimen such as R-CHOP may be ideal considering his more advanced presentation.

Breast Cancer

Kellie Jones Weddle

	CORE PRINCIPLES	CHAPTER CASES
1	Mammography and clinical breast examinations are common screening modalities used in patients with an average risk of developing breast cancer.	**Case 97-1 (Question 1)**
2	Prevention can include both surgery (prophylactic mastectomy ± bilateral oophorectomy) and chemoprevention. Tamoxifen and raloxifene are two agents approved for breast cancer prevention.	**Case 97-1 (Question 2)**
3	Breast cancer is the most common cancer diagnosed in American women. Many risk factors have been associated with the development of breast cancer; however, the two most common risk factors are gender and age.	**Case 97-2 (Question 1),** **Case 97-3 (Question 1)**
4	A painless mass is a common presenting symptom for patients. To diagnose the disease and determine the histology, a mammogram and a biopsy are performed. Staging is also performed to determine the extent of disease.	**Case 97-3 (Questions 2–4)**
5	Tumor-specific characteristics help guide treatment selection and contribute to prognosis. The most significant factors are hormonal status (estrogen and progesterone receptor status) and human epidermal growth factor receptor 2 (HER2) status.	**Case 97-3 (Question 5)**
6	Local and systemic treatment can include surgery, radiation, hormonal therapy, chemotherapy, and/or biologic therapy.	**Case 97-3 (Questions 6–9)**
7	Early-stage disease is highly curable. In the adjuvant setting (after surgery), patients can receive hormonal therapy or biologic therapy, depending on tumor-specific factors and may receive chemotherapy, depending on the size of the disease and the presence of positive axillary lymph nodes.	**Case 97-3 (Questions 7–9)**
8	Adjuvant chemotherapy can include regimens containing anthracyclines, cyclophosphamide, and taxanes. Biologic therapy such as trastuzumab can be incorporated if the patient has HER2-positive disease.	**Case 97-3 (Questions 6–8)**
9	Metastatic disease is considered incurable. Decisions regarding therapy will depend on the hormonal status of the tumor, toxicities from previous treatment, or other preexisting comorbidities. Therapies could include systemic therapy (hormonal therapy, chemotherapy, or biologic therapy)	**Case 97-4 (Questions 1–5)**

or local treatment (radiation therapy or surgery).

BREAST CANCER

Incidence, Prevalence, and Epidemiology

Breast cancer is the most common malignancy in American women and is second to lung cancer in mortality rates. It arises from the tissues of the breast, usually the ducts (tubes that carry milk to the nipple) and lobules (glands that make milk). In 2017, it is estimated that 255,180 individuals will be diagnosed with breast cancer, and approximately 41,070 are expected to die from their disease. Approximately 2,470 cases are estimated to be diagnosed in men, indicating this is not a disease solely of women.[1]

The incidence of breast cancer has continued to decline from 1999 through 2004 due to the decreased use of hormone-replacement therapy. This decline follows the results of the Women's Health Initiative study, which demonstrated increased risk of breast cancer in those receiving hormone-replacement therapy.[2] One in eight women are expected to develop the disease over the course

of their lifetime. However, this frequently quoted statistic may overestimate the risk of breast cancer because it is derived from women who live to 110 years of age.[3]

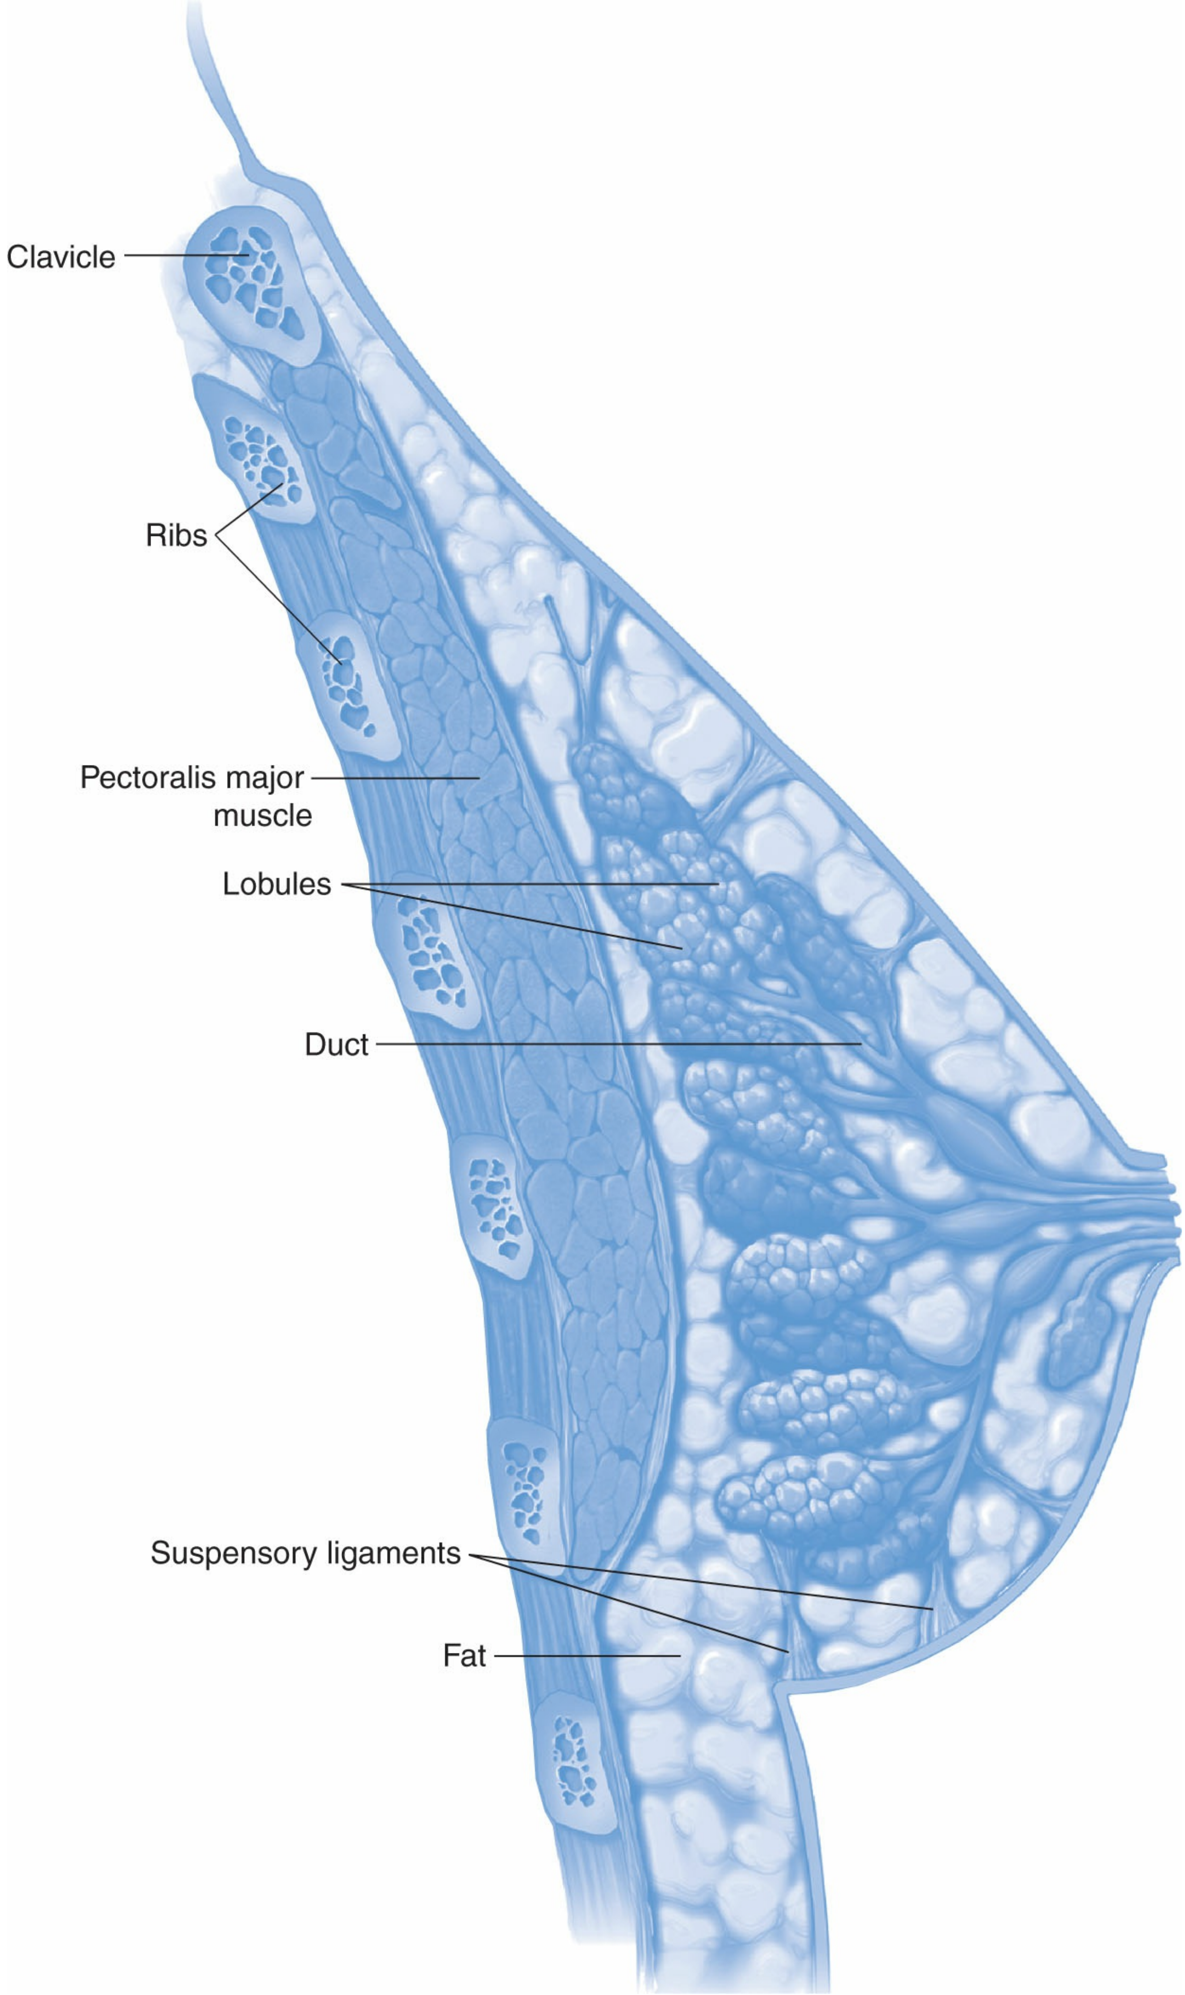
If breast cancer is diagnosed early, it is curable. The likelihood of diagnosing breast cancer is increased by the use of standardized screening methods. Currently, many different guidelines are available for breast cancer screening including recommendations from the American Cancer Society (ACS), National Comprehensive Cancer Network (NCCN), and the US Preventive Services Task Force (USPSTF).

Pathophysiology

The breast itself is composed of many different structures including fat, muscle, ducts, and lobules (Fig. 97-1). Lobules arise from glandular tissue that forms into a spoke-like formation to constitute a lobule of two layers of epithelial cells. The ducts connect the milk-secreting lobules to the nipple.[4] A breast cancer is defined by where the tumor cells originate. The two most common histologic types of breast cancer are ductal and lobular carcinoma. Ductal tumors may be classified as either invasive ductal carcinoma (IDC) if it has invaded through the basement membrane of the duct, or ductal carcinoma in situ (DCIS) if it has not. Likewise, lobular tumors may be classified similarly (i.e., invasive lobular carcinoma [ILC] or lobular carcinoma in situ [LCIS]). Other types of breast cancers include inflammatory (which will be discussed later in the chapter) and rare histologies such as tubular or medullary carcinomas or sarcomas.

Clinical Presentation and Diagnosis

Most patients will present with early-stage disease, where the 5-year survival rate is approximately 98%.[5] Many present with a painless lump found upon breast examination (either by themselves or by a clinician) or with a small mass found only on routine mammogram. Patients who present with metastatic disease typically present with symptoms of their disease based on the metastatic site (such as bone pain with bone metastases or shortness of breath with lung metastases).



Clavicle
Ribs
Pectoralis major muscle
Lobules
Duct
Suspensory ligaments
Fat

Figure 97-1 Anatomy of the breast. (Asset provided by Anatomical Chart Co.)

Treatment will be determined based on the stage of disease. Staging is completed by evaluating the size of the tumor (either radiographically or from the surgical specimen), the extent of positive lymph nodes (on physical examination and surgical removal through an axillary lymph node dissection or sentinel lymph node dissection), and the extent of disease (through radiologic examinations including computed tomography [CT] scan of the chest, abdomen, and pelvis and a bone scan to identify any metastatic disease).

Overview of Treatment

The treatment of breast cancer includes multiple modalities. Surgery, radiation therapy, hormonal therapy, chemotherapy, and biologic therapy can all be used in many different combinations based on a patient's specific disease. If therapy is given before surgery, it is called neoadjuvant therapy, and if treatment is administered after surgery it is termed adjuvant therapy. Early-stage disease may be treated with surgery; other factors will determine whether additional therapy is needed. The staging of a patient's tumor may require radiation and/or chemotherapy, and tumor-specific characteristics decide whether hormonal or biologic therapy will be added. In patients with metastatic disease, the goal is palliation of symptoms and improvement in quality of life.

SCREENING

CASE 97-1

QUESTION 1: M.P. is a 42-year-old woman with no personal history of breast cancer. She has a cousin who was diagnosed with breast cancer at the age of 65 years. M.P. is in her doctor's office today to discuss routine breast cancer screening. Based on M.P.'s personal and family history, would M.P. be considered an average-risk or high-risk patient and what modalities of screening are recommended for average-risk and high-risk patients?

The guidelines for cancer screening for breast cancer were recently updated in 2015 and led to major changes in the recommended screening modalities and intervals of obtainment for women of average risk of developing breast cancer.6 For the average risk patient, screening involves a mammogram and a breast self-examination (if the woman chooses to do so). Although the risk of breast cancer is low in one's 20s, breast self-examination allows a woman to become more familiar with her body and better able to discern changes as she ages. Clinical breast examinations have long been part of the screening guidelines, but with the new changes in recommendations, this component of screening has been removed due to a lack of benefit of detecting breast cancer in a woman with average risk.

Screening mammography has been the gold standard for breast cancer for many decades. With the newer recommendations, a change has occurred as to when to start mammograms and the intervals in which they should be obtained. In the older recommendations, mammography was recommended annually starting at the age of 40. In the newer guidelines, women of average risk should have the opportunity to begin annual mammograms between the ages of 40 to 44 and then annual mammograms should commence at the age of 45 through 54. Once a woman turns 55, she should transition to biennial screening or have the opportunity to continue annual screening. The guidelines also recommend for women to continue screening mammograms as long as their overall health is good and their life expectancy is 10 or more years.

For many years, there has been controversy regarding the utility of mammography and when screening should begin (40 or 50 years of age). This controversy has stemmed from recommendations by the USPSTF.7 Their newest recommendations state that the decision to start screening mammograms before the age of 50, should be an individual decision. Women may choose to begin biennial screening between the ages of 40-49, but that this may lead to more false positive results and unnecessary biopsies. The guidelines state that the largest benefit for screening mammograms occur in women ages 50 to 74 and there are insufficient data to support the utility of annual mammograms in women greater than or equal to the age of 75. While these screening recommendations can be confusing, the controversy that has stemmed from the changes has heightened the awareness to the general public of the importance of breast cancer screening.

M.P. has no first-degree relatives with breast cancer or other family members affected by early breast cancer. M.P. is an average-risk patient, and she should start standard screening modalities and intervals of testing with annual mammograms and clinical breast examinations. She may also decide to do breast self-examinations.

Individuals considered high risk include those that (a) have a known BRCA gene mutation, (b) are untested for the BRCA gene mutation but have a first-degree relative with a BRCA mutation, (c) have a lifetime risk of experiencing breast cancer of approximately 20% to 25% or more based on risk estimation models, or (d) have a strong family history of breast cancer.[6] Screening with breast magnetic resonance imaging (MRI) is recommended in high-risk individuals. Annual mammography and breast MRIs should be initiated starting at the age of 30 years in this population. An MRI allows a radiologist to see a contrasted view of the breast and is more sensitive to detecting breast cancer. In addition, breast tissue in younger patients can be denser due to higher levels of estrogen, making mammography less sensitive.[8]

PREVENTION

CASE 97-1, QUESTION 2: M.P. works at her local hospital as a nurse and is volunteering this year at their breast cancer awareness seminar that is offered by her hospital. She was asked to prepare a talk for the event about breast cancer awareness. She wants to discuss breast cancer prevention. What are the common modalities of breast cancer prevention that M.P. should address and what chemopreventive agents should she include?

Prevention is key with any cancer. Women who are considered high risk for breast cancer may decide to undergo prophylactic mastectomy with reconstruction as an alternative to living with the prospect that they may develop breast cancer in their life. This modality of prevention is very successful, but does not completely eliminate the risk for developing breast cancer.[9] In addition, prophylactic oophorectomy may also be completed to remove the largest source of estrogen in a premenopausal patient. This does not however eliminate the risk completely from developing breast cancer.[10]

Chemoprevention is also another option. Two agents approved for prevention are tamoxifen and raloxifene, both are selective estrogen receptor modulators (SERMs). The Breast Cancer Prevention Trial (or P1 trial) was conducted in more than 13,000 high-risk women, who were randomly assigned into three groups: those older than 60 years, 35 to 59 years of age with an increased risk of breast cancer based on a score of at least 1.66 as determined by the Gail risk model, or older than 35 years with a history of LCIS (a risk factor for developing invasive breast cancer).[11] Women received tamoxifen 20 mg daily or placebo for 5 years of therapy. Tamoxifen significantly decreased the risk of developing breast cancer ($p < 0.00001$). In addition, this study illustrated toxicities associated with tamoxifen therapy, especially in women older than 50 years of age. In those patients, a higher risk of deep vein thrombosis, stroke, pulmonary embolism, and endometrial cancers was identified.[11]

Raloxifene was also approved for chemoprevention in breast cancer. This originated from observations made in osteoporosis studies with raloxifene where patients who had received raloxifene therapy had a decreased risk of breast cancer. With this information, a large randomized chemoprevention trial of more than 19,000 postmenopausal women was conducted evaluating the use of raloxifene 60 mg daily compared to tamoxifen 20 mg daily for 5 years.[12,13] There was no difference in the number of invasive breast cancers diagnosed in the two treatment arms (relative risk, 1.02; 95% confidence interval, 0.82–1.28). Interestingly, more noninvasive breast cancers were identified in the raloxifene group (80 cases) compared with tamoxifen (57 cases); however, the clinical significance of this difference is unknown. The tamoxifen arm reported more hot flashes and endometrial cancer, and the raloxifene arm demonstrated fewer thromboembolic events and cataracts but more musculoskeletal problems and weight gain. Based on the results of this trial, raloxifene received an indication for chemoprevention in high-risk women. The aromatase inhibitors, exemestane and anastrozole, have been studied in the chemopreventive setting in postmenopausal patients (NCIC CTG MAP III trial and IBIS II trial, respectively). Although both trials demonstrated reductions in breast cancer incidences, neither agent has been compared with tamoxifen or raloxifene and so they are not approved for use as a preventive therapy at this time.[14,15]

M.P. should include information on prophylactic mastectomy and both tamoxifen (for pre- and postmenopausal patients) and raloxifene (in only postmenopausal patients) in her talk for women with a high risk of breast cancer but not exemestane or anastrozole.

RISK FACTORS

CASE 97-2

QUESTION 1: B.W., a 55-year-old woman, is found to have a 2.2 cm mass in the upper, outer quadrant of her left breast during a routine screening mammogram. The rest of her physical examination is unremarkable, and she has no complaints. All laboratory values, including the complete blood count and liver function tests, are within normal limits. A chest X-ray is negative. B.W. reports that she had her first menstrual cycle at the age of 10 years and has had regular periods since that time. She is married but has never been pregnant. What are B.W.'s risk factors for developing breast cancer?

Many different risk factors have been identified to be associated with the development of breast cancer. However, in greater than 50% of patients, there are no identifiable risk factors beyond increased age and female gender[16] (Table 97-1). One's risk increases with each decade of life, and the median age of diagnosis is between 60 and 65 years of age. If the patient has had a previous history of breast cancer or atypical hyperplasia from previous breast biopsies, this increases her risk of developing breast cancer.

Breast cancer is a hormonally mediated disease, and many factors are associated with hormonal influences. Early menarche (generally defined as younger than 12 years of age) and late menopause (generally defined as older than 55 years of age) expose a woman to more estrogen throughout her lifetime, increasing her risk (Relative risk [RR] = 1.5 for age <12 years and RR = 2 for ages >55 for late menopause).[17] Based on the results of the Women's Health Initiative, the use of hormone-replacement therapy was shown to increase one's risk of breast cancer.[18] Nulliparity, or having children after the age of 30 years, has been associated with an increased risk (RR increased up to 3.5).[17] Oral contraceptives have long been thought to increase the risk of breast cancer. Earlier forms of oral contraceptives contained much higher doses of estrogen compared with products today. The dose of estrogens in those products was thought to increase a woman's risk of developing breast cancer. However, a meta-analysis demonstrated no difference in risk no matter the dose of estrogen in the oral contraceptives.[19] Hereditary breast cancers (one or more first-degree relatives with the disease) only account for approximately 10% of breast cancer cases; however, these individuals have the highest risk of developing breast cancer.[20]

Table 97-1

Risk Factors for Developing Breast Cancer

Known Risk Factors
Gender: female > male
Personal history of breast cancer
Family history of breast cancer (first-degree relatives)
Benign breast "cancer" (i.e., atypical hyperplasia)
Early menarche (<12 years of age), late menopause (>55 years of age)
Late first pregnancy (≥30 years) or no pregnancy
Advancing age
Long-term use of hormone-replacement therapy (estrogen)
Previous chest wall irradiation
Possible Risk Factors
Alcohol
Obesity
High-fat diet

Sources: Carlson RW, Allred DC, Anderson BO, et al. Invasive breast cancer. J Natl Compr Canc Netw. 2011; 9:136; Chlebowski RT, Hendrix SL, Langer RD, et al. Influence of estrogen plus progestin on breast cancer and mammography in healthy postmenopausal women: the Women's Health Initiative randomized trial. JAMA. 2003; 289:3243.

B.W. has risk factors that increase her risk of developing breast cancer. B.W. started menses early at the age of 10 years and therefore has been exposed longer to estrogen, and she does not have any children. She is also 55 years of age, and the risk of breast cancer increases with each decade of life. Therefore, all of these are considered risk factors for B.W.

INHERITED BREAST CANCER MUTATIONS

CASE 97-3

QUESTION 1: C.D., a 37-year-old woman, is found to have a 2.2 cm mass in the outer quadrant of her right breast during a mammogram. All of her laboratory values were normal, and her chest X-ray was negative. Her family history is significant in that her mother died of breast cancer at the age of 42 years and her 44-year-old sister had a breast tumor removed 5 years ago. With C.D.'s family history, what genetic testing could be performed for her or for anyone else in her family? If C.D. did not have a family history of breast cancer, what other tests could be conducted to estimate her risk of developing breast cancer?

C.D. has two first-degree relatives with early-age breast cancer. This would indicate a possible inherited genetic mutation. Genetic testing for the presence of BRCA1 and BRCA2 mutations should be discussed with C.D. By the age of 70, a person with a BRCA1 mutation has a ~60% risk of developing breast cancer and a

40% risk of developing ovarian cancer.

BRCA2 mutation carriers have a slightly lower risk of breast cancer (~40%) and a lower risk of developing ovarian cancer (~20%).[20,21]

One population with a high incidence of BRCA mutations is those of Ashkenazi Jewish descent, where 1 in 50 individuals are BRCA carriers.[22] C.D. should meet with a genetic counselor to discuss risks and benefits of genetic testing for her and her family members. The results would then play a role in future screening and preventive strategies.

Patients can assess their risk of developing breast cancer by using validated risk tools. One such instrument for average-risk patients is the Gail model, which takes into account numerous factors such as age at menarche, age of first live birth, presence of atypical hyperplasia, and number of previous breast biopsies. This model is available online (www.cancer.gov/bcrisktool/). Other models that have been validated include BRCAPRO and the Breast Cancer Risk Assessment Tool (for average-risk patients).[23,24] BRCAPRO is a statistical program that uses information from both affected and unaffected relatives to predict the likelihood if a person would have an inherited mutation in BRCA1 or BRCA2.[21] This tool would be used in an individual with a high risk of developing breast cancer. There are numerous resources for patients and family members to help understand their risk of developing breast cancer. Concerned individuals should have a conversation with their physician regarding their risk of breast cancer and the utility of these risk assessment tools based on their personal and family history.

Clinical Presentation

CASE 97-3, QUESTION 2: What are the typical signs and symptoms of breast cancer and does C.D. have any?

Typical presentation involves the identification of a painless lump on clinical examination by a healthcare professional, by the patient, or by visualization of a painless lump on mammography. Other symptoms are nipple discharge or retraction, or skin changes of the breast.[25,26] Less than 10% of patients will present with metastatic disease. Symptoms upon presentation can reflect their metastatic disease (i.e., back pain: bone metastases; headaches/nausea/vomiting: brain metastases; dyspnea: lung metastases; or abdominal pain: liver metastases).[25,26] C.D. had a painless lump identified on mammogram as her presenting sign.

Diagnosis

CASE 97-3, QUESTION 3: After the identification of C.D.'s breast mass on mammogram, what diagnostic procedures should be done to determine C.D.'s type and stage of breast cancer?

Workup for breast cancer includes radiographic examinations, patient history, and a physical examination. If a mass is palpated, a mammogram is completed to identify the abnormality. A breast ultrasound can also be added after the mammogram to differentiate fluid-filled cysts (which are usually benign) versus discreet masses. Once identified, a biopsy would then be performed to diagnose the disease. This is achieved with a core biopsy—the standard method used to obtain a tissue sample. This procedure uses a large bore needle for tissue collection and allows for distinguishing invasive versus noninvasive disease. Other methods are available for tissue diagnosis such as fine-needle aspiration and excisional biopsy, but the core biopsy is considered the standard approach.[25,26]

Full radiologic testing should also be completed including a CT scan of the chest, abdomen, and pelvis, and bone scan to assess for metastatic disease. The most common places for breast cancer to metastasize are the bone, lung, liver, lymph nodes, and the brain.[27] Evaluation for brain metastases will usually be performed if the patient is experiencing signs and symptoms such as blurry or double vision, uncontrolled nausea/vomiting, headaches, and unsteady gait. These tests are used to determine the extent and stage of the disease and ultimately help determine the prognosis and treatment of the patient. C.D. will need to undergo a biopsy and full staging with a CT scan of the chest, abdomen, and pelvis, and a bone scan.

Types of Breast Cancer and Staging

CASE 97-3, QUESTION 4: C.D. had a core biopsy performed which revealed IDC. Other staging tests included a CT scan of the chest, abdomen, and pelvis and a bone scan. All tests were negative. Physical examination revealed ipsilateral lymph node involvement. Mammogram revealed a 2.2 cm mass in the right breast. What are the common types of breast cancer and what stage is C.D.'s breast cancer?

The histology of breast cancer is typically divided into two categories: invasive and noninvasive (in situ) disease. IDC is the most common type found (~75% of cases) and ILC is second (~5%–10%). The noninvasive tumors are less common (DCIS and LCIS; ductal carcinoma in situ and lobular carcinoma in situ, respectively).[25,26] Other less common histologies include medullary, mucinous, tubular, and papillary. One of the most aggressive forms of breast cancer is inflammatory breast cancer, which is distinctly different from the other types of breast cancer mentioned. Breast cancer can take years to develop into a mass that is identifiable on physical examination or mammogram. In contrast, the onset of inflammatory breast cancer is sudden and can develop in weeks. Presentation includes a breast that looks "inflamed," red, and has the look of an orange peel (peau d'orange). The diagnosis may be delayed because the skin has the appearance of cellulitis with antibiotics prescribed first; however, the symptoms do not improve with treatment.

Staging is conducted to evaluate the extent of disease. This is completed to understand a patient's prognosis and to help to determine the best treatment course. Staging of breast cancer is determined using the TNM (T, tumor size; N, nodal status; M, any site of metastatic disease) classification. This information is determined by both clinical and pathologic examination. In 2010, the breast cancer staging system was updated by the American Joint Commission on Cancer.[28] Stage I disease involves small tumors (< 2 cm) with no lymph node involvement and is highly curable (~98% 5-year survival). Stage II includes small tumors with lymph node involvement or larger tumors (>2 cm and ≤ 5 cm) with no lymph node involvement. Stage III tumors are larger (>5 cm) with lymph node involvement with a 5-year survival of approximately 80%. Stage IV disease has metastasized to other distant organs and has the poorest prognosis with a 5-year survival of approximately 26% (Table 97-2).[25,26,29] Most patients will present with stage I or II disease due to routine screening. Based on C.D.'s clinical staging, she is considered to have stage II disease based on the size of her disease and the involvement of ipsilateral lymph nodes.

Prognostic Factors

CASE 97-3, QUESTION 5: Further pathologic analysis of C.D.'s breast tumor reveals estrogen receptor (ER)-positive and progesterone receptor (PR)-positive disease. Human epidermal growth factor receptor (HER2) testing of the tumor was negative. What routine prognostic factors are evaluated in all breast cancer patients?

Table 97-2

American Joint Committee on Cancer Staging for Breast Cancer

Stage	T	N	M
0	Tis	N0	M0
IA–B	T1–T1a	N0-N1mi	M0
IIA–B	T0–T3	N0–N1b	M0
IIIA	T0–T3	N1–N2	M0
IIIB	T4	N0–N2	M0
IIIC	Any T	N3	M0
IV	Any T	Any N	M1

T, tumor size and/or invasion; N, presence of lymph nodes; M, metastatic disease; N0, no lymph node involvement; N1, movable ipsilateral lymph nodes; mi, micrometastasis; N2, ipsilateral axillary lymph nodes (fixed or matted), or clinical ipsilateral internal mammary nodes with no axillary lymph node involvement; N3, ipsilateral infraclavicular lymph nodes, clinical ipsilateral internal mammary lymph nodes, clinical axillary lymph nodes, or ipsilateral supraclavicular lymph nodes with or without axillary or internal mammary lymph node involvement; Tis, carcinoma in situ; T1, ≤2 cm; T2, >2 to 5 cm; T3, >5 cm; T4, any size with skin invasion or direct invasion to the chest wall; T0 and T1 tumors with nodal micrometastasis only are excluded from stage IIA and are classified as stage IB.

In addition to staging, other prognostic factors should be evaluated to help determine a patient's treatment course. Prognostic factors such as size of the tumor and lymph node status are important. A larger tumor size denotes a poorer prognosis than a smaller tumor size, and the presence of disease in the lymph nodes leads to a poorer prognosis than lymph node-negative disease. Further, presence of a high number of positive lymph nodes is directly related to a poorer prognosis. Pathologic testing of the breast tumor gives important prognostic factors such as ER and PR and HER2 status.[30] Tumors that are ER- or PR-positive tend to denote a slower-growing, indolent disease and have a more favorable prognosis than ER- and/or PR-negative disease. Approximately two-thirds of breast cancer patients diagnosed have ER- and/or PR-positive disease. If a patient has ER- and/or PR-positive disease, hormonal therapy is a treatment option. Tumors that are HER2-positive generally denote more aggressive disease. Approximately 25% of breast cancers test positive for HER2 gene amplification. Although this is indicative of a more aggressive disease, it is a positive predictor for response to trastuzumab.

HER2 positivity is determined by two different methods, immunohistochemistry or fluorescence in situ hybridization (FISH). Either method could be used to determine HER2 status. Immunohistochemistry determines the overexpression of the HER2 protein, and results are reported as 1+, 2+, and 3+. Patients with 3+ overexpression are considered positive for HER2 and will respond to trastuzumab therapy or other HER2-targeted therapies. If a patient is determined to have 2+ overexpression (an equivocal test), then further testing would be conducted with FISH. FISH testing evaluates the HER2 gene amplification by denoting a ratio of the number of gene copies of HER2 compared to the control, and only those patients with positive FISH testing will respond to HER2-targeted therapies.[30]

Other pathologic tests are completed such as nuclear grade (which determines the degree of differentiation of the tumor cells) as well as tests to evaluate the growth fraction of the disease (such as S-phase fraction, Ki-67, and mitotic index). Clinicians use all of these factors (positive and negative) to determine a patient's prognosis and treatment course.

Other tools allow clinicians to take a more individualized approach (i.e., hormonal therapy alone, chemotherapy alone, or a combination of chemotherapy and hormonal therapy) to treatment. One such tool is Adjuvant!Online (**www.Adjuvantonline.com**), which can be used in early-stage breast cancer patients after surgery to evaluate their individual risk factors and determine treatment benefit versus risk of recurrence. This tool uses clinical factors to estimate an individual's percent risk reduction in recurrence after adjuvant treatment (the benefit with hormonal therapy alone versus the benefit of hormonal therapy and chemotherapy). In addition, genetic profiling has led to the creation of gene arrays to evaluate a patient's risk of recurrence based on their treatment course. Many patients today present with early-stage disease, which is highly curable. Clinicians can use these tests to determine which patients should receive more or less therapy based on their recurrence score. One such test is the Oncotype DX assay for patients with ER- and/or PR-positive and lymph node-negative disease and assigns a patient a recurrence score.[31] Based on the score, clinicians and patients can decide the best treatment course such as hormonal therapy alone versus the combination of hormonal therapy and chemotherapy.

Treatment

CASE 97-3, QUESTION 6: C.D. was diagnosed with a stage II, ER-positive and PR-positive, HER 2-negative IDC of the right breast. Her staging workup was negative as indicated previously with a negative CT scan of the chest, abdomen, and pelvis, and a negative bone scan. Based on this information what would be C.D.'s likely treatment course?

LOCAL TREATMENT (SURGERY AND RADIATION THERAPY)

Surgery is the definitive treatment in early-stage breast cancer. Many years ago, a more radical approach to the surgical removal of breast cancer was used. This approach, called a radical mastectomy, involved the removal of the entire breast, both the major and minor pectoralis muscle, and a full axillary lymph node dissection on the side of the breast cancer. Increased morbidity was associated with this approach such as shoulder dysfunction and a poor cosmetic appearance. Today, a modified radical mastectomy is used that removes the entire breast along with an axillary lymph node dissection while leaving the pectoralis muscles intact. This approach leads to equivalent survival compared with the radical surgery.[32–34] Radiation may be offered in addition to a modified radical mastectomy if the tumor is greater than 5 cm in size, if the patient has greater than four positive lymph nodes, or if positive tissue margins were present after surgery.[35,36] This further improves the local control of the disease. These guidelines are widely debated and the subject of numerous studies evaluating patient populations who would benefit from adjuvant radiation therapy.

Conservative approaches to surgery, such as lumpectomy, segmental mastectomy, or quadrantectomy, are also available. If a patient has a small tumor and wishes to preserve the breast, this surgical approach could be used; however, not all patients are candidates for this procedure. Those who are not candidates can include those with multicentric disease (numerous tumors throughout the breast), large tumors in relation to the size of the breast, and inflammatory breast cancer.[25,26] If the decision is to proceed with breast-conserving surgery, the patient must also undergo adjuvant radiation therapy. Because the surgery only removes the primary tumor, the rest of the breast should

---

be treated with radiation therapy to prevent recurrence of disease. Similar survival rates are observed with modified radical mastectomy versus breast-conserving surgery plus radiation therapy.[33,37]

Larger tumors do not preclude a patient from undergoing breast-conservative surgery. However, to be eligible for this surgery, patients would receive neoadjuvant chemotherapy to help shrink the tumor to a size conducive to breast-conserving techniques. Neoadjuvant chemotherapy also allows the oncologist to assess response to treatment whereas the tumor is still in place and allows the opportunity to discontinue a particular chemotherapy regimen if the patient is not responding. Most patients will respond to chemotherapy; however, for those who do not, further chemotherapy (with a different regimen) or radiation therapy may be offered.[37]

The presence and extent of nodal disease is assessed through an axillary lymph node dissection. This involves the removal of at least 10 lymph nodes on the same side of the primary tumor to assess for the presence of breast cancer. Lymph node dissection may result in lymphedema, thromboembolism, and infection.[38–40] Sentinel lymph node biopsy is one way to avoid the comorbidities associated with the axillary lymph node dissection. In this procedure, a blue dye (labeled with a radiocolloid) is injected around the breast tumor. Time is given for the dye to drain from the tumor to the lymph nodes. The surgeon is able to identify the sentinel nodes because of the presence of radiocolloid and the blue color. The breast (and presumably the cancer) drains first into the sentinel lymph nodes. Only one or two of the sentinel lymph nodes will be removed, reducing the risk of lymphedema, thromboembolism, and infection.

Many consider this procedure the standard of care for assessment of the axillary lymph nodes.[38,41–43]

C.D. could either undergo breast-conserving surgery plus radiation therapy or a modified radical mastectomy, but with C.D.'s family history she may also choose to undergo bilateral mastectomies to prevent the development of contralateral breast cancer.

SYSTEMIC THERAPY (CHEMOTHERAPY, HORMONAL THERAPY, AND BIOLOGIC THERAPY)

Surgery and radiation therapy eradicates most tumor cells; however, microscopic disease is difficult to detect and treat locally. Microscopic cancer deposits can migrate throughout the body and serve as sites for disease recurrence. To diminish the chance of recurrence, systemic adjuvant chemotherapy, hormonal therapy, and/or biologic therapy is given. The determination of which single modality or combination of therapies is based on the patient's prognostic factors: ER/PR status and HER2 positivity. As mentioned earlier, tools such as the Oncotype DX genetic assay can estimate risk recurrence based on these tumor-specific characteristics and assist in determination of therapy.

The size of the tumor and other prognostic factors are also evaluated to determine the course of therapy; see Table 97-3. The NCCN provides treatment guidelines to help with treatment planning.[37] Patients with small tumors (0.6–1 cm) and negative lymph nodes can be further divided into two groups based on favorable and unfavorable prognostic features. Favorable prognostic features would include hormone-positive disease. These patients can be offered hormonal therapy without chemotherapy. Those individuals with poor prognostic features (tumors with lymphatic invasion, high nuclear grade, hormone receptor-negative, or HER2-positive disease) would be offered chemotherapy with or without trastuzumab therapy.[25,26]

Tumors greater than 1 cm in size are generally offered treatment with systemic chemotherapy. If the patient is ER- and/or PR-positive, they are additionally treated with hormonal therapy after chemotherapy. Biologic therapy with trastuzumab is added to chemotherapy if the patient has HER2-positive disease and assuming there are no contraindications such as cardiac disease. Patients should be fully informed of the absolute benefit of chemotherapy, because in those with early-stage disease the benefit from chemotherapy could be as low as 2% to 3%. The Early Breast Cancer Trialists' Collaborative Group conducts an overview analysis every 5 years on the effects of chemotherapy and hormonal therapy in breast cancer randomized trials. In 2005, the 15-year survival updates were published.[44] Although no standard regimen has been identified, combination regimens are superior to single-agent therapy (recurrence rates and mortality for combination chemotherapy, respectively: hazard ratio (HR), 0.77; $p < 0.00001$ and HR, 0.83; $p < 0.0001$, respectively; single-agent therapy recurrence rates and mortality: HR, 0.86; $p = 0.001$ and HR, 0.96; $p = 0.4$, respectively).[44,45] Updated meta-analyses have also included the use of taxanes to fixed anthracycline-based regimens. In the previous EBCTCG trial, taxanes were not included in the data analysis. With the incorporation of taxane therapy, breast cancer mortality was reduced: RR (event rate ratio: newer treatment versus control) = 0.86, SE (standard error) = 0.04, $p = 0.0005$.[46] This demonstrated the benefit of adding taxane therapy to standard adjuvant therapy for specific patients.

Table 97-3

Overview of the Selection of Adjuvant Treatment

	Adjuvant Hormonal Therapy		Adjuvant Chemotherapy[b]
Lymph Node-Negative Disease	**ER/PR (+)**	**ER/PR (−)**	

<0.5 cm	Yes	No	No
0.6–1 cm[a]	Yes	No	Consider
>1 cm	Yes	No	Yes
Lymph Node-Positive Disease	**ER/PR (+)**	**ER/PR (−)**	
	Yes	No	Yes

[a] Consider Oncotype DX testing: low recurrence score (<18) = adjuvant hormonal therapy; intermediate recurrence score (18–30) = adjuvant hormonal therapy ± chemotherapy; high recurrence score (≥31) = adjuvant hormonal therapy + chemotherapy.

[b] Give trastuzumab therapy if the patient is HER2 (+) and no contraindications.

Source: NCCN Guidelines. Breast Cancer. V2 http://www.nccn.org/professionals/physicians_gls/pdf/breast.pdf. Accessed August 2,2017

Looking back at C.D.’s tumor characteristics, she has stage II (2.2 cm with lymph node involvement), ER-positive, PR-positive, and HER2-negative breast cancer. Based on this information, C.D. would be a candidate for surgery and chemotherapy (based on the tumor size and lymph node-positive disease), followed by hormonal therapy due to her ER/PR-positive disease.

ADJUVANT CHEMOTHERAPY

CASE 97-3, QUESTION 7: C.D. underwent a right modified radical mastectomy and axillary lymph node dissection. She had 2 of 15 lymph nodes positive for disease. Her adjuvant treatment will consist of chemotherapy (due to the larger size of the tumor and positive lymph nodes). What are typical adjuvant chemotherapy regimens for the treatment of early-stage breast cancer, and what should C.D. receive?

Many different combination chemotherapy regimens are used in the adjuvant setting (Table 97-4). Anthracycline-containing regimens are commonly used. Doxorubicin or epirubicin in combination with an alkylating agent (cyclophosphamide) plus or minus fluorouracil is a typical regimen. In the most recent Early Breast Cancer Trialist’ Cancer Group analysis, anthracycline-based regimens had significantly lower recurrence rates and death compared to traditional cyclophosphamide, methotrexate, and fluorouracil (recurrence rate ratio, 0.89; $p = 0.001$; and cancer death rate ratio, 0.84; $p < 0.00001$, respectively).[44] A large pooled analysis demonstrated improved disease-free ($p < 0.00001$) and overall survival ($p < 0.0001$) with the addition of a taxane.[46] Updated meta-analyses have also included the use of taxanes to fixed anthracycline-based regimens. As discussed earlier, the optimal taxane regimen has yet to be identified, and the full benefit of the utility of taxane therapy in lymph node-negative disease is yet to be determined; however, the benefit is apparent in lymph node-positive disease and taxanes should be incorporated into the treatment regimen of those with lymph node-positive disease.

Table 97-4

Common Neoadjuvant and Adjuvant Chemotherapy Regimens

Regimen
HER2-Negative Disease
Dose dense[a] AC → paclitaxel every 2 weeks
Dose dense[a] AC → paclitaxel weekly
TC
CMF, classic (oral) or intravenous
CAF (oral/intravenous)
CEF
TAC
AC
AC → paclitaxel weekly
AC → docetaxel every 3 weeks
FEC/CEF followed by paclitaxel or docetaxel
FAC followed by paclitaxel or docetaxel
HER2-Positive Disease
AC → paclitaxel + trastuzumab ± pertuzumab
TCH ± pertuzumab
AC → docetaxel + trastuzumab ± pertuzumab
Docetaxel + cyclophosphamide + trastuzumab
FEC → paclitaxel or docetaxel + pertuzumab
Paclitaxel + trastuzumab
Pertuzumab + trastuzumab + docetaxel or paclitaxel → FEC

[a] Dose dense, given every 2 weeks instead of every 3 weeks. See source document for specific dosing; TCH, docetaxel, carboplatin, trastuzumab.

A, adriamycin; C, cyclophosphamide; E, epirubicin; F, fluorouracil; M, methotrexate; P, paclitaxel; T, docetaxel; →, followed by.

Congestive heart failure is a well-known toxicity associated with anthracycline chemotherapy. If a patient has heart failure or other preexisting cardiac disease, anthracyclines must be used cautiously. To avoid potential toxicity, taxane regimens such as docetaxel and cyclophosphamide have been compared to a standard anthracycline-containing regimens, doxorubicin and cyclophosphamide. After 7 years of follow-up, both disease-free and overall survival were significantly better in the taxane arm compared with the anthracycline arm (81% vs. 75%; p = 0.033 and 87% vs. 82%; p = 0.032, respectively).[47] Although the results are encouraging, these data do not have the track record of the anthracycline-containing regimens that are still considered the mainstay of therapy for adjuvant chemotherapy in early-stage breast cancer. Studies are currently underway to identify specific populations that may not respond to anthracycline therapy, thereby avoiding the risk of cardiac toxicity in these individuals.[48] If these specific cases are identified, more nonanthracycline-based chemotherapy regimens will be incorporated into clinical practice. Based on C.D.'s lymph node–positive breast cancer, a typical adjuvant chemotherapy regimen would consist of doxorubicin and cyclophosphamide (AC) or fluorouracil and doxorubicin and cyclophosphamide (FAC) given every 3 weeks for four cycles followed by a taxane such as paclitaxel weekly for 12 weeks (see Table 97-4 for commonly used adjuvant chemotherapy regimens).

Trastuzumab therapy can be incorporated into a patient's adjuvant chemotherapy regimen if the tumor is HER2-positive. Trastuzumab was first studied in the metastatic setting and demonstrated improved overall survival when added concurrently with chemotherapy.[49] Because of its robust activity in the metastatic setting, it was then studied in early breast cancer to see whether the same benefit could be achieved. Two large trials were conducted concurrently addressing different questions regarding the use of concurrent, sequential, and maintenance trastuzumab.[50,51] Patients received the classic AC regimen for four cycles followed by paclitaxel weekly given either sequentially or concurrently. Trastuzumab therapy was started after the completion of the AC regimen to reduce potential cardiac toxicities associated with doxorubicin and trastuzumab.[50,51] The results of these trials were combined and published in full. Disease-free and overall survival were significantly improved with the addition of trastuzumab (52% decrease in recurrence rates, $p < 0.0001$; and 33% reduction in mortality, $p = 0.015$, respectively).[50,51] Four-year follow-up data continued to demonstrate significant improvements with trastuzumab compared to chemotherapy alone. Based on these data, trastuzumab was approved for use in early-stage, HER2-positive disease after the completion of AC therapy followed by sequential paclitaxel therapy for 1 year.[52] The use of maintenance trastuzumab was further studied in the HERA Trial (Herceptin Adjuvant Trial).[53] In that trial, patients were randomly assigned to complete 1 or 2 years of maintenance trastuzumab therapy. One year of trastuzumab therapy is the current standard of practice for maintenance therapy in the adjuvant setting. Because C.D. does not have HER2-positive disease, trastuzumab therapy should not be used.

CHEMOTHERAPY TOXICITY

CASE 97-3, QUESTION 8: C.D. is to undergo four cycles of AC chemotherapy followed by weekly paclitaxel for 12 weeks. What are the common toxicities associated with this treatment course? If the tumor was HER2-positive and C.D. received trastuzumab, what toxicities would be associated with its use?

Doxorubicin is an anthracycline chemotherapy agent. It works through multiple mechanisms, but inhibition of topoisomerase II may be most important.[54] By inhibiting this enzyme, double-strand DNA breaks occur. Common toxicities include myelosuppression, nausea/vomiting, and alopecia. A well-known toxicity of anthracyclines is the risk of cardiomyopathy due to the formation of oxygen free radicals and doxorubicin metal complexes. These toxicities can be acute (with symptoms similar to an arrhythmia or myocardial infarction) or chronic (with a patient demonstrating symptoms of congestive heart failure).[55] The risk of cardiotoxicity increases with larger anthracycline cumulative doses.[56,57] With the typical doses of anthracyclines used in the adjuvant setting, a patient will not reach the cumulative doses known to increase the risk of cardiotoxicity. If a patient has underlying cardiac dysfunction, baseline evaluation of ejection fraction through either an echocardiogram or a multigated acquisition scan should be completed.[56,58,59] Other known risk factors for the development of anthracycline-induced cardiotoxicity include age older than 70 years, hypertension, preexisting coronary artery disease, and previous cardiac irradiation or anthracycline exposure, which may warrant cardiac evaluation.[60,61]

Cyclophosphamide is an alkylating agent that works by forming cross-links in DNA, thus inhibiting DNA synthesis.[54] Common toxicities are nausea/vomiting, myelosuppression, and alopecia. The alkylating agents, although rare, are also associated with a risk of secondary leukemias.[54]

Paclitaxel, a taxane chemotherapy derived from the Pacific yew tree, works by binding to the β-tubulin subunit of microtubules, preventing disassembly and ultimately causing inhibition of mitosis. Common toxicities associated with paclitaxel include nausea/vomiting, myelosuppression, neuropathy, and hypersensitivity reactions due to the modified polyoxyethylated castor oil (Cremophor EL) solvent in paclitaxel. All patients should be premedicated with dexamethasone and H_1 and H_2 blockers to prevent hypersensitivity.[62]

Trastuzumab is a monoclonal antibody targeted against the extracellular HER2 protein. The classic toxicity associated with trastuzumab is cardiac toxicity, but is different from that with anthracyclines. Trastuzumab cardiotoxicity is considered reversible and believed to be a result of HER2 blockade (HER2 signaling is responsible for cardiomyocyte growth, repair, and survival).[60,61] In those patients who will receive long-term trastuzumab therapy, baseline cardiac function should be evaluated similar to doxorubicin and then periodically with echocardiogram or a multigated acquisition scan during therapy. C.D. does not have a history of cardiac disease, so a baseline cardiac evaluation before AC therapy may not occur. C.D. should be counseled on the common toxicities associated with her chemotherapy, such as myelosuppression, nausea/vomiting, alopecia, neuropathy, cardiomyopathy, and hypersensitivity reactions.

HORMONAL THERAPY

CASE 97-3, QUESTION 9: After the completion of her adjuvant chemotherapy, C.D. will receive hormonal therapy because her disease is ER/PR-positive. What are the common adjuvant hormonal regimens used? What regimen would be appropriate for C.D.?

Breast cancer is a hormonally mediated disease, and therapies that alter hormonal levels are an integral component to the treatment plan. This therapy is offered to patients with ER- and/or PR-positive disease. Therapeutic options include SERMs, luteinizing hormone-releasing hormone (LH-RH) agonists, and AIs. Menopausal status of the patient is used to help guide selection of therapy.

Traditionally, tamoxifen has been the gold standard for adjuvant hormonal therapy. Tamoxifen is a SERM, which works by blocking estrogen from binding to the ER. It does not alter estrogen production. Tamoxifen has antiestrogenic activity in the breast, although it has estrogenic effects in other areas such as bone.[63,64] Tamoxifen can be used in both premenopausal and postmenopausal women and is given 20 mg orally daily for 5 years based on the data from the National Surgical Adjuvant Breast and Bowel Project B-14 trial.[65] Tamoxifen should be initiated after chemotherapy because it can antagonize the antitumor activity of chemotherapy if given concurrently.[66] Common toxicities associated with therapy are hot flashes and vaginal discharge. More thrombosis, pulmonary embolisms, and strokes can occur in patients (older than 50 years of age) receiving tamoxifen compared to placebo (risk ratio, 1.60, 3.19, 1.59, respectively).[11]

Ovarian suppression is an alternative therapy for premenopausal patients because the ovaries are the largest source of estrogen. This is typically achieved through the use of LH-RH agonists. Surgery or radiation can also induce ovarian ablation; however, surgery is irreversible and offers an immediate effect whereas radiation may offer an incomplete response and slower onset.[67] If a woman would like to maintain fertility throughout chemotherapy, a thorough discussion with her physician should occur. Studies with the use of LH-RH agents have been tested as a means to preserve fertility but have shown mixed results.[68] Combination data with an LH-RH agonist with tamoxifen have not shown significantly better outcomes than each modality alone.[68,69]

Postmenopausal patients also have the option of AI therapy. Aromatase inhibitors inhibit the production of estrogen by preventing the conversion of androstenedione and testosterone to estrone and estradiol. There are two classes of agents: nonsteroidal AIs (anastrozole and letrozole) and the steroidal AI, exemestane. These agents are highly selective for the aromatase enzyme and have less toxicity than tamoxifen and other hormonal agents. Aromatase inhibitors should only be used in postmenopausal women. If used in the premenopausal setting, initial surges of estrogen occur due to the body's compensation mechanisms (i.e., hypothalamic–pituitary axis) and negative feedback loop. Table 97-5 provides a list of adjuvant hormonal therapies that can be used. If used as single therapy, AIs are given for 5 years.

The optimal hormonal therapy regimen for the adjuvant setting has not been identified. In premenopausal women, the options are 5 years of tamoxifen therapy plus or minus ovarian suppression with an LH-RH agonist. If the patient continues to be premenopausal at the end of 5 years of adjuvant tamoxifen therapy, the patient may consider five additional years of therapy. There are conflicting data to support this recommendation. Based on newer data, the American Society of Clinical Oncology published an updated practice guideline for adjuvant hormonal therapy.[70–72]

If, after 2 to 3 years, the patient becomes postmenopausal, then 2 to 3 years of an AI may be given to complete a total of 5 years of therapy. If the patient is postmenopausal at the beginning of adjuvant hormonal therapy, an option would be to take an AI for 5 years. There have been no prospective comparisons of the AIs with each other; therefore, any can be used as first-line treatment.[73,74] Another clinical option is 5 years of tamoxifen, and, if the patient is postmenopausal after the end of 5 years, an additional 5 years of an AI can be given. This was found to be beneficial in an extended study of hormonal therapy (the BIG 1–98 trial). At the 2.4-year follow-up, additional letrozole therapy was associated with a superior 4-year disease-free survival (93% with extended letrozole vs. 87% in the tamoxifen arm; $p < 0.001$).[75] However, in the 8.1-year follow-up data, the additional letrozole therapy did not improve outcomes compared with letrozole monotherapy in terms of disease-free and overall survival.[76] Each individual's length of therapy should be determined based on the patient's risk of recurrence and their ability to tolerate therapy. Table 97-6 lists adjuvant hormonal therapy options.

Table 97-5

Adjuvant Hormonal Therapies

Type	Dose	Toxicities
Nonsteroidal		
Anastrozole Letrozole	1 mg daily PO 2.5 mg daily PO	Common toxicities: myalgias/arthralgias, hot flashes, osteoporosis
Steroidal		
Exemestane	25 mg daily PO	Common toxicities: myalgias/arthralgias, hot flashes, osteoporosis
SERMs		
Tamoxifen	20 mg daily PO	Common toxicities: hot flashes, vaginal discharge Rare but serious side effects: deep vein thrombosis, pulmonary embolism, abnormal uterine bleeding

Source: Jones KL, Buzdar AU. A review of adjuvant hormonal therapy in breast cancer. Endocr Relat Cancer. 2004;11:391; Buzdar AU, Howell A. Advances in aromatase inhibitors: clinical efficacy and tolerability in the treatment of breast cancer. Clin Cancer Res. 2001;7:2620.

C.D. is premenopausal, so she would start with tamoxifen therapy. If after 2 to 3 years of therapy, C.D. becomes postmenopausal, she could continue the tamoxifen for a total of 5 years or convert to an AI to complete a total of 5 years of therapy then continuing the AI for an additional 5 years. Because of her age, she will likely continue to be premenopausal after chemotherapy and be maintained on tamoxifen for 5 years. If she remains premenopausal, she should have a discussion with her physician on the merits of continuing tamoxifen for a total of 10 years. If she completes 5 years of tamoxifen therapy and is postmenopausal at that time, then extended use of an AI for an additional 5 years would be recommended. At this time, ovarian suppression with an LH-RH agonist could also be added because she is premenopausal to chemically suppress her ovarian function.

METASTATIC BREAST CANCER

Treatment—Endocrine Therapy

CASE 97-4

QUESTION 1: T.R. is a 65-year-old, postmenopausal woman diagnosed with breast cancer at the age of 48 years. At the time of diagnosis she was premenopausal. She underwent surgery with a modified radical mastectomy and was found to have a 1.5-cm IDC of the right breast. She had 2 of 10 lymph nodes positive. Her breast cancer was ER-positive, PR-positive and HER2-negative. T.R. went on to complete adjuvant chemotherapy with AC therapy for four cycles followed by weekly paclitaxel for 12 weeks. After completion of her chemotherapy, she received 5 years of tamoxifen therapy. Ten years after completing her therapy, she experiences pain in her right arm and rib cage. A bone scan revealed metastatic breast cancer. What would be an appropriate treatment regimen for T.R. at this time?

Early-stage breast cancer is curable. However, if a patient develops metastatic disease, the goal of treatment shifts from cure to palliation and stabilization of disease. Treatment is offered to improve quality of life and alleviate symptoms from treatment or disease. The mean survival time after diagnosis of metastatic disease is approximately 2 to 4 years; however, this can range from months to many years depending on the site of the metastases.[77] The choice of therapy is based on the site of disease and other factors that help guide therapy such as ER and PR status. Endocrine therapy is more likely to be effective in patients with bone-only disease whereas chemotherapy may be used when there is visceral disease (i.e., liver or lung). Patients with organ involvement tend to have more rapidly growing disease that generally requires therapy with a quicker onset of action such as chemotherapy.[25] In addition to systemic therapy (chemotherapy and/or hormonal and/or biologic therapy), the clinician needs to determine whether or not local therapy (such as radiation or surgery) would be appropriate for a patient. Radiation therapy can be used to target painful bone metastases, to prevent further tumor growth, and to relieve pain. Surgery may be performed on bones with impending fractures, spinal cord compression, or brain metastases for palliation. These modalities of treatment only affect the local site of disease, so a combination of local and systemic therapy would need to be administered to fully treat the patient. If a patient is experiencing worsening symptoms such as shortness of breath due to lung metastases or increased abdominal pain due to liver metastases, the use of chemotherapy may be preferred over hormonal therapy because of its quicker onset of action.[78] Disease recurrence greater than 5 years after diagnosis illustrates a more indolent-growing disease and is a favorable prognostic factor. Tumors with ER- and/or PR-positive characteristics would also be considered a good prognostic factor. Once therapy is initiated, response to therapy should be monitored periodically. Tumor markers such as CA.27.29 and CA.15.3 are commonly monitored in metastatic breast cancer. A clinical examination in combination with radiologic tests and tumor markers is assessed to determine response to therapy. Based on T.R.'s metastatic bone disease and ER/PR-positive tumor characteristics, the use of hormonal therapy would be the most appropriate agent to initiate. T.R. received tamoxifen therapy in the adjuvant setting. Because she progressed after taking tamoxifen therapy, this would not be reinitiated. An AI would be started because she is postmenopausal and should be continued until there is evidence of progression of disease via radiologic findings or increases in tumor markers.

Table 97-6

Overview of Adjuvant Hormonal Therapy

Option 1	**Option 2**	**Option 3**
Premenopausal at time of therapy initiation (Patients can complete one of 3 different options)		
Tamoxifen × 5 years ± LH-RH agonist or ovarian ablation	If still premenopausal after 2–3 years of tamoxifen therapy, complete a total of 5 years of tamoxifen	If still premenopausal after 5 years of tamoxifen, consider an additional 5 years of tamoxifen
	If postmenopausal after 2–3 years: **A.** Complete 5 years of tamoxifen followed by 5 additional years of an AI OR **B**. Convert to an AI × 2–3 years for a total of 5 years of hormonal therapy	If postmenopausal after 5 years of therapy, give AI × 5 additional years
Postmenopausal at time of therapy initiation (Preferred to start with an AI if the patient is postmenopausal at the onset of therapy)		
Any AI × 5 years	Tamoxifen × 2–3 years then an AI to complete a total of 5 years	Tamoxifen × 4–6 years then an AI for 5 additional years

AI, aromatase inhibitor; LH-RH, luteinizing hormone-releasing hormone.

CASE 97-4, QUESTION 2: T.R. is started on anastrozole 1 mg orally daily. What are other hormonal agents that can be used in the treatment of metastatic breast cancer?

Hormonal therapy in the metastatic setting can provide long progression-free survival in patients. If the patient responds for an extended period of time, the likelihood of response to another hormonal agent is high.[74] A patient may take multiple hormonal therapies before ever having to receive chemotherapy. As before, the decision regarding which hormonal agent to use is based on one's menopausal status. If the patient is premenopausal, the options include tamoxifen and LH-RH agonists; however, if the patient has received a SERM in the adjuvant setting, this would not be used again in the metastatic setting. Aromatase inhibitors are indicated for use in first-line therapy in the metastatic setting for postmenopausal women. If an AI is chosen as the first-line agent in the metastatic setting, use of another AI after progression would include one from another category (i.e., nonsteroidal vs. steroidal AI). For example, if anastrozole was used as first-line therapy for metastatic disease, then when the patient progresses, exemestane can be used.

Many other hormonal agents are available for use. The pure antiestrogen, fulvestrant, is the only drug in a unique category of agents. It exerts its mechanism via binding and blocking of the ER and downregulates the number of ER s. Fulvestrant is administered as an intramuscular injection and is dosed initially as 500 mg on days 1, 14, and 28, then 500 mg monthly.[79,80] It is approved for use after failure of tamoxifen therapy in the metastatic setting.[79] This is an alternative for patients with compliance issues due to its once-monthly intramuscular dosing. Other hormonal agents used in metastatic disease are megestrol acetate, progestins, and high-dose estrogens (higher doses have been found to inhibit cancer cell growth). These agents were used routinely before the approval of AIs. Now they are reserved for use after multiple hormonal therapy failures due to the toxicities associated with these therapies such as weight gain, vaginal bleeding, and thromboembolic events.[25]

Newer data have evaluated a class a drugs called the mTOR (mammalian target of rapamycin) inhibitors.[81] These agents have demonstrated the ability to block resistance pathways of endocrine therapy. In the BOLERO-2 trial, patients who had failed previous AI therapy were randomized to everolimus 10 mg orally daily plus exemestane 25 mg orally daily versus exemestane plus placebo.[82] Progression-free survival was statistically significantly better in the combination arm, but follow-up overall survival results did not demonstrate the same results.[82] FDA approval was granted to this combination therapy in the metastatic setting after patients have failed a nonsteroidal AI.

Another new class of agents just recently approved in the first-line metastatic setting for HER2-negative, ER-positive patients is the cyclin-dependent kinase (CDK) inhibitors. Palbociclib, in combination with letrozole, was found to increase PFS in the phase II, Paloma-1 trial.[83] Overall survival has yet to be determined, and a large phase III trial is currently underway. This agent targets the inhibition of CDK 4 and 6 and inhibits cell growth and division. Serious side effects identified included neutropenia, pulmonary embolism (3 patients), back pain (2 patients), and diarrhea (2 patients).[83] T.R. was started on anastrozole therapy. She could have been initiated on any of the AIs. If her disease progresses, options include sequential exemestane, exemestane plus everolimus, fulvestrant, and then other agents such as megestrol acetate, high-dose estrogens, or androgens. The goal is to continue T.R. on multiple lines of hormonal therapy (as long as she is responding) before administering chemotherapy.

Prevention of Skeletal Events

CASE 97-4, QUESTION 3: In addition to anastrozole therapy, what other supportive care medicines should be added to T.R.'s regimen?

Patients with bone metastases are commonly treated with bisphosphonate therapy to decrease the risk of skeletal-related events (i.e., pathologic fractures, spinal cord compression, need for surgery, or radiation to the bone). Bisphosphonates act by inhibiting bone resorption. This ultimately will halt osteoclastic activity leading to stabilization of bony involvement, prevention of fractures, and reduction in calcium levels.[84,85] Bisphosphonates used are pamidronate 90 mg intravenously (IV) for 2 hours or zoledronic acid 4 mg IV for 15 minutes. Either of these agents can be administered once a month. Bisphosphonates are typically well tolerated although they may cause nausea, increased bone pain, and fever. Reduced doses should be used in patients with underlying renal dysfunction. A more well-known but uncommon side effect is osteonecrosis of the jaw.[86] The mechanism by which this occurs is not fully understood, but prevention is critical. If dental extractions or surgery is needed, patients should not be initiated on bisphosphonate therapy until these procedures are completed. If these procedures are required after initiation of therapy, an oral maxillofacial surgeon should be consulted.

A more recently approved agent for use in the prevention of skeletal-related events in solid tumors is the humanized monoclonal

---

antibody, denosumab. This therapy offers a unique mechanism of action, targeting the RANK ligand, which is a mediator in osteoclast activity. Inhibition of osteoclastic activity by denosumab reduces bone pathology in osseous metastases. Denosumab has been compared prospectively with zoledronic acid in metastatic breast cancer patients and demonstrated significant delays in and prevention of skeletal-related events.[87] Denosumab is administered as a subcutaneous injection and is given once a month. It has similar toxicities to zoledronic acid, but the dose does not require adjustments for declining renal function. Denosumab has been added to the American Society of Clinical Oncology guidelines for the prevention of skeletal events in metastatic breast cancer and other solid tumors.[88] T.R. can start on bisphosphonate therapy with zoledronic acid 4 mg IV or denosumab 120 mcg SC once a month to help prevent skeletal-related events.

Progression of Disease

CASE 97-4, QUESTION 4: T.R. has a long progression-free survival on hormonal therapy. Over the course of 4 years, she progresses on sequential anastrozole, then fulvestrant, then exemestane plus everolimus, and eventually, megestrol acetate. Each time she has progressed, the progression-free interval has shortened. Follow-up staging tests now reveal new liver lesions measuring 1 cm × 1 cm and 2 cm × 1 cm. A CT scan of the chest was negative. She is not currently experiencing any symptoms of her disease. What should the treatment course include now that T.R. has progressed after numerous lines of endocrine therapy?

Because T.R. has progressed through multiple lines of hormonal therapy and the progression-free interval has shortened with each treatment course, chemotherapy would now likely be the best option. Patients with a good performance status, little previous treatment, prolonged progression-free intervals, and limited metastatic disease are more likely to respond to further treatment with chemotherapy.[78] Chemotherapy is continued as long as the person is receiving benefit and is tolerating toxicities associated with treatment. If the disease progresses or the toxicities become intolerable, therapy should be changed or stopped. Patients experiencing toxicities may be placed on a chemotherapy holiday until toxicities are resolved or until therapy is tolerable.

In the metastatic setting, stabilization of disease and palliation of symptoms are considered when deciding what chemotherapy regimen to use. Sequential (single agent) versus combination chemotherapy should be discussed. Combination chemotherapy is generally associated with more toxicities than sequential treatment; however, it provides improved response rates.[25,89–91] Patients with substantial symptoms from their disease may initially be given combination therapy to rapidly shrink the tumor. Combination therapies that have demonstrated improvements in survival are docetaxel and capecitabine, paclitaxel and gemcitabine, and doxorubicin and paclitaxel. Based on T.R.'s lack of symptoms, sequential therapy would be the best option for her at this time. This would offer her less toxicity and reserve other chemotherapeutic agents for the future.

Chemotherapy decisions can be very complex. There is no one standard regimen, and decisions should be made on an individual basis based on the patient's prior treatment, concurrent comorbidities, and time from adjuvant therapy to metastatic disease.

Most individuals today will have received anthracycline and taxane chemotherapy in the adjuvant setting. If the patient's disease recurs quickly after adjuvant therapy (i.e., less than one year), the disease is considered resistant to that treatment and different agents should be selected. If a patient receives adjuvant paclitaxel and progresses on therapy, there are data to support the use of docetaxel in the treatment of metastatic disease because of the lack of cross-resistance between taxanes.[92,93] Other chemotherapeutic agents with mechanisms similar to taxanes, such as eribulin or ixabepilone, have been approved for use in previous taxane failures. These agents offer additional options to patients who had responded to previous therapies.[25]

Previous toxicity is also considered when selecting therapy. In patients with preexisting neuropathies either from diabetes or previous chemotherapy, taxanes may not be an appropriate choice because these agents can also cause neuropathy. Additionally, capecitabine may be chosen over intravenous chemotherapy because this agent is administered orally. Table 97-7 provides a list of commonly used agents/regimens in the metastatic setting. Clinical trials are always an option for patients if they have a good performance status. Many clinical trials are available and should be discussed with the patient if clinical trials are a possibility. Because T.R. has received an anthracycline and taxane agent in the adjuvant setting, an agent such as capecitabine would be an appropriate choice. This is an oral agent and also has the indication for first-line treatment of metastatic disease after failure of anthracycline and taxane chemotherapy.

Table 97-7

Commonly Used Chemotherapy Agents in the Metastatic Setting

HER2-Negative	
Sequential or single agent	Doxorubicin, epirubicin, liposomal doxorubicin, paclitaxel, docetaxel, capecitabine, vinorelbine, gemcitabine, albumin-bound paclitaxel, eribulin, ixabepilone
Combination chemotherapy	FAC, CAF, FEC AC, EC, CMF, GT docetaxel/capecitabine, gemcitabine/carboplatin
HER2-Positive	
Chemotherapy + trastuzumab	Pertuzumab/trastuzumab/docetaxel, pertuzumab/trastuzumab/paclitaxel, paclitaxel/carboplatin, docetaxel, vinorelbine, capecitabine
If previously received trastuzumab	Lapatinib/capecitabine, trastuzumab + other first-line agents, trastuzumab/capecitabine, trastuzumab/lapatinib, ado-trastuzumab emtansine
Single-agent therapy used after failing standard options listed here	Cyclophosphamide, mitoxantrone, cisplatin, etoposide (oral), vinblastine, fluorouracil (continuous infusion), ixabepilone

A, doxorubicin; C, cyclophosphamide; E, epirubicin; F, fluorouracil; G, gemcitabine; H, trastuzumab; M, methotrexate; T, paclitaxel.

Biologic and Other Targeted Therapies

CASE 97-4, QUESTION 5: Would T.R. be a candidate for any biologic therapy for the treatment of her metastatic breast cancer if she was HER2-positive?

Trastuzumab revolutionized the treatment of HER2-positive breast cancer. Newer biologic therapies are also available for use in the metastatic setting. Trastuzumab is a fully humanized monoclonal antibody that binds to the extracellular HER2 receptor and works via antigen-dependent cellular cytotoxicity. When chemotherapy alone was compared with chemotherapy plus trastuzumab in HER2-positive metastatic breast cancer, the addition of trastuzumab therapy significantly increased survival.[49] This was the first study of its kind using biologic therapy and demonstrating survival benefit in metastatic breast cancer. Current practice is to continue the trastuzumab in patients who progress on a chemotherapy regimen but switch to an alternative chemotherapy agent.

As with all chemotherapeutic agents, breast cancer can become resistant to therapy. Trastuzumab provided significant improvement in overall survival for patients with HER2-positive disease; however, trastuzumab resistance occurs. Newer pathways and resistance patterns have been identified to help clinicians understand the complexity of this disease. Two therapies are now approved for use in HER2-positive patients.[94] Pertuzumab offers a novel mechanism of action for HER2-positive patients. This agent is a monoclonal antibody similar to trastuzumab but blocks the extracellular domain on the HER2 receptor and blocks ligand-dependent heterodimerization with HER1, HER3, and HER4. The binding is different from trastuzumab in that trastuzumab binds to domain IV while pertuzumab binds to domain II of the HER2 receptor. The CLEOPATRA trial evaluated pertuzumab in combination with docetaxel and trastuzumab versus docetaxel and trastuzumab and placebo for the first-line treatment of metastatic breast cancer.[95] At a median follow-up of 50 months, the pertuzumab arm demonstrated improved OS of 56.5 months versus 40.8 months in the docetaxel + trastuzumab arm (HR, 0.68; 95% CI, 0.56 to 0.84; $p < 0.001$).[95] Those treated with pertuzumab experienced more diarrhea, rash, mucosal inflammation, and febrile neutropenia. Pertuzumab is approved for use in the first-line metastatic setting and the neoadjuvant setting in combination with docetaxel and trastuzumab.

Because pertuzumab does target the HER2 receptor, there is a concern regarding cardiac toxicity associated with its use. In the cardiac assessment of the CLEOPATRA trial, the incidence of cardiac adverse events (all grades) was similar between arms: 16.4% versus 14.5% in the placebo arm and the pertuzumab arm, respectively. Most patients experienced asymptomatic decreases in left-ventricular ejection fraction which resolved upon removal of the drug.[95,96]

Ado-trastuzumab emtansine (also known as TDM-1) is a unique formulation of an antibody–drug conjugate: Trastuzumab linked to DM1, a maytansine derivative. Maytansine is a potent microtubular inhibitor. Once the drug binds to the HER2 receptor, it is internalized and then undergoes degradation, releasing the cytotoxic agent to induce apoptosis. This agent was approved based on the results from the EMILIA trial comparing ado-trastuzumab to capecitabine and lapatinib in patients who had failed previous taxanes and trastuzumab.[97] Ado-trastuzumab improved both PFS and OS. Common toxicities for this agent include peripheral neuropathy, fatigue, anemia, increased liver enzymes, and myelosuppression. As with other HER2-targeted therapies, the concern for cardiac toxicity was evaluated. Less cardiotoxicity was identified in the ado-trastuzumab group compared to the combination arm (1.8% vs. 3.3%, respectively). This drug's name is very similar to traditional trastuzumab and hence the FDA recommendation for the addition of the prefix ado- to the name.[98] The approved indication of this agent includes use in patients with HER2-positive metastatic breast cancer who have previously received trastuzumab and a taxane, separately or in combination.

Lapatinib was the second HER2 target agent approved after trastuzumab. It is an oral tyrosine kinase inhibitor (small molecule) that inhibits both the activity of HER2 and the epidermal growth factor receptor. Lapatinib received approval based on a study in which capecitabine was compared with capecitabine plus lapatinib.[99] This trial included patients whose disease had progressed during or after an anthracycline, taxane, and trastuzumab therapy. Time to progression was statistically significantly better with the combination therapy compared to capecitabine alone (HR, 0.46; 95% confidence interval, 0.34–0.71; $p < 0.001$).[99]

Toxicities commonly associated with lapatinib are diarrhea and rash. Concerns of cardiotoxicity associated with lapatinib have been closely monitored in these trials. Because one of the mechanisms of lapatinib is blockade of HER2 (like trastuzumab), there is concern regarding its cardiotoxicity potential. Currently, data do not demonstrate an increased risk of cardiac dysfunction with lapatinib; however, long-term data are needed.[100] Lapatinib's approved indications include use in combination with capecitabine or combined with letrozole therapy or in those who have failed prior anthracyclines, taxanes, and trastuzumab for metastatic breast cancer.

One concern with lapatinib is its inhibition of the cytochrome P-450 (CYP) 3A4 and 2C8 isoenzymes. Because of this, when a patient is initiated on therapy, a full review of medications should occur to ensure no drug–drug interactions. Recommendations are included in the package insert for use and dosing of lapatinib with CYP3A4 inhibitors and inducers.[101]

If TR had HER2-positive disease, a common first-line regimen to use in the metastatic setting would be pertuzumab, trastuzumab, in combination with docetaxel based from the data of the CLEOPATRA trial. Second-line therapy in those that are exposed to previous trastuzumab therapy could include ado-trastuzumab emtansine or lapatinib in combination with capecitabine therapy.

Other unique targeted therapies are being evaluated in metastatic breast cancer. Poly-ADP-ribose polymerase (PARP) inhibitors potentially offer unique activity for patients with triple-negative breast cancers (ER/PR/HER2-negative disease). These tumors are typically refractory to chemotherapy and difficult to treat. PARP is an enzyme that repairs DNA breaks and is overexpressed in triple-negative breast cancers. Hence, this class of investigational inhibitors is expected to enhance the activity for cytotoxic therapies such as DNA-damaging agents. Initial studies have been promising, and currently phase III trials are underway to evaluate the antitumor activity of PARP inhibitors in the metastatic setting.[102] Other agents in the pipeline are mTOR (mammalian target of rapamycin) inhibitors, HSP90 (heat shock protein 90) inhibitors, multitargeted inhibitors of vascular endothelial growth factor receptor, and platelet-derived growth factor as well as other monoclonal antibodies.[102]

Lung Cancer

Sara K. Butler

	CORE PRINCIPLES	CHAPTER CASES
1	Non-small-cell lung cancer (NSCLC) and small-cell lung cancer (SCLC) together account for more cancer-related deaths than any other malignancy for both men and women. Smoking is the biggest risk factor, and is proportional to the number of pack years. For former smokers, the risk for developing the disease decreases over time after smoking cessation.	**Case 98-1 (Question 1)**
2	Chances for survival are increased for those whose disease is detected early. The U.S. Preventive Services Task Force recommends annual screening with low-dose computed tomography in patients 55–80 years old with at least a 30-pack-year smoking history in current smokers or those who have quit within 15 years as this did increase detection and improve survival.	**Case 98-1 (Question 1),** **Table 98-3**
3	The initial signs and symptoms vary according to location and stage of the disease. Many patients are asymptomatic upon initial diagnosis, or signs and symptoms may be masked by other concurrent conditions such as chronic obstructive pulmonary disease.	**Case 98-1 (Question 2),** **Case 98-2 (Question 1),** **Table 98-1**
4	Surgery, radiotherapy, and chemotherapy are all modalities used in the treatment of NSCLC. Treatment decisions are individualized according to disease stage, tumor histology (e.g., adenocarcinoma, squamous), presence or absence of molecular marker mutations (e.g., epidermal growth factor receptor (EGFR), anaplastic lymphoma kinase (ALK)), performance status, comorbidities, and patient preference.	**Case 98-1 (Questions 2, 3),** **Case 98-2 (Questions 1–7),** **Tables 98-4–98-6**
5	Small-cell lung cancer tumors generally have a higher proliferation rate than NSCLC tumors. Hence, chemotherapy and radiotherapy are the primary treatments. These tumors tend to grow more centrally and rapidly than NSCLC tumors; therefore, surgical resection is usually not performed.	**Case 98-3 (Questions 1–4)**
6	Most NSCLC cytotoxic chemotherapy regimens are cisplatin-based or carboplatin-based doublets, which are given for 4–6 cycles. Maintenance therapy has been shown to be beneficial for patients receiving pemetrexed, bevacizumab, and erlotinib therapies. Targeted therapies are currently limited to the treatment of some late stage inoperable NSCLCs, but their use is under investigation for patients diagnosed with earlier stages of the disease.	**Case 98-1 (Question 4),** **Case 98-2 (Questions 1–3),** **Tables 98-4–98-6**

⑦ Most SCLC cytotoxic chemotherapy regimens are cisplatin-based or carboplatin-based doublets in combination with etoposide or sometimes irinotecan if extensive-stage disease. Investigations have not shown the utility for targeted agents in treating this disease.	**Case 98-3 (Questions 3–6)**

LUNG CANCER

Lung cancers may be referred to as non-small-cell lung cancer (NSCLC) or small-cell lung cancer (SCLC) and, although there are many similarities between these two, treatments will often differ. Approximately 85% of lung cancers are classified as NSCLC and the remaining are classified as SCLC.[1] This chapter will initially focus on the presentation, diagnosis, and treatment of NSCLC, followed by a shorter section that describes SCLC.

Non-Small-Cell Lung Cancer

EPIDEMIOLOGY

Incidence for NSCLC in the United States is second to prostate cancer in men and breast cancer for women. Lung cancer is the leading cause of death relative to all of the other cancers. As with most solid tumors, survival is better for patients diagnosed with early-stage disease than it is for those with more advanced disease.[2] However, for many patients, the disease often goes undetected either due to the lack of noticeable symptoms or because they may be masked by concurrent diseases with similar symptoms such as chronic obstructive pulmonary disease (COPD).

PATHOPHYSIOLOGY

Non-small-cell lung cancer tumorigenesis is a multistep process in which neoplastic tissue arises from bronchial epithelium. These cells, which form the inner lining of bronchial tissue, develop genetic lesions to proto-oncogenes and tumor suppressor genes, resulting in the dysregulation of key molecular signaling pathways. As a result, cellular proliferation occurs and responsiveness to apoptotic signaling is often diminished. Eventually, accumulation of additional genetic abnormalities can influence the cell's ability to metastasize, resulting in the spread of tumorous tissue locally or to more distant sites in the lymph nodes and organs.

Non-small-cell lung tumors are classified further according to tumor tissue histology. The three major histologic types include squamous cell carcinoma, adenocarcinoma, and large cell carcinomas. Although these different variants were identified several decades ago, recently it has been demonstrated that the histology impacts chemotherapeutic agent selection. These three may be subcategorized further and other variants of NSCLC also exist; however, discussion in this chapter will be limited to these three. The adenocarcinomas and large cell carcinomas are commonly grouped together as nonsquamous carcinomas. These tumors commonly arise in the periphery of the lung and the smaller airways. After various periods of growth in the lung parenchyma or bronchial wall, these primary tumors invade the vascular and lymphatic system, enabling metastases to regional lymph nodes and more distant sites.[1]

RISK FACTORS AND CLINICAL PRESENTATION

There are several risk factors for developing lung cancer, but the biggest factor is cigarette smoking, which is estimated to increase the risk by up to 30-fold. The prevalence of smoking peaked in the early 1960s and has steadily decreased in the United States due to increased awareness of the harm of smoking. Death rates from lung cancer in both men and women have also followed this downward trend. For men, deaths due to lung cancer peaked in the 1980s and has since steadily decreased. For women, deaths due to lung cancer began to decline in the mid-2000s. Other risk factors include secondhand smoke, cigar and pipe smoking, occupational and environmental exposures, radon, asbestos, certain metals such as chromium and cadmium, various organic chemicals, radiation, air pollution, history of tuberculosis, and genetic factors. The latter appears to be related to those who exhibit the disease early in life. The probability of developing invasive lung cancer increases with age and peaks during the seventh decade of life.[2–4]

Table 98-1

Common Selected Signs and Symptoms for Lung Cancer

Cough
Hemoptysis
Wheeze
Dyspnea
Pain (e.g., chest wall)
Obstruction of vital structures (e.g., esophagus, superior vena cava)

Symptoms are highly dependent on tumor size, location within the chest cavity, and presence of metastases.

The disease is detected either when a person presents with signs and symptoms commonly associated with lung cancer or by chance, when the patient is under evaluation for other disorders or procedures. Selected signs and symptoms are listed in Table 98-1, but vary widely between patients according to tumor size, stage, and location.

DIAGNOSIS

If a malignancy comes under consideration, a computed tomography (CT) or positron emission tomography (PET)-CT scan of the abdomen and thoracic region is usually performed to identify any possible primary lesions and to look for possible metastases to lymph nodes and other organs or contralateral lung. If located, a pathologic evaluation is performed to confirm the diagnosis. Magnetic resonance imaging (MRI) of the head may be ordered if brain metastases are suspected. Preoperatively, specimens may be obtained through methods such as bronchial brushings, bronchial washings, fine needle aspiration biopsy, core needle biopsy, endobronchial biopsy, and transbronchial biopsy. Mediastinal lymph nodes are also sampled via mediastinoscopy to determine staging. If surgery is performed, specimens are evaluated during the procedure to determine the resection margin status, diagnose incidental nodules discovered during surgery, and sampling of regional lymph nodes. Postoperative evaluation provides pathology characteristics necessary for classifying tumor type and staging.[1]

Staging is performed to determine prognosis and to guide treatment decision-making. In general, the prognosis declines with increasing disease stage at initial diagnosis. Five-year overall survival rates are 54% for patients with disease that is locally limited and 4% for metastatic disease. For all stages, 5-year overall survival has only marginally improved over the last 30 years to 18%. Unfortunately, the disease has already metastasized in greater than 50% of patients upon initial presentation. However, earlier detection with spiral CT is promising and has resulted in a decrease in disease-related death in patients with at least a 30-pack-year smoking history.[2,4] Staging classification is reliant on anatomic characteristics and was updated by the International Association for the Study of Lung Cancer (IASLC) and adopted by the American Joint Committee on Cancer staging in 2010. Even though clinicians are placing more importance on molecular markers such as epidermal growth factor receptor (EGFR) mutations and tumor histology, the revised system still relies strictly on the TNM system of staging and places an emphasis on tumor size.[5,6] Table 98-2[5–7] illustrates how the TNM classification is used to determine the clinical stage.

OVERVIEW OF TREATMENT

Surgery, radiation, and systemic therapy (i.e., cytotoxic chemotherapy and targeted therapy) are all treatment modalities used in the treatment of NSCLC. If caught in the early stages of the disease, surgery offers the best chance of cure. Chemotherapy is associated with enhanced survival depending on the stage of disease. The remaining discussion of NSCLC in this chapter will outline the key aspects in the treatment of early and late stages of the disease.

Table 98-2

Clinical Staging for Non-Small-Cell Lung Cancer[5–7]

Clinical Stage	Tumor Characteristics
Stage I	Tumor ≤5 cm in greatest diameter with no nodal involvement
Stage II	Tumor >5 cm, but ≤7 cm in greatest diameter with no nodal involvement Tumor ≤7 cm with adjacent lymph nodes involved Tumor >7 cm or invading local structure (i.e., chest wall) with no nodal involvement
Stage III	Any tumor size with adjacent lymph nodes involved or ipsilateral mediastinal and/or subcarinal lymph nodes Tumor invading mediastinum, heart, great vessels, esophagus, or another tumor nodule in different ipsilateral lobe
Stage IV	Any tumor size, any nodal involvement and metastasis to the contralateral lobe, malignant pleural effusions or distant metastasis

Early Stage Non-Small-Cell Lung Cancer

CASE 98-1

QUESTION 1: A 69-year-old male patient, J.W., was found to have a 3-cm nodule on a chest X-ray done prior to an elective cataract surgery. The patient was a lifelong cigarette smoker, having started smoking in his early 20s, approximately one pack of cigarettes per day. He quit smoking 9 years ago. What screening methods might be available to detect the disease in asymptomatic patients? What risk factors does J.W. have for lung cancer?

The National Lung Screening Trial (NLST) was a randomized study comparing low-dose CT scans with chest radiography in over 50,000 patients with a heavy smoking history, examining lung cancer mortality.[8,9] The NLST did result in a higher incidence of confirmed diagnoses of lung cancer with low-dose CT, resulting in a 20% relative reduction in the rate of death from lung cancer. However, low-dose CT scans did result in a higher rate of false positives than chest radiography.[10] The NLST did result in the U.S. Preventive Service Task Force making a recommendation of annual screening for lung cancer with low-dose CT scans in adults 55 to 80 years old with a 30-pack-year smoking history and currently smoke or have quit within the last 15 years.[11]

The probability for developing the disease increases with age, and J.W.'s age is close to the median age of peak incidence. Men also have a slightly higher risk than women as discussed previously. Smoking is the largest risk factor for lung cancer development; however, what if a person stops smoking? Does the risk decrease with time? These questions are important for healthcare providers to address whether they are encouraging smoking cessation for their patients. In J.W.'s case, he stopped 9 years ago, so what impact would this smoking history have on development of the disease? In general, people who stop smoking, even well into middle age, avoid almost 90% of the risk attributable to tobacco. Shown in Table 98-3 are data demonstrating the relation between the age at which a person stops smoking and the cumulative percent risk (at age 75) for developing lung cancer.[12] J.W. stopped when he was approximately 60 years old; therefore, based on this table, the cumulative risk would approach 10% if he were 75 years old. Because he is 69 years old, his risk would be decreased but not to the extent that it would if a longer period of time had elapsed. If he were still smoking the risk would be expected to be closer to 16%. Hence, smoking cessation is an effective means for lowering the risk over time. He smoked for approximately 35 to 40 pack-years, so the total number of cigarettes would also increase his risk. According to data from the same studies, risk of disease for a one pack per day smoker would be approximately twice that of someone who smoked less than a half pack per day. Survival from the disease is also better for nonsmokers than for smokers.[12,13]

Table 98-3

Cumulative Risk (%) of Death from Lung Cancer at Age 75 Years

Smoking Status	Risk at Age 75
Lifelong nonsmoker	<1
Stopped at age 30	<2
Stopped at age 40	3
Stopped at age 50	6
Stopped at age 60	10
Continuing smoker	16

Frequently, patients will experience remorsefulness for having smoked, but it is never possible to attribute one’s disease to a single factor such as smoking. In fact, 90% of smokers never exhibit the disease. Furthermore, 15% of men and 53% of all women with lung cancer worldwide are never smokers.[14] This suggests that other factors such as genetics are associated with the development of the disease. Research has been directed at identifying genomic associated factors that have the potential to lead to the development of lung cancer in both smokers and nonsmokers. It has been shown that there can be some genetic associations, but the true impact of these genetic polymorphisms has not been fully elucidated.[3,15–18]

A more thorough history from J.W. would be helpful but recall for exposure to pollution, chemicals, and secondhand smoke exposure is difficult to quantify. Hence, the view held by much of society that lung cancer is a self-inflicted disease is not entirely true. In summary, there is limited history on J.W.’s exposure to environmental hazards such as radon and secondhand smoke. His age is close to that of peak incidence. Although he stopped smoking almost a decade ago, there is still some residual risk associated with past smoking history, and this would be expected to be higher for those with many pack-years history. Due to his heavy smoking history, J.W. may have benefited from low-dose CT scan screening to potentially provide earlier detection of lung cancer.

CASE 98-1, QUESTION 2: A CT scan was ordered for further evaluation and it showed an isolated spiculated nodule in the right upper lobe with no mediastinal or hilar adenopathy. The nodule showed no calcification. A CT-guided needle biopsy was performed which showed a well-differentiated adenocarcinoma consistent with a primary NSCLC. Further staging was carried out with PET scanning that demonstrated no additional areas of disease except for the nodule. What would be the best treatment plan for J.W., given the current information? Would surgery or neoadjuvant therapy be indicated?

The goals of therapy for this patient are to achieve a cure, especially since the disease appears to be in the early stage. Surgery is the best treatment modality for patients with stages I and II disease because these tumors are limited to one hemithorax and can be readily removed by excision. In most instances, lobectomy with node dissection is sufficient for local control. During surgery, the nodes would be sampled for presence of the disease and to confirm staging. J.W. appears to have limited disease, and so lobectomy would be recommended for him. For patients whose primary tumor or lymph node involvement extends to the proximal bronchus or proximal pulmonary artery, or crosses the major fissure, then a more extensive pneumonectomy is performed. Therefore, surgery is the treatment of choice, and final staging during surgery will guide further adjunct treatments. The tumors can often spread to mediastinal lymph nodes and for those patients (stage IIIA), then neoadjuvant chemotherapy can be recommended to reduce the tumor burden prior to surgery. If neoadjuvant therapy is chosen, the regimen is usually similar to those used in the adjuvant setting (Table 98-4).[19–24] Therefore, surgery is the primary treatment modality for patients with stages I, II, and early stage III disease. J.W.'s disease appears to be localized; therefore, surgical removal of the tumor would be indicated, and neoadjuvant chemotherapy would not be indicated because there does not appear to be disease in the mediastinum.[7]

CASE 98-1, QUESTION 3: J.W. was referred to a thoracic surgeon for resection. A right upper lobe lobectomy was performed with lymph node dissection. The pathology report revealed a 3.2 × 4 cm adenocarcinoma with three associated peribronchial lymph nodes containing cancer cells. Lymph nodes sampled from the mediastinum demonstrated no cancer. The patient's tumor was staged as a T2N1M0 (stage IIA) NSCLC. Now that the tumor is removed and staging of the disease is finalized, what additional therapy, if any, is recommended?

Although NSCLC tumors are minimally responsive to chemotherapy, evidence from several studies (Table 98-4) demonstrates that adjuvant treatment enhances patient survival, and therefore should be considered as part of the treatment plan for the patient. Though adjuvant treatment is often recommended, results from two other studies indicate that adjuvant treatment is not always effective.[25] This suggests that there is a need to identify subsets of patients who would likely benefit from treatment, and one group that does not seem to gain benefit are those with stage I disease. In the CALGB 9633 study, patients were randomly assigned to receive carboplatin and paclitaxel or placebo and a survival benefit was observed for those receiving chemotherapy. However, this survival was not uniform across the entire cohort. Subgroup analysis showed that adjuvant chemotherapy should not be considered standard of care for patients with stage IB disease unless the tumor size is greater than 4 cm. Collectively, these studies show that patients with stages II and IIIA disease gain the most benefit from adjuvant chemotherapy.[23] As summarized in Table 98-4, this chemotherapy usually includes cisplatin or, if the patient is unable to tolerate it, then carboplatin. A second agent, usually selected from one of those listed in Table 98-4, is added as doublet therapy, and the goal is for patients to receive four cycles. Toxicity often becomes worse beyond four cycles and benefits are diminished thereafter. Therefore, cytotoxic chemotherapy is beneficial but has its limitations.

Radiation therapy is frequently used in the treatment of malignancies including later stages of NSCLC; however, it has no proven benefit for the treatment of early-stage disease. The PORT Group conducted a meta-analysis from nine randomized trials to evaluate the possible role of postoperative radiotherapy in patients with completely resected NSCLC. There were 707 deaths among 1,056 patients assigned postoperative radiotherapy and 661 among 1,072 assigned surgery alone (hazard ratio, 1.21 [95% confidence interval, 1.08–1.34]). This 21% relative increase in the risk of death with radiotherapy is equivalent to a reduction in overall survival from 55% to 48%. Subgroup analysis showed that the increased risk of death was greatest for patients with stage I/II, N0 or N1, but no clear evidence for those with stage III, N2 disease.[26] Separately, another postoperative radiotherapy study was conducted, using data from 7,465 patients in the Surveillance, Epidemiology, and End Results (SEER) database. The investigators for this study also found no benefit for radiotherapy, especially for patients with N1 and N0 nodal disease. However, an increase in survival was associated with radiotherapy for patients who had N2 nodal disease.[27] Consequently, radiation therapy is reserved for patients with more advanced NSCLC. In summary, adjuvant cytotoxic chemotherapy is recommended for all patients found to have stage II or III NSCLC at surgery, as well as for larger (>4 cm) tumors. Multiple prospective phase 3 studies have shown that platinum-based chemotherapy after surgery will increase the survival rate of patients after surgery by about 10%. Because J.W. has stage IIA disease, four cycles of a platinum-based doublet regimen would be indicated after surgery; however, he should not receive radiotherapy at this time.

Table 98-4

Adjuvant Chemotherapy Regimens for Non-Small-Cell Lung Cancer

Regimen	Schedule
Cisplatin, days 1 and 8	Every 28 days for 4 cycles[20]

Vinorelbine, days 1, 8, 15, 22	
Cisplatin, day 1 Vinorelbine, days 1, 8, 15, 22	Every 28 days for 4 cycles[21,22]
Cisplatin, day 1 Vinorelbine, days 1, 8	Every 21 days for 4 cycles[20]
Cisplatin, day 1 Etoposide, days 1–3	Every 28 days for 4 cycles[22]
Cisplatin, days 1, 22, 43, 64 Vinblastine, days 1, 8, 15, 22, then every 2 weeks after day 43	Every 21 days for 4 cycles[22]
Paclitaxel, day 1 Carboplatin, day 1	Every 21 days[23]
Other Acceptable Regimens	
Cisplatin, day 1 Gemcitabine, days 1, 8	Every 21 days[7]
Cisplatin, day 1 Docetaxel, day 1	Every 21 days[24]
Pemetrexed, day 1 Cisplatin, day 1 *nonsquamous etiology	Every 21 days for 4 cycles[7]

NSCLC, non-small-cell lung cancer.

Late Stage Non-Small-Cell Lung Cancer

CASE 98-2

QUESTION 1: L.L., an 85-year-old woman, presented with a mild cough, productive with nonbloody sputum, shortness of breath, and fever. She was initially seen by primary care physicians who treated her with antibiotics for possible pneumonia; however, the radiogram of the chest showed a persisting infiltrate in the left upper lung. This was later confirmed on a CT scan with the presence of a 6 × 3 × 3.6 cm mass in the left upper lobe. Mediastinal adenopathy and multiple pulmonary nodules were seen in the right upper lobe with associated scarring, the largest of them measuring 14 × 9 mm in the right upper lobe anteriorly. Transbronchial biopsy led to a diagnosis of adenocarcinoma. Because of the spread of disease to the contralateral lung, disease was staged as IV. Pertinent patient history included hypertension and hyperlipidemia. The patient also had a hemangioma of the brain resected in 1950 and a history of cervical cancer treated with an abdominal hysterectomy in 1952. She has never smoked. Upon evaluation, she was found to have a hemoglobin that was slightly low at 11.3 g/dL with a white blood cell count of 5,200 cells/μL and a platelet count of 245,000/μL. The electrolytes showed normal sodium of 143 mEq/L, normal potassium of 4.4 mEq/L, and creatinine of 1.08 mg/dL, with estimated creatinine clearance of 48 mL/minute. Her performance status was 0–1. What are the treatment options for patients such as L.L. with advanced (stages IIIB and IV) disease?

SURGERY

In general, tumors in patients with stages IIIB and IV disease are inoperable. These tumors often invade the carina, great vessels, vertebral bodies, more distant lymph nodes, metastases, and are frequently associated with malignant pleural effusions. Hence, combined-modality treatments such as cytotoxic chemotherapy and radiation are the preferred treatments for patients with advanced-stage disease.[28,29] Surgery to remove solitary metastatic sites may also be considered in selected patients, especially in patients with a solitary brain metastasis.[30]

RADIATION

Radiotherapy is the primary local treatment (i.e., definitive radiotherapy) for inoperable nonmetastatic NSCLC and is also used as a palliative modality for patients with incurable disease with symptoms such as pain or shortness of breath. For tumors classified as stage III, radiotherapy is often given concurrently with chemotherapy, as this has been shown to be superior to both radiation alone and also sequential radiation followed by chemotherapy.[7] The radiation dose, in combination with chemotherapy, usually ranges between 60 and 65 Gray (Gy), given in 2-Gy fractions. The recommended chemotherapy regimen for stage III disease with radiation is either cisplatin and etoposide or carboplatin and paclitaxel. If the patient has adenocarcinoma, then pemetrexed may be substituted for the etoposide or paclitaxel.[31–36] See Table 98-5 for specific chemoradiation regimens. Metastases may also be treated locally with radiotherapy. For example, brain metastases, spinal cord compression, and impending fractures of weight-bearing bones can be treated with radiation or surgery before systemic therapy commences. In contrast to patients with stage III disease, those with stage IV disease usually receive local treatment with radiotherapy, either before or after chemotherapy, because therapy given concurrently is often not well tolerated by patients with this stage of disease.

CHEMOTHERAPY

Patients with advanced disease and good performance status usually benefit from chemotherapy. Similar to early-stage disease, these tumors often respond to treatment with platinum-based doublet cytotoxic combination therapy, which refers to treatment with either cisplatin or carboplatin plus a second cytotoxic agent.[37–46]

Non-small-cell lung cancer was treated as a single disease despite recognition of its histologic and molecular heterogeneity, but recent clinical trials demonstrate that histology is an important factor for individualizing treatment based on either safety or efficacy outcomes. Hence, once the biopsy is obtained, it is crucial to differentiate the histologic subtype (i.e., squamous vs. nonsquamous). The role of histology in the management of advanced NSCLC is reviewed more extensively elsewhere.[37] In developed countries, an increasing incidence of adenocarcinoma and a decline in squamous cell carcinomas have been observed in recent years. This appears to be correlated to declines in smoking rates. Many agents are effective against all histologic types such as cisplatin, carboplatin, gemcitabine, and paclitaxel. However, other agents such as bevacizumab and pemetrexed are only indicated for use in patients who have the nonsquamous histology (see Table 98-6). Squamous cell histology is associated with increased risk for severe pulmonary hemorrhage compared with adenocarcinoma.[45] For pemetrexed, significant association between improved efficacy and the nonsquamous subtype has been reported.[47,48]

Table 98-5

Representative Chemoradiation Regimens for Inoperable Stage III Non-Small-Cell Lung Cancer

Regimen	Schedule
Cisplatin, days 1, 8, 29 and 36 Etoposide days 1–5, 29–33	Concurrent radiation of 45 Gy administered in 25 daily 1.8 Gy fractions over 5 weeks[31,32]
Cisplatin days 1 and 29 Vinblastine weekly × 5 doses	Concurrent radiation of 45 Gy administered in 25 daily 1.8 Gy fractions over 5 weeks[33]
Carboplatin AUC 5 on day 1 Pemetrexed on day 1 *nonsquamous etiology	Every 21 days for 4 cycles[34] Concurrent radiation of 70 Gy administered in 35 daily 2 Gy fractions over 7 weeks
Cisplatin on day 1 Pemetrexed on day 1 *nonsquamous etiology	Every 21 days for 3 cycles[35] Concurrent radiation of 66 Gy in 33 daily 2 Gy fractions over 6.5 weeks
Paclitaxel weekly for 7 weeks Carboplatin AUC 2 weekly for 7 weeks followed by Paclitaxel day 1 and carboplatin day 1	Concurrent radiation of 63 Gy in 34 daily 1.8 Gy fractions over 7 weeks Followed by consolidative chemotherapy every 21 days for 2 cycles[36]

Characterization of advanced NSCLC tumors at the molecular level has also become part of clinical practice. It is recommended that tumor tissues from patients with nonsquamous histology tumors should be analyzed for the presence of EGFR and ALK mutation status.[7] Tumors that are positive for EGFR somatic mutations are often more responsive to erlotinib therapy and have become the standard front-line treatment over cytotoxic chemotherapy.[49] This analysis is limited to patients with stages IIIB or IV disease, because erlotinib has not been proven to be beneficial in patients with earlier stage disease and EGFR mutations.[50] For the advanced disease setting, therefore, treatment decisions are becoming more individualized on the basis of tumor histology and somatic mutations. As more targeted therapies, designed to inhibit other targets, are approved, it is likely that their use will be based upon at least some of these same principles.

Patients who respond to treatment or achieve stable disease after four to six cycles may be given maintenance therapy. The intention of such additional treatment would be to prolong the response and survival made possible by first-line treatment, while minimizing the chances for toxicity associated with platinum-based doublet regimens. Maintenance therapy differs from second-line therapy in that second-line treatment is only used when the patient has progressed during or after first-line treatment or is unable to tolerate it. Maintenance may be given as continuation maintenance, which refers to the use of one of the agents given in first line. Often, biologic agents that were given as part of the first-line regimen (e.g., bevacizumab or cetuximab) are continued due to their better tolerability relative to the cytotoxic agents.[44,51] For adenocarcinoma, pemetrexed should be given as continuation maintenance treatment due to an improved overall survival compared to placebo.[52] Alternatively, the agent may be different from those used in first-line treatment and is referred to as switch maintenance. Pemetrexed, erlotinib, and docetaxel are three agents for which there is supportive clinical trial data in the switch maintenance setting.[7,47,53] The first two agents are associated with an improvement in overall survival and have an indication for use in this setting.[54]

Table 98-6

Representative Initial Regimens for Advanced or Metastatic Non-Small-Cell Lung Cancer

Regimen	Schedule
Paclitaxel, day 1 Carboplatin, day 1	Every 21 days[38]
Cisplatin, day 1 Paclitaxel, day 1	Every 21 days[38]
Cisplatin, day 1 Gemcitabine, days 1, 8, 15 *squamous etiology	Every 28 days[38,39]
Cisplatin, day 1 Docetaxel, day 1	Every 21 days[38]
Pemetrexed, day 1 Cisplatin, day 1 *nonsquamous etiology	Every 21 days[39]
Pemetrexed, day 1 Carboplatin, day 1	Every 21 days[40]
Nab-paclitaxel days 1, 8, 15 Carboplatin, day 1	Every 21 days[41]
Cisplatin, day 1 Vinorelbine, days 1, 8 Cetuximab weekly *nonsquamous etiology	Every 21 days[42]
Cisplatin, day 1 Gemcitabine, days 1, 8 Bevacizumab, day 1 *nonsquamous etiology	Every 21 days[43]
Paclitaxel, day 1	Every 21 days[43,45]

Carboplatin, day 1 Bevacizumab, day 1 *nonsquamous etiology	
Pemetrexed, day 1 Cisplatin, day 1 Bevacizumab, day 1 *nonsquamous etiology	Every 21 days[46]

PALLIATION

Patients with metastatic NSCLC receive benefit from palliative care early after diagnosis, rather than waiting until end-of-life care. This palliative care includes helping the patient cope with the psychosocial aspects of their disease through methods such as counseling (e.g., expectation of treatment outcomes and affordability of treatment). In a study of patients with metastatic disease, subjects were randomly assigned to receive either early palliative care integrated with standard oncologic care vs. standard oncologic care alone. Patients assigned to early palliative care experienced a better quality of life and survival (11.6 vs. 8.9 months) than patients assigned to standard care alone. They also experienced fewer depressive symptoms (16% vs. 38%). The results show that palliative care is appropriate and potentially beneficial when it is introduced at the time of diagnosis at the same time as other beneficial therapies.[55]

In conclusion, L.L. would not likely receive benefit from surgical removal of the primary tumor or metastatic site. Instead, chemotherapy is the treatment of choice with a pemetrexed-based regimen along with maintenance pemetrexed for controlling disease that has already spread. Consideration for palliative care would also be beneficial.

CASE 98-2, QUESTION 2: The tumor tissue was sent out for analysis of the presence of an EGFR mutation. What characteristics in L.L. would prompt a decision to send a tumor specimen for analysis of an EGFR mutation?

The importance of this analysis is underscored by the fact that patients with EGFR mutation-positive advanced-stage tumors respond better to treatment with erlotinib than they do with conventional chemotherapy.[49] Furthermore, erlotinib is better tolerated than doublet platinum-based therapies; therefore, patients with EGFR mutation-positive tumors would be expected to experience better outcomes related to both tumor response and tolerability.[56] Soon after erlotinib was approved by the US Food and Drug Administration (FDA), investigators noticed that patients who were women, Asian, and nonsmokers tended to respond to erlotinib therapy more frequently than other populations. However, it was subsequently realized that presence of mutations in EGFR was a better predictor of response to erlotinib therapy than demographic factors and smoking status. The prevalence of EGFR mutations is between 10% and 15% for the overall population, but is 35% in white nonsmokers, and 65% for Asian nonsmokers.[57] Hence, the probability that L.L., a nonsmoking white woman, has a tumor with this somatic mutation is higher than for other categories of patients such as smokers or men. Further, the observed incidence of these mutations is less than 3% for patients with squamous cell histology; therefore, it is not recommended to test patients with this histology.[7] L.L. was diagnosed with adenocarcinoma, which is a nonsquamous subtype, and mutation testing is thus warranted on that basis alone.

The question arises that patients who fall into the category with multiple clinical predictors of response could be started empirically on erlotinib therapy without the need to test for EGFR mutations. In L.L.'s case, she would be classified as having three of these clinical predictors: female, nonsmoker, and adenocarcinoma. However, studies with populations of patients from developed countries with NSCLC showed that those who had three or more of these characteristics experienced a 49% response rate, whereas those with sensitizing EGFR mutations experienced a much higher 67% response rate.[58] This indicates that EGFR mutation is a better predictor of response to erlotinib therapy than presence of multiple clinical predictors.

Additionally, a second EGFR inhibitor, afatinib, is now available for patients with activating mutations of EGFR. Afatinib is an irreversible inhibitor of EGFR (whereas erlotinib is reversible) that has been shown to be superior to treatment with conventional chemotherapy as well as a second-line option for patients who have progressed on front-line erlotinib therapy.[59–62]

Application of this EGFR testing is useful for small molecule tyrosine kinase inhibitors (e.g., erlotinib, afatinib), but not for antibody molecules (e.g., cetuximab) that also block EGFR. The antibody molecules function to block the receptor external to the cell surface, and they also stimulate immune responses (e.g., antibody-dependent cell-mediated cytotoxicity, complement) against the tumor. It is likely that even without presence of the mutation(s), the antibody molecule still binds and can function through several mechanisms to promote an antitumor effect.[43] Small molecule inhibitors, however, also bind the receptor internal to the cell surface and can inhibit the active ATP binding region, which is constitutively activated in tumors with EGFR mutations.

CASE 98-2, QUESTION 3: L.L. was started on erlotinib therapy based on a positive EGFR mutation and, within 8 weeks of therapy, had obtained a partial response. What benefit from erlotinib therapy can L.L. expect in terms of prolonged survival?

Although there is short-term benefit for patients with EGFR mutation-positive tumors to receive erlotinib, it is not yet clear if there is a longer-term benefit. The response rate for erlotinib treatment is approximately 67%, time to disease progression is 11.8 months, and overall survival is approximately 24 months. As of yet, there are no data to support that treatment with small molecule inhibitors prolongs overall survival relative to doublet platinum-based therapy.[49] It is much easier to demonstrate an effect on tumor response and time to progression (such as with erlotinib) than it is for overall survival in most cancer studies. Showing improvement in overall survival is difficult because study subjects who are randomly assigned to one arm of a study can exhibit progressive disease and could hypothetically cross over to receive the competing treatment once they are classified as off study. The competing treatment could prolong overall survival and confound interpretation of the overall survival benefit for the test treatment (e.g., erlotinib). Further study is required to establish the benefit of erlotinib or afatinib treatment on overall survival. There is also no evidence to show that addition of erlotinib to chemotherapy is superior to either treatment alone. Hence, at this time, treatment for L.L. (single-agent erlotinib) would be expected to prolong her progression-free survival, but it is not yet known whether erlotinib prolongs overall survival.

CASE 98-2, QUESTION 4: If L.L.'s tumor was classified as having wild-type EGFR instead, what treatment should L.L. receive?

If the biopsy results had shown that the tumor EGFR was wild type (i.e., no mutation), then L.L. would be considered for a platinum-based doublet such as one shown in Table 98-6. Because her disease is nonsquamous, the adjunct agent selected would most likely be pemetrexed. Scagliotti et al. randomly assigned patients with advanced stage NSCLC to receive either cisplatin plus gemcitabine versus cisplatin plus pemetrexed. Although the median survival time was similar between the two arms, there were differences depending on tumor histology. Patients who received pemetrexed and had adenocarcinoma experienced a median overall survival of 12.6 months, whereas those who received gemcitabine had shorter survival. In contrast, those with squamous carcinoma who received pemetrexed experienced a 9.4-month median overall survival, whereas those who received gemcitabine had longer survival.[39] Therefore, if L.L.'s tumor had been wild type for EGFR, she could receive cisplatin and pemetrexed as first-line treatment because her disease is adenocarcinoma. Consideration could also be given for using cisplatin and paclitaxel together with bevacizumab. As mentioned previously, the latter agent is approved for use only in patients with nonsquamous cell NSCLC.[44] Those who respond to treatment with four to six cycles of cytotoxic therapy should receive maintenance therapy with pemetrexed and bevacizumab afterward based on the AVAPERL trial.[46]

CASE 98-2, QUESTION 5: As discussed in Chapter 94, Adverse Effects of Chemotherapy and Targeted Agents, the adverse effect profiles for cisplatin and carboplatin differ from each other. If a platinum-based regimen had been selected instead of erlotinib for L.L., what characteristics about L.L. could be used to guide the selection of carboplatin versus cisplatin?

Cisplatin is predominantly associated with ototoxicity, nephrotoxicity, and neurotoxicity, whereas carboplatin is predominantly associated with myelosuppression. This would be her first cycle of chemotherapy; therefore, she is not expected to have depleted reserves of myeloid progenitor cells. Her estimated creatinine clearance is 48 mL/minute and, based upon this, would be considered to have moderate renal impairment. In this case, carboplatin may be preferred over cisplatin because it is associated with less renal toxicity and it is dosed according to the Calvert formula, which accounts for renal function:

$$\text{Total carboplatin dose (mg)} = \text{AUC (GFR} + 25) \quad \text{(Eq. 98-1)}$$

where AUC is the area under the concentration–time curve and GFR is glomerular filtration rate.[63] A typical dose of carboplatin in this setting would be determined based on an AUC to account for renal function instead of the typical weight (or m^2)-based dosing. The AUC targets are commonly 4 to 6 mg/mL × minute for most doublet regimens. If a patient with moderate renal function were to receive a fixed dose that is similar to that given to a patient with normal renal function, then systemic exposure would be higher. This higher exposure could result in greater toxicity, notably greater myelosuppression. By dosing the drug according to the patient's renal function, the risk for overdosing a patient with decreased renal function is minimized. For example, if L.L.'s carboplatin dose is ordered as AUC 5 mg/mL × min, then her dose would be calculated as dose = 5 mg/mL × minute (48 mL/min + 25), which is 365 mg. In contrast, if her renal function were within normal range for estimated creatinine clearance (e.g., 100 mL/minute), her carboplatin dose would be 625 mg (~70% higher). Several different methods may be used to estimate renal function, such as the Cockroft and Gault equation, and the dose calculations will differ according to the method chosen. The American Society of Clinical Oncology (ASCO) has developed recommendations for the dosing of carboplatin. It is recommended to cap the GFR or CrCl at 125 mL/minute within the Calvert equation.[64] Usually, the choice of method is institution specific, because there is no evidence to show that one estimation method is superior to the other. By consistently using the same formula, providers reduce variability in systemic exposure and thus increase the predictability of tolerance to the drug. If the patient's GFR is estimated based upon serum creatinine measurements by the isotope dilution mass spectrometry method, then the GFR should be capped to a maximum of 125 mL/minute, because serum creatinine values can be underestimated when they fall below 0.7 mg/mL, as can happen in some patients. The FDA issued this safety alert to avoid administration of high doses to patients with normal renal function and thus likely avoiding drug-related toxicity.[64]

In conclusion, L.L. should receive erlotinib as first-line therapy. If her tumor had contained wild-type EGFR (instead of mutant), then a platinum-based doublet (i.e., cisplatin or carboplatin) could be considered with pemetrexed therapy. She has moderate renal impairment; therefore, an agent such as cisplatin would not be favored because it is associated with a high incidence of renal toxicity. Carboplatin would be a safer choice because the dose would be selected based upon her renal function, and is associated with a lower incidence of renal toxicity than cisplatin.

CASE 98-2, QUESTION 6: L.L. experienced minor grade diarrhea and skin rash and otherwise tolerated erlotinib treatment very well without any impact on her daily activities and quality of life. L.L. continued erlotinib therapy, and at 9 months, there is no evidence of disease progression. The plan is to continue this therapy until the disease relapses. What types of side effects should L.L. be monitored while receiving erlotinib therapy?

In general, therapy with erlotinib is well tolerated, especially relative to cytotoxic chemotherapy. Diarrhea and rash are the two most common adverse effects of EGFR TKI therapy.[65] The diarrhea can be treated with loperamide in most cases. Rash requires intervention in approximately one-third of cases, and it is desirable to treat it with agents such as 2% topical clindamycin, minocycline, or doxycycline, and topical 1% hydrocortisone (discussed in Chapter 94, Adverse Effects of Chemotherapy and Targeted Agents). Erlotinib dose reduction (in 50-mg decrements) could also be considered, although this would likely shorten the anticancer benefit experienced with this agent.[65]

As mentioned earlier, NSCLC is primarily a disease in those older than 60 years. L.L. is 85 years old, and there is concern that patients, particularly more than 80 years old, may not tolerate cytotoxic chemotherapy as well as younger patients. Hence, elderly patients are often undertreated. However, recent studies suggest that survival benefits are greater in elderly patients who receive doublet therapy versus single agent.[66] More studies of various regimens are needed that would focus on treatment of elderly patients, particularly effects on survival, quality of life, and tolerability. Such studies would investigate the best clinical parameters that enable prediction of response and tolerability to therapies, and also the doses associated with the best outcomes. Because the majority of patients have wild-type EGFR, cytotoxic chemotherapy is first line. Therefore, considerations must be given to patient preferences, comorbidities, and performance status. It is not uncommon for those with advanced age to live alone. Caretakers who could help the patient monitor for and treat adverse effects of chemotherapy (dehydration from diarrhea or vomiting, febrile neutropenia, etc.) would be an essential consideration, particularly in this population. Even though L.L. is able to continue treatment beyond 9 months, most patients eventually exhibit progressive disease within 1 to 2 years. These patients can often be re-biopsied. Approximately 40% of these cases develop secondary mutations in EGFR that render the tumor resistant to erlotinib treatment.[67] At such time, consideration can be given for second-line treatment with afatinib.

CASE 98-2, QUESTION 7: In addition to EGFR mutation testing, L.L.'s pathology was analyzed for ALK fusion rearrangement. If this returned positive, how would that impact the initial choice of treatment for L.L.?

Anaplastic lymphoma kinase (ALK) rearrangement consisting of a fusion of EML4 and ALK is a predictive marker that is present in 2% to 7% of NSCLCs and has been validated to identify patients who may benefit from ALK inhibitors such as oral crizotinib or ceritinib. Patients are more likely to be ALK-positive if they are never smokers or have adenocarcinoma histology. Therefore, it is standard of care to determine whether ALK rearrangement is present in all patients with adenocarcinoma histology.[68,69] Initial therapy with crizotinib resulted in an improvement in progression-free survival of 10.9 months versus 7.0 months for patients receiving platinum-pemetrexed doublet chemotherapy.[70] Additionally, crizotinib has been shown to improve progression-free survival over chemotherapy in patients who have already received chemotherapy in the first-line setting.[71] Recently, a new oral ALK inhibitor that is 20 times more potent than crizotinib, ceritinib, was approved for treatment of patients after progression on therapy with crizotinib.[72]

The ALK inhibitors are generally well tolerated with the main adverse events being visual disorders, nausea, vomiting, diarrhea, and fatigue. The visual disorders usually present within the first 2 weeks of therapy and most commonly present as flashing or trailing lights and the presence of floaters.[73]

In conclusion, initial therapy for NSCLC is predominately focused on initial staging, role of therapy, and then histology present. After progression of disease, there are many chemotherapeutic options that may result in some progression-free survival although overall survival is still dismal. Recently, a new targeted approach to the treatment of progressive NSCLC was introduced with the approval of nivolumab. Nivolumab is a programmed cell death 1 (PD-1) receptor inhibitor that gained FDA approval for advanced, previously treated squamous cell NSCLC based on the CheckMate 017 trial. This trial demonstrated an improved overall survival in patients receiving nivolumab over docetaxel (1-year OS 42% with nivolumab vs. 24% with docetaxel, HR for death, 0.59, $p < 0.001$).[74] It is expected that the use of PD-1 inhibitors will expand beyond squamous histology as well as exploring a role in first-line therapy.

Small-Cell Lung Cancer

EPIDEMIOLOGY

Small-cell lung cancer (SCLC) accounts for approximately 13% of all lung cancer histology and affects both sexes in equal distribution. The disease is much more highly attributable to smoking than NSCLC. As the numbers of people who smoke have decreased in the United States since its peak in the 1960s, the incidence of SCLC has also declined, resulting in ~2.4% decrease per year.[75] Relative to NSCLC, these tumors generally have a more rapid doubling time, a higher growth fraction, and early development of widespread metastases. As a consequence, SCLC is highly sensitive to chemotherapy and radiotherapy; however, most patients eventually die from recurrent disease.[76,77]

PATHOPHYSIOLOGY

Small-cell lung cancer is a malignancy thought to be derived from neuroendocrine cells in the bronchus and is readily diagnosed on small specimens such as bronchoscopic biopsies, fine needle aspirates, core biopsies, and cytology. As the name suggests, these tumors consist of small cells that may be round, oval, or spindle-shaped, with limited volume of cytoplasm, poorly defined cell borders, and finely granular chromatin.[78]

CLINICAL PRESENTATION

Most SCLCs usually arise centrally and present as a large hilar mass with bulky mediastinal lymphadenopathy that can cause cough and dyspnea. Very rarely do patients diagnosed with SCLC present with the primary tumor located in the lung periphery, as can be the case with adenocarcinoma NSCLC. Due to smoking, patients with lung cancer may have had previously existing symptoms such as cough and dyspnea that are related to the presence of other smoking-related diseases such as COPD. Therefore, these symptoms may not prompt patients to seek medical attention quickly.[79]

DIAGNOSIS AND OVERVIEW OF TREATMENT

In general, diagnostic procedures are similar to those used to diagnose NSCLC. Staging of SCLC is used to determine prognosis and treatment. The median overall survival for patients with limited-stage disease ranges from 17 to 26 months and, for extensive stage, 3 to 12 months.[79] (These data were collected

---

from an analysis of 14 studies of SCLC, and thus wide ranges for survival are reported.) Surgery (e.g., thoracotomy) is appropriate for less than 5% of patients with early stage disease, mainly due to the tendency for these tumors to be bulky and to metastasize quickly. The limited role for surgery, therefore, enables the use of a simple two-stage system instead of the TNM system used for other solid tumors. In the Veterans Administration Lung Study Group staging system, limited-stage disease is defined as disease confined to the ipsilateral hemithorax and encompassed in a tolerable radiation field, and extensive disease is defined as disease beyond the ipsilateral hemithorax including malignant pleural effusions or hematogenous metastases.[80–82]As discussed subsequently, patients with limited-stage disease are treated with a combined-modality approach (i.e., chemotherapy and radiation), and extensive stage is treated with chemotherapy. Only approximately 30% of patients present with limited stage and the rest with extensive-stage disease.[75]

CLINICAL PRESENTATION AND PATHOPHYSIOLOGY OF SMALL-

CELL LUNG CANCER

CASE 98-3

QUESTION 1: M.W. is a 63-year-old woman who presented to her primary doctor with a complaint of heartburn and pain in the right side of her upper abdomen; she also had a feeling of gas in the stomach. In addition, she noticed a 20-lb weight loss within 3 months, although she attributed this to changes in her diet. She was not complaining of any coughing. There was no shortness of breath. The evaluation with chest radiograph demonstrated the presence of a large mass in the right perihilar region with extension to the mediastinum and significant mediastinal adenopathy with narrowing of the trachea and its displacement to the left by the mass. The follow-up PET-CT scan confirmed presence of that large mass and no other areas of abnormality within the abdomen or pelvis. The patient also had a brain MRI that showed no evidence of metastatic disease. After that, the patient had a bronchoscopic evaluation and a biopsy of the mediastinal mass. Pathology came back positive for small-cell lung carcinoma histology. Having disease only limited to the chest and mediastinum, the patient was diagnosed with limited-stage SCLC. Peripheral blood chemistry, LDH, and counts were normal. What features of M.W.'s disease are suggestive for SCLC?

M.W.'s chief complaints were heartburn and pain in the upper right side of her abdomen, not necessarily common symptoms of SCLC. Location of the tumor is a determining factor in specific symptoms that a patient can experience, and can serve as an indicator of the invasiveness of the disease. Although M.W. did not complain of cough, her presentation is representative of patients diagnosed with this disease in that the tumor was centrally located with spread to the mediastinum. She also experienced weight loss and, although she attributed this to her diet, it is a symptom experienced by patients with rapidly growing disease and associated with appetite suppression.

M.W. did not experience all of the symptoms that are frequently found in patients. Fatigue, especially together with decreased physical activity, is a common complaint as well as hemoptysis.[83] Owing to the central location of most of these tumors, approximately 10% of patients can experience superior vena cava syndrome (SVCS). This is a very serious complication and requires immediate medical attention as a result of the growing tumor impinging upon the superior vena cava. This can restrict blood return to the heart, resulting in head and facial swelling.[84,85]

CASE 98-3, QUESTION 2: What potential complications might patients such as M.W. experience during the course of their disease?

Patients with SCLC frequently experience paraneoplastic syndromes as a result of their disease, and these often differ from patients who have NSCLC. For example, patients with NSCLC have a higher tendency to develop hypertrophic pulmonary osteoarthropathy and hypercalcemia. On the other hand, patients with SCLC have higher incidence rates for hyponatremia, Cushing syndrome, and neurologic paraneoplastic syndrome. The serum concentrations of antidiuretic hormone are often elevated in SCLC, but few of these cases fulfill the criteria for SIADH and are mostly asymptomatic. In some cases, ectopic production of atrial natriuretic factor contributes to the disorder in sodium homeostasis. Because SCLC is usually responsive to cytotoxic agents, the treatment of choice for hyponatremia is chemotherapy. If further management is needed (i.e., if the cancer is nonresponsive to chemotherapy or symptomatic), fluid restriction, intravenous hypertonic saline, and treatment with demeclocycline are options, depending on severity.[1] The serum concentrations of adrenocorticotropic hormone are elevated in approximately half of patients with lung cancer but Cushing syndrome develops in only 5% of those with SCLC. Low serum sodium and Cushing syndrome are both poor prognostic indicators for the disease.[86]

Unlike M.W., most patients already have metastatic disease at diagnosis, and the most common sites include bone, liver, adrenal glands, and brain. Patients with hepatic and adrenal lesions do not usually experience symptoms, even if they have elevations of bilirubin, alkaline phosphatase, or hepatic transaminases.[87] In contrast, brain metastases are symptomatic in more than 90% of cases, and patients can often present with central nervous system complications (e.g., seizures) as the first sign of the disease.[1]

CASE 98-3, QUESTION 3: M.W. reads about various treatments for her disease online. What is the utility for each of the three treatment modalities (i.e., surgery, radiation, and chemotherapy) for the treatment of her disease?

TREATMENT MODALITIES FOR SMALL-CELL LUNG CANCER

Surgery

As mentioned earlier, surgery has a very limited role as part of the treatment for patients with SCLC. In general, patients with tumors larger than 3 to 7 cm and presence of any disease in the lymph nodes or distant metastases do not benefit from surgery.[88] The percentage of patients who fit this category is less than 5%. If surgery is chosen, the procedure usually includes lobectomy with mediastinal nodal dissection and sampling. Thereafter, patients would receive adjuvant radiation and chemotherapy and then prophylactic cranial irradiation as described in the subsequent sections.

Radiation

Small-cell lung cancer is responsive to radiation therapy; therefore, it is useful in treating patients with limited-stage disease. These treatments are usually given as fractionated doses over the course of 3 to 7 weeks, and total dosage targets range between 45 and 70 Gray (Gy). The optimal dose and frequency of administration of radiation is still under investigation. Three-dimensional conformal radiation (intensity modulated radiation therapy) is the preferred method and the radiation is delivered from an external source concurrently with multidimensional imaging to assure tumor movement of less than 1 cm is achievable (movement as a result of breathing during the procedure).[89–92] In addition

---

to their cytotoxic effects, many chemotherapeutic agents also sensitize tumors to radiation. Hence, radiotherapy should start concurrently with chemotherapy, usually at the first or second cycle. Due to the high incidence of metastases to the brain (i.e., greater than 50% of patients with SCLC), prophylactic cranial irradiation consisting of 25 to 30 Gy given for 10 to 15 fractions is the standard of treatment for patients with limited-stage and extensive-stage disease after completion of initial chemotherapy or chemoradiation and minimal residual systemic disease.[93,94]

Chemotherapy

The proliferative indices for SCLC cells are high and early metastatic spread is common. Therefore, systemic chemotherapy is the treatment of choice for its utility in treating metastases and because it is effective for tumor cells progressing through the cell cycle. In general, most of the regimens are platinum-based combinations with etoposide or, less commonly, irinotecan (the latter proven to be efficacious in Japanese patients) as outlined in Table 98-7.[95] If a tumor response is observed, the benefit is usually seen early in the treatment course. Prolongation of treatment beyond six cycles is usually not recommended for this disease because the maximum effect of the treatment is achieved in this time frame. Further, toxicity after treatment with these agents accumulates and diminishes the overall benefit to the patient beyond six courses.[99,100] Hence, treatment is usually stopped after four to six cycles and the patient is closely monitored for recurrence of the disease.

As mentioned previously, SCLC has a very high rate of recurrence; therefore, second-line therapy is usually implemented. Several choices of agents are available as shown in Table 98-7, and the selection is dependent on the overall condition of the patient (e.g., performance status, toxicity from previous regimen) and the length of time after the first-line regimen was completed. Many of these agents are given as single-agent therapy except for the CAV regimen. In general, a recurrence that occurs within 6 months of treatment with first-line therapy is considered resistant and other agents are selected. If recurrence occurs after 6 months, then the same agents used for the first-line regimen may be used again. To date, no targeted agents are approved for use in treating SCLC.

Table 98-7

Representative Chemotherapy Regimens for Small-Cell Lung Cancer

Limited-Stage SCLC (maximum 4–6 cycles)
Cisplatin, day 1 Etoposide, days 1–3, then every 21 days[91]
Carboplatin, day 1 Etoposide, days 1–3, then every 21 days[69]
Extensive-Stage SCLC (maximum 4–6 cycles)
Cisplatin, day 1

Etoposide days 1–3, then every 21 days[71]
Carboplatin, day 1 Etoposide, days 1, 2, 3, then every 21 days[96]
Cisplatin, day 1 Irinotecan days 1, 8, 15, then every 28 days[97]
Cisplatin, day 1 Irinotecan days 1, 8, then every 21 days[98]
Chemotherapy for Relapsed Disease[78]
Clinical trial preferred
If relapse occurs <2–3 months after first line and PS 0–2: paclitaxel, docetaxel, gemcitabine, irinotecan, or topotecan (oral or IV), ifosfamide
If relapse occurs >2–3 months up to 6 months: topotecan (oral or IV), irinotecan, paclitaxel, docetaxel, oral etoposide, vinorelbine, gemcitabine, or cyclophosphamide/doxorubicin/vincristine (CAV)
If relapse occurs >6 months: original regimen

PS, performance status; SCLC, small-cell lung cancer.

In conclusion, M.W.'s disease would not be a good candidate for surgical removal because there is lack of proven benefit. Small-cell lung tumor cells proliferate rapidly; therefore, they are usually responsive to chemotherapy and radiation treatment. This systemic therapy would also be favored because the tumor tends to metastasize quickly and it provides a way to eradicate disease that may have spread.

CASE 98-3, QUESTION 4: M.W. begins therapy with intravenous cisplatin on day 1 combined with etoposide on days 1 to 3 given in a 21-day cycle. Four to six cycles are planned, and she will also receive concurrent radiation.[92,101] For M.W., what is the goal of therapy? What objective baseline data should be acquired prior to starting treatment? What monitoring parameters should be utilized?

TREATMENT WITH CHEMOTHERAPY AND RADIATION

The goal of therapy for a patient with limited-stage disease such as M.W. would be to increase overall survival and achieve a potential cure. In patients with limited-stage disease, response rates of 70% to 90% are expected after a regimen such as the one M.W. is receiving, whereas response rates of 60% to 70% are expected for patients with extensive-stage disease.[78] If M.W. had been diagnosed with extensive-stage disease, then the goals would have been to increase overall survival and for palliation of symptoms. Given the complications that can arise as a result of SCLC, treatment could be used to minimize these adverse events. For example, radiotherapy is often used in treating patients with SVCS because it would reduce tumor size and enable resumption of more normal blood flow. Therefore, if a patient has acceptable performance status (e.g., 0–2) and minimal to no comorbidities, then treatment such as the one that M.W. is receiving is the best course of action.

A treatment regimen such as cisplatin and etoposide plus radiation is tolerated by most patients, especially because the number of cycles is usually limited to six. However, administration of these cytotoxic agents is associated with several adverse effects, some of which can be life-threatening. Hence, the clinician is expected to anticipate these events and plan treatment accordingly to minimize complications. The patient is receiving cisplatin, which causes several different adverse effects such as renal insufficiency, sensory neuropathy, ototoxicity, and is considered highly emetogenic (refer to Chapter 94, Adverse Effects of Chemotherapy and Targeted Agents). Hydration and diuresis are required with cisplatin doses greater than 40 mg/m^2 to maintain a urine output of 100 to 150 mL/hour before administration of the drug. The intravenous fluids are often supplemented with potassium and magnesium to counteract electrolyte wasting from cisplatin. Monitoring of serum creatinine, electrolytes including magnesium and calcium, is performed usually before each infusion of chemotherapeutics. An appropriate antiemetic regimen must be implemented to prevent both acute and delayed nausea and vomiting. For etoposide, neutropenia is usually the dose-limiting toxicity. Therefore, monitoring of absolute neutrophil count (ANC) is important and, if the counts do not recover before the next dose is due, then delays in treatment or dosage reductions occur. In phase III clinical trials for this regimen, grade 4 leukopenia occurred in approximately 35% to 40% of patients, and any grade fever and infection in greater than 20%.[90,91] Therefore, consideration must be given toward the use of colony-stimulating factors to manage this latter event, usually after radiation is completed (refer to Chapter 94, Adverse Effects of Chemotherapy and Targeted Agents).

In conclusion, the goal of M.W.'s therapy is a potential cure. Hydration with fluids supplemented with potassium and magnesium must be initiated prior to cisplatin therapy to prevent cisplatin-induced renal toxicity. During therapy, clinicians must observe for decreased ANC due to etoposide and may need to implement delays in therapy or use of a colony-stimulating factor (e.g., granulocyte colony-stimulating factor, filgrastim). Supportive care such as anti-emetics during therapy to prevent or manage cisplatin-associated acute- and delayed-phase nausea and vomiting will also be essential.

CASE 98-3, QUESTION 5: M.W. tolerated therapy very well with mild esophagitis and cough during treatment. She did not experience any vomiting due to aggressive antiemetic use, nor did she exhibit any neuropathy or hearing loss. What adverse conditions that M.W. experienced are associated with her treatment?

Both esophagitis and cough are likely attributable to radiation effects. If esophagitis worsens to grade 3 or more, patients can lose the ability to swallow and may require a feeding tube. During therapy, cough can develop and patients may become concerned that it is a sign of worsening disease. Radiation-induced pneumonitis, acute (in first 3 months) and chronic (4–12 months), can be a frequent cause of the new onset of cough, which can be ameliorated with corticosteroid treatment.

CASE 98-3, QUESTION 6: After two cycles of chemotherapy with concurrent radiotherapy, a CT scan indicates a partial response. Therefore, an additional four cycles of cisplatin and etoposide were planned. How is the course of M.W.'s disease likely to proceed?

The chances for long-term survival greater than 5 years are very low, even for the patient with no other comorbidities and limited-stage disease such as M.W. At the completion of chemotherapy, M.W. should be offered therapy with prophylactic cranial irradiation because brain metastases occur in greater than 50% of patients with SCLC. Prophylactic cranial irradiation not only reduces the incidence of metastatic disease but also increases overall survival.[93] Within a year of completing therapy, most patients experience progressive or relapsed disease. The duration of the remission is the single largest predictor of outcome and patients are classified as having either sensitive or refractory disease, depending on length of this duration. Approximately half of those tumors that are deemed sensitive in this setting will respond to second-line therapy.[100] Therefore, most SCLC tumors become resistant to therapy either during first-line or salvage therapy. Patients can also exhibit second primary tumors, especially NSCLC, during the course of the disease.

Colorectal Cancer

Marlo Blazer

CORE PRINCIPLES

		CHAPTER CASES
1	Family history, patient-specific factors, and environmental factors are identified as risk factors for colorectal cancer. Environmental factors could be modified to reduce the risk of colorectal cancer.	**Case 99-1 (Question 1)**
2	Early detection of colorectal cancer through screening reduces cancer-related mortality. Most patients at low risk of colorectal cancer are recommended to begin screening at the age of 50 years.	**Case 99-1 (Question 2)**
3	Patients may be asymptomatic at diagnosis or have nonspecific symptoms. Carcinoembryonic antigen may be elevated in patients with colorectal cancer, but it cannot be used alone for diagnosis.	**Case 99-2 (Question 1)**
4	Adjuvant combination chemotherapy with fluorouracil and oxaliplatin is currently considered the standard of care for patients with stage III colorectal cancer after surgery with curative intent.	**Case 99-2 (Questions 2, 3)**
5	All patients diagnosed with localized colorectal cancer should undergo routine surveillance visits with their oncologist for a period of 5 years after completion of their definitive therapy.	**Case 99-2 (Question 5)**
6	During the last decade, newer chemotherapy agents (oxaliplatin, irinotecan) and targeted therapies (bevacizumab, ramucirumab, ziv-aflibercept, cetuximab, panitumumab, regorafenib) have increased the overall survival of patients with metastatic colorectal cancer. Fluoropyrimidines (fluorouracil or capecitabine) remain the backbone of therapy in the first- and second-line treatment of advanced cancer. The right combination and sequencing of these agents is vital to improving the care of patients with colorectal cancer.	**Case 99-3 (Question 1)**
7	Utilization of specific predictive markers helps maximize the desired outcome in colorectal cancer. Patients with RAS mutant tumors do not derive any benefit from anti–epidermal growth factor receptor (EGFR) monoclonal antibody therapy.	**Case 99-3 (Question 4)**
8	Myelosuppression, diarrhea, and peripheral neuropathy are potential dose-limiting toxicities associated with chemotherapy agents used in the treatment of colon and rectal cancers. Prevention strategies, diligent monitoring, and adequate supportive-care measures are vital to effective toxicity management and should be used to maintain patient safety and enhance quality of life.	**Case 99-2 (Questions 3, 4),** **Case 99-3 (Question 3)**

⑨ Severe, life-threatening adverse effects are uncommon, but potential hazards are associated with targeted colorectal cancer therapies and avoiding their use is warranted in patients at increased risk of experiencing these complications. Prevention and treatment strategies are available for common adverse effects such as hypertension associated with vascular endothelial growth factor therapy or EGFR inhibitor–induced dermatologic toxicity.	**Case 99-3 (Questions 3, 5, 6)**
⑩ Certain genetic variants of key enzymes involved in the catabolism of fluorouracil and irinotecan are associated with increased toxicity from these agents. The clinical utility of identifying these variants in an effort to avoid or manage these toxicities continues to be elucidated.	**Case 99-3 (Question 2)**

COLORECTAL CANCER

Epidemiology, Etiology, and Pathophysiology

Colorectal cancer is the malignant growth of tumor that begins from the inner wall of the colon or rectum. It is the third most commonly diagnosed cancer in the United States and the second leading cause of cancer-related deaths. In 2015, it is estimated that there will be 132,700 new cases of colon and rectum cancer with the median age at diagnosis of 68 years, and 49,700 people will die from this disease. During the last decade, new agents and better predictive markers have enabled improvement in the detection, safety, and survival of patients with colorectal cancer. The age-adjusted 5-year relative survival rate in 1975 (based on 1975–2007 data) was 48.6% and is estimated to be 64.9% in 2015 (2005–2011 data).[1]

The formation of colorectal cancer is a multistep process. It begins with an abnormal growth of tissue known as a polyp (adenoma) originating from the innermost wall of the colon. The process of transformation from a polyp to malignant disease can take up to 10 to 15 years.[1] Once this transformation occurs, the cancer begins to spread through the wall of the colon or rectum, where it can eventually invade the blood, lymph nodes, or other organs directly. The vast majority of colon and rectal cancers are classified as adenocarcinomas, meaning that they arise from the glandular tissue responsible for producing the secretions of the gastrointestinal tract. Approximately two-thirds of these cancers will arise from the colon, and the remainder will form in the rectum. Colorectal cancer is among the few cancers that can be prevented by removal of precancerous tissue; therefore, early detection is crucial.

The etiology of colorectal cancer is complex, involving patient-specific, environmental, and genetic factors. Of these, age is considered the most important risk because greater than 90% of patients diagnosed are older than 50 years of age.[2] Other patient-specific risk factors are family history of colon cancer, history of previous colonic polyps, and inflammatory bowel disease (ulcerative colitis or Crohn's disease). Environmental factors like a diet consisting primarily of red meat, high fat, and low fiber can also increase the risk of colorectal cancer, as can a sedentary lifestyle, obesity, excessive alcohol consumption, and long-term smoking.[2,3] Smoking, particularly early in life, has been shown to increase the risk of developing colorectal cancer. Patients who smoked more than 12 pack-years of cigarettes before the age of 30 are at increased risk of recurrence after a diagnosis of stage III colon cancer.[3]

Hereditary syndromes account for 5% to 6% of all colorectal cancers.[4] Specific inherited syndromes include hereditary nonpolyposis colon cancer, also known as Lynch syndrome, and familial adenomatous polyposis (FAP). Although accounting for <1% of all colorectal cancer cases, FAP is associated with a lifetime risk of colorectal cancer of greater than 90% because of an autosomal dominant germline mutation causing the development of 10s to 1,000s of polyps distributed in the colon and rectum, usually beginning in adolescents.[5] Lynch syndrome accounts for 2% to 3% of colorectal cancers.[5] It is an autosomal dominant disorder that also has an early age of onset (age 20–25 years) and is associated with an increased risk of other cancers, such as endometrial cancer, cancers of the urinary tract, small intestine, ovary, stomach, pancreas, biliary tract, brain, and skin. Screening for both of these inherited syndromes begins at an early age (age 10–12 years for FAP and age 20–25 for Lynch syndrome).[5]

Celecoxib, a cyclo-oxygenase-2 inhibitor, is US Food and Drug Administration (FDA) approved for the treatment of patients with known FAP. However, the routine use of NSAIDs for the prevention of colorectal cancer in the general population is not recommended because of concerns of toxicity.

Clinical Presentation and Diagnosis

Symptoms associated with the development of colon and rectal cancers are often subtle and can mimic "generalized" symptoms associated with numerous other benign conditions, such as abdominal pain, constipation, diarrhea, bloating, rectal bleeding, and other sudden changes in bowel habits or caliber. Unintentional weight loss, anemia, and weakness may also be present, particularly in advanced stages of the disease. A diagnosis is made once a colonoscopy or sigmoidoscopy is performed and a biopsy is obtained to confirm the presence of cancer. Additional diagnostic procedures would be performed before initiating treatment, including a computed tomography (CT) scan of the chest, abdomen, and pelvis as well as laboratory collection of blood to obtain a baseline carcinoembryonic antigen (CEA) level. These determine the extent of disease and provide a means to monitor for recurrence or progression after or on treatment. For cancers of the rectum, an endoscopic ultrasound may also be performed to aid in the preoperative or clinical staging of the tumor. Definitive or pathologic staging for all tumors of the colon and rectum takes place during surgical resection.

Treatment Overview

The therapeutic modalities available to the patient with colorectal cancer are similar to those used in other solid tumors. Surgery, radiation, and chemotherapy all have roles in both localized and advanced disease, but how each of these strategies is used, and sequencing, depends on the location and extent of disease and on the goal of therapy. In general, surgery is utilized as the primary initial modality for patients with stages I, II, and III disease. It may also be employed in selected patients with metastatic stage IV disease at some point during their treatment course. Radiation is usually reserved for patients with rectal cancer. This chapter will primarily focus on the use of systemic therapy (i.e., chemotherapy and targeted therapy) for patients diagnosed with colon and rectal cancer.

Stage of disease at diagnosis determines the initial treatment. Colorectal cancer, like other solid tumors, utilizes the TNM staging system, but it is unique in that it is the depth of invasion of the primary tumor and not its size that determines the "T" in the TNM staging. Like other solid tumors, the remaining components of this classification system are lymph node involvement (N) and metastatic spread (M). Colon and rectal cancers are staged in the exact same manner; however, rectal tumors lie in closer proximity to the anal sphincter, therefore the risk of localized treatment failure and of recurrence at the initial site of disease is increased. An area of controversy in the management of colon cancer is whether or not all patients with stage II disease should receive adjuvant therapy. Although the routine use of adjuvant chemotherapy in this setting is not recommended, it should be considered for stage II patients with the following high-risk features: T4 lesions, bowel obstruction or local perforation at presentation, poorly differentiated histology, lymphovascular invasion, inadequate lymph node sampling, and positive margins after surgery.[5]

Etiology

CASE 99-1

QUESTION 1: O.B., a 35-year-old woman, recently learned that her 58-year-old father was diagnosed with colon cancer. O.B. is obese and smokes a half-pack of cigarettes per day. She loves eating out and spends most of her evening watching TV at home. O.B. would like to know the risk factors for colorectal cancer. She would also like to know whether there is anything she can do to reduce her risk of developing colorectal cancer in the future.

O.B. is at an increased risk of developing colorectal cancer given her family history of colon cancer. In addition, she is obese, lives a sedentary lifestyle, and smokes. She eats out, but no information is given about her diet. There are modifiable risk factors, which she could address to lower her risk of developing colorectal cancer. O.B. can lose weight through exercise and adopt a high-fiber, low-fat diet. In addition, she can stop smoking, which can help reduce the risk of colorectal as well as other cancers.

Screening

CASE 99-1, QUESTION 2: O.B. would like to know whether there is a way to screen for colorectal cancer. If there is, does this method detect cancer early? Her father had a colon cancer diagnosis; therefore, O.B. wonders when she should get screened for colorectal cancer.

Colon and rectal cancers are among the few cancers that can be prevented by removal of precancerous tissue; therefore, early detection is crucial. As described above, formation of colorectal cancers is a multistep process, and the early precancerous tissue is identifiable and can be removed. Colorectal cancer is not always asymptomatic, but early detection of colorectal cancer through screening has been proven to reduce mortality. A variety of screening methods exist, including fecal screening tests, digital rectal examination, barium enemas, endoscopy, and CT colonography. Fecal screening tests are designed to detect occult blood in the stool and are relatively inexpensive and noninvasive. There are two main types: the fecal occult blood test (FOBT) and the fecal immunochemical test (FIT). The FOBT been shown to reduce mortality from colorectal cancer by 33%, but the test does require diet restrictions prior to sampling.[6] The FIT uses antibodies to detect hemoglobin or other blood components and, compared with FOBT, has no drug or food interactions. Screening guidelines acknowledge that FIT may be more sensitive than FOBT[7]; however, neither is preferred over the other, possibly because of a lack of mortality data with FIT along with potential cost/out-of-pocket difference between the two tests. Endoscopic screening for colorectal cancer includes either flexible sigmoidoscopy or colonoscopy, and both offer the ability to remove polyps and obtain biopsy samples during the procedure. The advantages of sigmoidoscopy are that no sedation is required, a simple preparation (two Fleet enemas) is used, and it can be performed in various settings. Patients may choose flexible sigmoidoscopy over colonoscopy if they do not want to go under sedation or undergo an extensive bowel preparation. Sigmoidoscopy has been shown to reduce incidence of colorectal cancer by 33% and mortality because of colorectal cancer by 43%.[8] However, flexible sigmoidoscopy allows for examination only of the sigmoid colon and rectum, while colonoscopy examines the entire colon. As such, colonoscopy is the most widely accepted screening tool; it has been shown to reduce the incidence of colorectal cancer by 77% and is associated with significant risk reduction in both right- and left-sided colon cancer incidences.[7,9] A relatively new method known as CT colonography provides two- and three-dimensional images of the colon. As with endoscopic procedures, it requires complete bowel preparation to remove feces from the intestine. This screening technique has demonstrated an approximate 80% sensitivity to detect polyps >6 mm in size and 90% sensitivity for polyps >1 cm.[10] However, any cancerous lesion detected will ultimately necessitate an examination by colonoscopy.

CEA is a tumor marker that is detected in the blood and has been evaluated as a screening tool, but its primary utility is in monitoring response to treatment and not screening. Healthy smokers are likely to have twice the CEA level compared with nonsmokers. Further, administration of therapies given for metastatic colon cancer can cause false elevation of CEA without disease progression, so even in monitoring response to treatment, it is only used in conjunction with other modalities.

The American Cancer Society, the US Multi-Society Task Force on Colorectal Cancer, and the American College of Radiology have jointly published screening recommendations for the early detection of colorectal cancer.[11] According to their recommendations, any man or woman at average risk of developing colorectal cancer should begin screening at age of 50 years (Table 99-1). Patients at average risk of developing colorectal cancer will not have genetic predisposition or history of a family member with colorectal cancer. In addition, patients in this category will have no history of polyps, previous history of colorectal cancer, inflammatory bowel disease, chronic ulcerative colitis, or Crohn’s colitis.

O.B. is a 35-year-old woman with a first-degree relative with a diagnosis of colon cancer at the age of 58. It is less likely she would develop colorectal cancer through a hereditary syndrome because her father was diagnosed after the age of 50. She does, however, have nearly double the life time risk of developing colorectal cancer because a first-degree relative had colorectal cancer.[12] Because O.B.’s father had colorectal cancer diagnosed before the age of 60, she is at increased risk for developing the disease and should consider initiating a colorectal screening program at the age of 48 or 10 years earlier than her father was diagnosed (at age 58).[10]

Table 99-1

American Cancer Society Screening Recommendation for Colorectal Cancer by Age and Risk

Average Risk	Begin screening at age of 50 years Annual DRE and FOBT or FIT (stool DNA test, interval uncertain) and one of the following: ■ Sigmoidoscopy every 5 years[a] ■ CT colonography every 5 years[a]

	■ Colonoscopy every 10 years[a] ■ Barium enema every 5 years[a]
Family History	Begin screening at age of 40 years or 10 years younger from first-degree relative colorectal cancer diagnosis
Hereditary nonpolyposis colon cancer	Begin screening at age of 20–25 years or 10 years younger from first-degree relative colorectal cancer diagnosis
Familial adenomatous polyposis	Begin screening at age of 10–12 years
Inflammatory bowel disease, Chronic ulcerative colitis, or Crohn's colitis	Begin screening at 8–15 years after diagnosis

[a] Interval of surveillance is shown for negative findings. If polyps are found at screening, interval of surveillance may change based on biopsy results.[8]

CT, computed tomography; DRE, digital rectal examination; FIT, fecal immunochemical test; FOBT, fecal occult blood test.

Clinical Presentation

CASE 99-2

QUESTION 1: B.R. is a 66-year-old white man who was in his usual state of health until recently, when he decided to visit his general practitioner owing to progressively worsening gastrointestinal symptoms, including abdominal cramping and changing bowel habits. He admits to also having some blood in his stool at times, which he attributes to his hemorrhoids. His family history is notable for a paternal uncle with gastric cancer. He occasionally drinks alcohol and has never smoked nor used illicit or recreational drugs. On physical examination he is a well-nourished, well-developed man who is afebrile, alert and oriented, and in no apparent distress. He has no palpable masses and no hepatomegaly, and his abdomen is soft and nontender with normal active bowel sounds. The rest of his review of systems is unremarkable. His performance status is excellent. He does have a history of type II diabetes mellitus and hypercholesterolemia, which are both controlled on his current medication regimen. Vital signs and laboratory values obtained are as follows:

Blood pressure, 108/71 mm Hg
Heart rate, 95 beats/minute
Respiratory rate, 18 breaths/minute
White blood cell (WBC) count, 4.8 × 10^3 cells/μL
Hemoglobin, 11.6 g/dL
Hematocrit, 35.1%
Platelet count, 208 × 10^3 cells/μL
Total bilirubin, 0.3 mg/dL
Serum creatinine, 0.8 mg/dL
Blood urea nitrogen, 15 mg/dL
Alkaline phosphatase, 61 IU/L
Lactate dehydrogenase, 366 IU/L
Albumin, 4.2 g/dL
Hemoglobin A1C, 6.2%

Are any of the symptoms that B.R. is exhibiting associated with colorectal cancer?

Although the symptoms B.R. is describing are nonspecific in nature, the changes in bowel habits in addition to the blood in his stools are symptoms associated with the development of colorectal cancer. Given his age, symptoms, and lack of prior cancer screening, additional workup is warranted with one of the screening modalities mentioned earlier in this chapter, preferably colonoscopy.

Chemotherapy for Localized Colorectal Cancer

ADJUVANT THERAPY

CASE 99-2, QUESTION 2: After a colonoscopy, B.R. is found to have a moderately differentiated adenocarcinoma of the colon lying 18 cm from the anal verge invading through the muscularis propria with lymphovascular invasion and involvement of 8 of 25 regional lymph nodes. A CT scan of his chest, abdomen, and pelvis shows no evidence of metastatic disease. A baseline CEA level of 8.0 ng/mL (normal range, 0–3.0 ng/mL for nonsmokers and 0–6.0 ng/mL for smokers) is reported. After surgical resection, would B.R. benefit from adjuvant chemotherapy? Which chemotherapy agents or regimen gives B.R. the best chance to avoid a future recurrence?

Historically, fluorouracil (also known as 5-fluorouracil and often abbreviated as 5-FU), a fluoropyrimidine, combined with leucovorin was considered the standard chemotherapy for adjuvant treatment of stage III colon cancer based on studies that showed both an improvement in disease-free survival (DFS) and overall survival (OS) over no chemotherapy after surgery.[13] For patients with Stage II disease, only those with certain high risk features (tumors that were adherent to or invaded other organs, were obstructive, or in patients that experienced bowel perforation) appeared to gain any benefit from fluorouracil/leucovorin given after surgery.[13] Leucovorin stabilizes the binding of an active metabolite of fluorouracil known as fluorodeoxyuridine monophosphate to its intracellular target thymidylate synthase, ultimately enhancing the cytotoxicity of fluorouracil. Fluorouracil is administered primarily in two different ways—as a bolus injection over 3 to 5 minutes, and this is followed by a continuous infusion over 24 to 46 hours (depending on the regimen). Single-agent capecitabine, an oral prodrug of fluorouracil, offers convenient administration and is as effective as intravenous (fluorouracil modulated with leucovorin).[14] At present, the combination of fluorouracil and leucovorin or capecitabine monotherapy are the preferred adjuvant regimes for stage III colon cancer for patients that are over the age of 70, because this population does not seem to benefit from the addition of other cytotoxic agents to this fluoropyrimidine backbone.[15,16]

For patients younger than 70 years of age, the addition of oxaliplatin, a platinum agent, to the fluoropyrimidine backbone (either capecitabine alone or fluorouracil with leucovorin) is considered the current standard of care in the adjuvant setting for patients with stage III disease, because several landmark trials have shown the addition of oxaliplatin in this population can improve both DFS and OS over fluorouracil and leucovorin alone.[17,18] The increase in DFS and in OS with the addition of oxaliplatin was less pronounced for those patients with Stage II (node negative) disease, and so the use of oxaliplatin in this population is controversial.[15] There were several fluorouracil and oxaliplatin regimens historically used in clinical practice. However, more current practices recommend that when combining fluorouracil with additional cytotoxic agents, the infusional modality be primarily utilized rather than bolus (IV push) regimens to maximize efficacy while minimizing toxicity, although the infusional regimens do still contain a small portion of the entire fluorouracil dose given as an initial bolus injection.[19]

As stated, oxaliplatin may also be combined with capecitabine as the fluoropyrimidine backbone. This is considered equally effective to the combination with fluorouracil modulated with leucovorin, with the main difference seen in toxicity patterns. Capecitabine is given orally typically as a twice daily dose for 14 days of each 21-day cycle. Often the decision of which fluoropyrimidine to choose is multifactorial owing to the nuances of clinical practice. Potential factors that play a role in the agent chosen can include, but are not limited to, toxicity differences, institutional resources (ambulatory pump availability, etc.), insurance coverage, and patient preference. Additional factors that could influence the selection of a capecitabine-based regimen include the presence of renal impairment and relevant drug–drug interactions, particularly concomitant warfarin use. Regimens that are commonly used in the adjuvant treatment of colon cancer are noted in Table 99-2.

Irinotecan in combination with fluorouracil and leucovorin has been evaluated in the adjuvant setting for stage III colon cancer. The use of irinotecan did not produce any benefit in terms of DFS; however, toxicities were increased with the combination of irinotecan and fluorouracil versus fluorouracil alone.[20] Therefore, irinotecan is not an agent used at present time in the adjuvant setting for colorectal cancer. In addition, some of the biologics available for the treatment of metastatic colon cancer, such as bevacizumab and cetuximab, have been studied in the adjuvant setting as well. To date, none of the biologics approved for metastatic colon cancer (bevacizumab, ramucirumab, ziv-aflibercept, cetuximab, panitumumab, or regorafenib) are approved or recommended in the adjuvant setting.[17]

Table 99-2

Selected Regimens Used in Metastatic or Advanced Colorectal Cancer

Selected Colorectal Cancer Treatment Regimens—Metastatic Disease	
Regimen	**Dosing**
Oxaliplatin-Based Regimens	
mFOLFOX6[a]	■ Oxaliplatin 85 mg/m^2 IV over 2 hours, day 1

	■ Leucovorin 400 mg/m^2 IV over 2 hours, day 1 ■ Fluorouracil 400 mg/m^2 IV bolus on day 1, then 1,200 mg/m^2/day × 2 days (total 2,400 mg/m^2 over 46–48 hours) IV continuous infusion Repeat every 2 weeks
mFOLFOX6 + Bevacizumab	■ Oxaliplatin 85 mg/m^2 IV over 2 hours, day 1 ■ Leucovorin 400 mg/m^2 IV over 2 hours, day 1 ■ Fluorouracil 400 mg/m^2 IV bolus on day 1, then 1,200 mg/m^2/day × 2 days (total 2,400 mg/m^2 over 46–48 hours) IV continuous infusion ■ Bevacizumab 5 mg/kg IV, day 1 Repeat every 2 weeks
mFOLFOX6 + Panitumumab	■ Oxaliplatin 85 mg/m^2 IV over 2 hours, day 1 ■ Leucovorin 400 mg/m^2 IV over 2 hours, day 1 ■ Fluorouracil 400 mg/m^2 IV bolus on day 1, then 1,200 mg/m^2/day × 2 days (total 2,400 mg/m^2 over 46–48 hours) IV continuous infusion ■ Panitumumab 6 mg/kg IV over 60 minutes, day 1 Repeat every 2 weeks
CapeOX[a,b]	■ Oxaliplatin 130 mg/m^2 IV over 2 hours, day 1 ■ Capecitabine 850–1,000 mg/m^2 twice daily PO for 14 days Repeat every 3 weeks
CapeOX[b] + Bevacizumab	■ Oxaliplatin 130 mg/m^2 IV over 2 hours, day 1 ■ Capecitabine 850–1,000 mg/m^2 PO twice daily for 14 days ■ Bevacizumab 7.5 mg/kg IV, day 1 Repeat every 3 weeks
Irinotecan-Based Treatment Regimens	
FOLFIRI	■ Irinotecan 180 mg/m^2 IV over 30–90 minutes, day 1 ■ Leucovorin 400 mg/m^2 IV infusion to match duration of irinotecan infusion, day 1 ■ Fluorouracil 400 mg/m^2 IV bolus day 1, then 1,200 mg/m^2/day × 2 days (total 2,400 mg/m^2 over 46–48 hours) continuous infusion Repeat every 2 weeks
FOLFIRI + Bevacizumab	■ Irinotecan 180 mg/m^2 IV over 30–90 minutes, day 1 ■ Leucovorin 400 mg/m^2 IV infusion to match duration of irinotecan infusion, day 1 ■ Fluorouracil 400 mg/m^2 IV bolus day 1, then 1,200 mg/m^2/day × 2 days (total 2,400 mg/m^2 over 46–48 hours) IV continuous infusion ■ Bevacizumab 5 mg/kg IV, day 1 Repeat every 2 weeks
FOLFIRI + Cetuximab	■ Irinotecan 180 mg/m^2 IV over 30–90 minutes, day 1 ■ Leucovorin 400 mg/m^2 IV infusion to match duration of irinotecan infusion, day 1 ■ Fluorouracil 400 mg/m^2 IV bolus day 1, then 1,200 mg/m^2/day × 2 days (total 2,400 mg/m^2 over 46–48 hours) IV continuous infusion ■ Repeat every 2 weeks

	■ Cetuximab 400 mg/m^2 IV over 2 hours first infusion, then 250 mg/m^2 IV over 60 minutes weekly ■ OR ■ Cetuximab 500 mg/m^2 IV over 2 hours, day 1, every 2 weeks
FOLFIRI + Panitumumab	■ Irinotecan 180 mg/m^2 IV over 30–90 minutes, day 1 ■ Leucovorin 400 mg/m^2 IV infusion to match duration of irinotecan infusion, day 1 ■ Fluorouracil 400 mg/m^2 IV bolus day 1, then 1,200 mg/m^2/day × 2 days (total 2,400 mg/m^2 over 46–48 hours) IV continuous infusion ■ Panitumumab 6 mg/kg IV over 60 minutes, day 1 Repeat every 2 weeks

FOLFIRI + ziv-aflibercept Currently approved only in the second-line setting	■ Irinotecan 180 mg/m^2 IV over 30–90 minutes, day 1 ■ Leucovorin 400 mg/m^2 IV infusion to match duration of irinotecan infusion, day 1 ■ Fluorouracil 400 mg/m^2 IV bolus day 1, then 1,200 mg/m^2/day × 2 days (total 2,400 mg/m^2 over 46–48 hours) continuous infusion ■ Ziv-aflibercept 4 mg/kg IV over 60 minutes Repeat every 2 weeks
FOLFIRI + Ramucirumab Currently approved only in the 2nd line setting	■ Irinotecan 180 mg/m^2 IV over 30–90 minutes, day 1 ■ Leucovorin 400 mg/m^2 IV infusion to match duration of irinotecan infusion, day 1 ■ Fluorouracil 400 mg/m^2 IV bolus day 1, then 1,200 mg/m^2/day × 2 days (total 2,400 mg/m^2 over 46–48 hours) continuous infusion ■ Ramucirumab 8 mg/kg IV over 60 minutes ■ Repeat every 2 weeks
Fluoropyrimidine Treatment Regimens[b]	
Capecitabine[d] ± Bevacizumab	■ Capecitabine 850–1,250 mg/m^2 PO twice daily, days 1–14 ■ ± Bevacizumab 7.5 mg/kg IV, day 1 Repeat every 3 weeks
Bolus or infusional 5-FU/leucovorin (Roswell Park regimen)	■ Leucovorin 500 mg/m^2 IV over 2 hours, days 1, 8, 15, 22, 29, and 36 ■ Fluorouracil 500 mg/m^2 IV bolus 1 hour after start of leucovorin, days 1, 8, 15, 22 29, and 36 Repeat every 8 weeks
Simplified biweekly infusional 5-FU/leucovorin[d] ± Bevacizumab	■ Leucovorin 400 mg/m^2 IV over 2 hours on day 1 ■ Fluorouracil bolus 400 mg/m^2 IV and then 1,200 mg/m^2/day × 2 days (total 2,400 mg/m^2 over 46–48 hours) continuous infusion ± Bevacizumab 5 mg/kg IV on day 1
Miscellaneous Combination Regimens	
IROX	■ Oxaliplatin 85 mg/m^2 IV over 2 hours

Shown to be inferior in the first line to FOLFOX-based therapy	■ Irinotecan 200 mg/m^2 over 30 or 90 minutes every 3 weeks
FOLFOXIRI ± Bevacizumab Increased PFS vs. FOLFIRI alone; however, no data regarding superiority vs. sequencing patients from FOLFOX to FOLFIRI or vice versa (± Bevacizumab)	■ Irinotecan 165 mg/m^2 IV day 1 ■ Oxaliplatin 85 mg/m^2 day 1 ■ Leucovorin 400 mg/m^2 day 1 ■ Fluorouracil 1,200 mg/m^2/day × 2 days (total 2,400 mg/m^2 over 48 hours) continuous infusion starting on day 1 Repeat every 2 weeks ■ ± Bevacizumab 5 mg/kg IV, day 1
Salvage Therapy	
Regorafenib Used post progression on irinotecan, oxaliplatin, fluorouracil, and an EGFR-inhibitor (if RAS wild-type)	160 mg PO daily in the morning with a low-fat breakfast on days 1–21. Repeat every 28 days
Trifluridine/Tipiracil Used post-progression on irinotecan, oxaliplatin, fluorouracil, and an EGFR-inhibitor (if RAS wild-type)	35 mg/m^2 orally twice daily, after morning and evening meals, on days 1–5 and days 8–12 of each 28-day cycle Dose is based on trifluridine content of combination tablets BSA was capped at 2.3 m^2 in registrational trial

[a] Oxaliplatin combined with either fluorouracil or capecitabine (as in mFOLFOX6 or CapeOX) for 6 months of therapy is also used in the adjuvant setting (post-surgery) for Stage III colon cancer.

[b] Phase II data exists for bi-weekly regimens with oxaliplatin given at 85 mg/m^2 every two weeks and capecitabine given on day 1 to 7 and days 15 to 21.

[c] Fluorouracil or capecitabine ± bevacizumab is an appropriate therapy in a poor performance status patient where concerns of the added toxicity of oxaliplatin or irinotecan outweigh benefit.

[d] Capecitabine alone or fluorouracil with leucovorin alone for 6 months of therapy are also appropriate as adjuvant therapy for high-risk stage II colon cancer patient or as adjuvant therapy for patients older than 70 years old with stage III colon cancer post-surgery.

B.R. has extensive lymph node involvement, and this means he has stage IIIC disease (refer to key websites #3 and #4 for more information on staging guidelines), which places him at a high risk of recurrence; therefore, he should receive adjuvant chemotherapy after surgery. The goal of adjuvant therapy is to eradicate any residual, undetectable disease left behind after surgery and to reduce his risk of recurrence. The initial cycle of B.R.'s adjuvant chemotherapy should begin approximately 4 to 6 weeks after his surgery and continue for a total of 6 months.

ADVERSE EFFECTS OF FLUOROURACIL AND OXALIPLATIN

CASE 99-2, QUESTION 3: B.R. is scheduled to receive a modified FOLFOX6 (mFOLFOX6) regimen in the adjuvant setting. What potential adverse effects should B.R. be made aware of before receiving this regimen? Are any dose-limiting side effects associated with this therapy? Are there any preventive measures that can be taken to limit the severity of these adverse effects?

The goal of therapy in this setting is a cure; therefore, clinicians typically try to remain aggressive and limit chemotherapy dose reductions or delays while trying to maintain an acceptable toxicity profile. There are a number of chemotherapy-related toxicities that may occur during adjuvant therapy or after its completion.

Toxicities related to fluoropyrimidines include hand-foot syndrome (HFS, also called palmar-plantar erythrodysesthesia), mucositis, diarrhea, hematologic toxicities (neutropenia), photosensitivity, and rarely, cardiac toxicity (vasospastic angina). HFS is managed primarily with supportive-care measures, such as the application of topical moisturizers in addition to temporary withdrawal of fluorouracil-based therapy to allow time to heal. (See Chapter 94, Adverse Effects of Chemotherapy and Targeted Therapy for further discussion of HFS.) Once healed or decreased in its severity, fluorouracil-based therapy is often resumed at a reduced dose. The frequency and severity of HFS is increased with capecitabine versus fluorouracil.[21] Severe neutropenia is typically managed with chemotherapy dose reductions or delays, and in some cases clinicians may use the administration of granulocyte colony-stimulating factors, such as filgrastim or pegfilgrastim, to prevent febrile neutropenia while maintaining dose intensity. The incidence of neutropenia is higher with bolus fluorouracil than with infusional fluorouracil or with capecitabine.[22,23] Severe mucositis is uncommon and is mainly associated with bolus fluorouracil.[20,21] Moderate-to-mild symptoms can also occur, however, with capecitabine or infusional fluorouracil, and these can be managed with supportive-care measures, such as mild narcotic pain medications or mouthwashes that contain a local anesthetic such as lidocaine. Strategies for preventing this complication are also important and include stressing the importance of good oral hygiene and avoidance of harsh substances, which may irritate the oral mucosa or inhibit saliva production, such as alcohol, alcohol-based mouthwashes or rinses, spicy foods, and anticholinergic medications. As is the case with many fluorinated pharmaceutical agents, fluorouracil and capecitabine cause photosensitivity, which may result in mild-to-severe sunburns after sun exposure. Therefore, during fluoropyrimidine therapy, prolonged exposure to direct sunlight should be avoided and use of a sun block of SPF-15 or higher during outdoor activities is recommended.

Oxaliplatin is the newest member of the platinum family of antineoplastics, and it offers a different antitumor profile and resistance pattern than cisplatin or carboplatin. Of the three agents, oxaliplatin is highly active against colorectal tumors. Myelosuppression, primarily neutropenia and thrombocytopenia, and neurotoxicity are dose-limiting toxicities associated with its use. Oxaliplatin causes an acute, reversible neuropathy consisting of either paresthesias or dysesthesias and in some instances muscle spasms. One particular phenomenon that is distressing for patients is an involuntary laryngopharyngeal dysesthesia that can create the sensation of an inability to swallow or breathe. The acute phenomenon is reported to occur in greater than 90% of patients receiving oxaliplatin.[24,25] Although our understanding of the event is limited, it is known to be triggered by direct contact with anything cold. This sensitivity to cold as well as the aforementioned reactions generally occur within minutes of receiving the infusion and can persist up to 7 days. Avoidance of cold objects, including the eating or drinking of cold foods and beverages, should be emphasized to patients after each dose of oxaliplatin. The use of gloves, socks, and scarves can also be recommended, especially in cold weather. Delayed, cumulative neurotoxicity may also occur, and it is potentially irreversible and occurs in a dose-dependent manner. It initially develops in the distal extremities and slowly progresses in a glove and stocking distribution pattern. It is typically characterized by a persistent sensation of numbness, tingling, or burning in the extremities.

Hypersensitivity reactions have also been observed with oxaliplatin use with a reported incidence of 10% to 25%, and although the appearance of the reaction is arbitrary in that it can manifest with any dose, the median number of doses reported in those that have reacted is 7 to 9.[26] Typically, the symptoms of hypersensitivity occur during the infusion, but delayed reactions are also possible. The severity of these allergic reactions can range from mild itching or flushing to anaphylaxis. After a reaction, mild cases are often managed through premedication with antihistamines or corticosteroids (e.g., diphenhydramine 50 mg IV or orally and either dexamethasone 20 mg or another corticosteroid 15 minutes before oxaliplatin IV) in addition to prolonging the infusion of oxaliplatin. More severe reactions generally warrant discontinuation of the drug; however, there are reports in which desensitization protocols have been used successfully, allowing for continued administration.[27,28] Regardless of what is chosen, this strategy accompanies all subsequent doses of oxaliplatin.

Liver toxicity has also been reported with oxaliplatin and is mainly characterized by sinusoidal injury. This can occur in as high as 51% of patients, although blatant liver failure with oxaliplatin is rare. Splenomegaly has been reported to correlate with sinusoidal liver injury and this manifestation may also contribute to thrombocytopenia that may last long after oxaliplatin is discontinued.[29]

The primary role of chemotherapy in this setting is to reduce the risk of relapse and prolong DFS by eradicating residual, undetectable disease. A total of 6 months of adjuvant therapy is considered the current standard of care after surgery with curative intent (12 cycles of an every 2-week regimen like FOLFOX, or 8 cycles of an every 3-week strategy of capecitabine with or without oxaliplatin). A large ongoing trial is currently evaluating the necessity of 6 months versus 3 months of therapy, but the results are pending.[30] Because B.R. will receive a combination of fluorouracil and oxaliplatin in the adjuvant setting, the toxicities of these agents should be discussed before initiation of therapy. The toxicity of fluorouracil will vary depending on its dose, route, and schedule of administration. At doses used in the treatment of colorectal cancer, bolus administration is associated with more severe neutropenia and mucositis, whereas continuous infusion administration is associated with more severe HFS. Fluorouracil is also associated with photosensitivity, so B.R. should be counseled

---

on the use of SPF-15 or greater sunscreen when outdoors because of the increased risk of sunburn. The main toxicities of oxaliplatin are thrombocytopenia, neuropathy, liver toxicity, and hypersensitivity reactions. To minimize the acute neuropathy after each dose, B.R. should be counseled on the avoidance of cold objects, including the eating or drinking of cold foods and beverages. The use of gloves, socks, and scarves can also be recommended, especially in cold weather. B.R. will also have labs drawn at regular intervals prior to administration of chemotherapy to ensure that his neutrophils and platelets are at a sufficient level to give chemotherapy and to monitor for changes in liver function that can occur with oxaliplatin.

PERIPHERAL SENSORY NEUROPATHY

CASE 99-2, QUESTION 4: After eight treatments of adjuvant therapy, B.R. begins complaining of a constant numbness and tingling in his toes bilaterally. It is not interfering with his daily activities but is described as more of a nuisance. Which drug is most likely responsible for this and what course of action should be taken?

As explained earlier, the severity of peripheral sensory neuropathy (PSN) can worsen with continued doses of oxaliplatin and is not readily reversible; therefore, it is imperative that clinicians and patients work together to minimize its negative impact on various activities of daily living such as being able to button a shirt, walking up or down stairs, or realizing whether one's foot is actually touching the brake pedal as the car approaches a red light. In the hallmark clinical trial in the adjuvant setting, during the 6 months of therapy with oxaliplatin, fluorouracil, and leucovorin, 12.5% of patients reported grade 3 PSN; however, this increased to 24.1% in the 18 months after treatment assessment, indicating that PSN will continue to worsen even after cessation of oxaliplatin.[17] It does appear that over time PSN can improve off oxaliplatin as at 4 years post-adjuvant treatment grade 1, 2, and 3 PSN was observed in 11.9%, 2.8%, and 0.7%, respectively.[24] In the metastatic setting a "stop-and-go" approach to limit exposure to oxaliplatin while retaining its antitumor effects and has been shown to be beneficial in delaying the development of PSN without adversely affecting the outcomes of PFS and OS.[31,32] In this approach, oxaliplatin is withdrawn from therapy in patients with metastatic disease and is reinitiated when disease progression is noted. However, in the adjuvant setting where the goal is cure, the benefits of stopping therapy to decrease the risk of permanent PSN must be weighed against the risk of recurrent disease. Newer trials in the adjuvant setting recommend holding oxaliplatin for a period of 4 weeks in the setting of persistent grade >2 neuropathy (defined as persisting between treatments) and resuming at a dose reduction once PSN resolves to grade <1.[23] Further, permanent discontinuation of oxaliplatin is recommended for grade >2 neuropathy that does not resolve within 4 weeks.[23]

Several small trials have been conducted to evaluate the effectiveness of certain pharmaceutical agents in the management of chemotherapy-induced peripheral neuropathy. These trials have focused on either the prevention or treatment of chemotherapy-induced peripheral neuropathy and as a whole have yielded disappointing results. To date, no agent is recommended as a chemoprotectant for the prevention of oxaliplatin-induced PSN. Duloxetine, an antidepressant, has been studied in a randomized clinical trial and has shown to decrease specifically the pain component experienced by some patients with PSN including oxaliplatin-induced PSN.[33] In addition, tricyclic antidepressants such as nortriptyline and amitriptyline or an anticonvulsant such as gabapentin and pregabalin could be considered as these agents have proven beneficial and are recommended as initial therapy in other neuropathic pain settings.[34,35] It is important to note that when using adjunctive agents such as these to manage neuropathic pain, doses typically require upward titration after initiation. This strategy enables the clinician to find the dose that provides the greatest benefit. It is important to explain to the patient that these agents may take several weeks before a response is seen, and that the indication is for the pain associated with PSN—these agents have not been shown to improve numbness or tingling. Symptom relief generally requires continued daily use of these agents on a scheduled basis; however, it is important to consider weaning them with time if neuropathic symptoms either improve or show no improvement despite optimal dosing.

The timing of the symptoms that B.R. is experiencing is indicative of the cumulative toxicity oxaliplatin exerts on peripheral sensory nerves. Because B.R. has completed 8 of a planned 12 cycles of his adjuvant therapy and because his symptoms just started, the reaction would be graded as relatively mild in its severity at this point. He will likely benefit most from continued administration of oxaliplatin at a reduced dosage with diligent monitoring of his neuropathy.

Microsatellite Instability and BRAF

The ultimate goal of treatment is to individualize therapy based on patient and tumor characteristics. Prognostic markers provide information on disease outcome regardless of treatment provided. Predictive markers provide information on disease outcome based on treatment provided. As stated previously, in stage II disease, adjuvant therapy is only offered in those patients with high-risk disease. The definition of “high risk” stage II disease varies among different national guidelines but in general includes T4 tumors, less than 12 lymph nodes examined at surgery, poorly differentiated histology, perforation, and obstruction.[36] There has been increased interest in looking at microsatellite instability and mutations in BRAF to determine what stage II patients would benefit from adjuvant therapy.

Microsatellites are short repeating nucleotide sequences that are under surveillance by the mismatch repair (MMR) system. The MMR system is responsible for repair of errors that occur during DNA synthesis. Tumors are found to have microsatellite instability (MSI) if they have a defect in their MMR system. This defect results in the accumulation of mutations of microsatellites. In a pooled analysis of 5 trials of stage II and III patients where no adjuvant therapy was given, patients with MSI had a longer DFS than those that were microsatellite stable.[31] In addition, in the Stage II patients that were MSI, those treated with fluorouracil actually did worse in terms of DFS than those that were only treated with surgery.[37] At this time, it appears that MSI is prognostic in that it appears to convey a DFS benefit in stage II disease. It further appears that fluorouracil/leucovorin alone does not convey any benefit in stage II MSI disease. The benefit of adding oxaliplatin to a high-risk stage II MSI patient is unknown, and currently cannot be recommended based on MSI status alone.

The BRAF oncogene is downstream from the EGFR receptor. Mutations in BRAF have been associated with a poor prognosis, but to date, they lack any predictive value in both early stage and in advanced disease.[38,39]

Clinical Surveillance for Recurrence

CASE 99-2, QUESTION 5: After completing his treatment, how often and for how long should B.R. be monitored for recurrence of his disease?

Because the majority of recurrences occur within the first 2 to 3 years after completion of adjuvant therapy, both the American Society of Clinical Oncology and the National Comprehensive

Cancer Network (NCCN) have published guidelines that address the importance of patient follow-up and surveillance after definitive therapy for localized disease.[17,40] Both organizations agree that patients treated definitively for localized disease should be monitored regularly for at least 5 years. Because most recurrences occur relatively soon, surveillance screening should be more frequent for the first 2 years and include a history and physical examination, and CEA level performed every 3 to 6 months for these first 2 years, then semiannually thereafter for up to 5 years. In addition, future recommended imaging includes CT scan of the chest, abdomen, and pelvis performed at least annually for up to 5 years and colonoscopy within a year of surgical resection (or approximately 1 year from the original colonoscopy) and then repeated again in 3 years if no high grade adenomas are identified. During the surveillance period, development of a concerning symptom on physical examination, an abnormality on a CT scan, or a rise in CEA level above the upper limit of normal (3 ng/mL for nonsmokers or 6 ng/mL for smokers) would necessitate further evaluation for disease recurrence. After the 5-year surveillance period, an increased risk for recurrent disease remains; therefore, screening for colorectal cancer every 5 years in these patients will continue rather than the every 10-year screening recommended for the average-risk population.

B.R. should be monitored regularly for at least 5 years. Should B.R. remain disease-free throughout this 5-year surveillance period, he will be considered cured of his cancer. Because most recurrences occur relatively soon, his surveillance visits will be more frequent for the first 2 years with a history and physical examination and CEA level performed every 3 to 6 months, then semiannually thereafter. He should also have a CT scan of his chest, abdomen, and pelvis performed at least annually for 3 years. Another colonoscopy should be performed within a year of his surgical resection or approximately 1 year from his original colonoscopy, and then repeated again in 3 years.

Chemotherapy for Metastatic Colorectal Cancer

CASE 99-3

QUESTION 1: K.T. is a 64-year-old man treated approximately 2 years ago with adjuvant chemotherapy for colon cancer, which he tolerated well. On a routine surveillance visit, his CT scan shows a colon mass, two discrete liver nodules, and a nodule in the left lung that are consistent with metastatic disease. The biopsy of the liver was positive for adenocarcinoma of the colon. K.T. is feeling well and has been asymptomatic. No cytogenetics on the tumor was performed at this time. K.T.'s CBC and chemistry values were as follows:

WBC count, 7.8 × 10^3 cells/μL
Hemoglobin, 13.2 g/dL
Platelet count, 252 × 10^3 cells/μL
Serum creatinine, 1.1 mg/dL
Blood urea nitrogen, 15 mg/dL
Aspartate aminotransferase, 28 units/L
Alanine aminotransferase, 35 units/L
Alkaline phosphatase, 135 units/L
Total bilirubin, 0.8 mg/dL

K.T.'s CEA concentration was 22 ng/mL. What is the role of chemotherapy now that K.T. has a metastatic recurrence?

Metastatic colorectal cancer affects a substantial number of patients. Approximately 20% of patients have metastatic disease at initial presentation, and ~50% of patients diagnosed at any stage will eventually develop metastatic disease.[1,2]

Significant treatment advances have been made over the last decade for cases of advanced colorectal cancer such that the median OS is currently over 2 years in treated patients.[41–43] Treatments tend to include combination therapy (a fluoropyrimidine plus either irinotecan or oxaliplatin) for good performance status (PS) patients and mono-cytotoxic therapy (fluorouracil or capecitabine or irinotecan) for poor PS patients.[17] Further, agents directed against the vascular endothelial growth factor (VEGF) (e.g., the monoclonal antibodies, bevacizumab and ramucirumab, and the soluble decoy receptor, ziv-aflibercept) or against the epidermal growth factor receptor (EGFR) (cetuximab and panitumumab, both monoclonal antibodies) can be added to the chemotherapy backbone in qualifying patients. Given the number of agents currently available and that we tend to talk in terms of regimens (i.e., combining agents together) in the treatment of metastatic colorectal cancer, it is imperative to consider which agents have greater synergy and less toxicity when combined and how best to sequence these agents, because patients will most likely remain on some type of therapy throughout their disease course.

Irinotecan has been studied combined with a bolus regimen of fluorouracil and leucovorin (IFL) and an infusional regimen (FOLFIRI) as well as with capecitabine (XELIRI or CAPIRI). In general, both IFL and CAPIRI/XELIRI have fallen out of favor because of exorbitant toxicities and less efficacy than FOLFIRI.[17]

Oxaliplatin, as in the early stages of colon cancer, has been studied with both infusional fluorouracil, and leucovorin (FOLFOX) or with capecitabine (XELOX or CAPOX) in the metastatic setting. Both strategies of combining oxaliplatin with a fluoropyrimidine in the metastatic setting are equally efficacious, with again, the main differences being the toxicity profile of capecitabine versus fluorouracil /leucovorin.[19,44]

The decision to start with an oxaliplatin-based regimen (FOLFOX or XELOX) or an irinotecan-based regimen (FOLFIRI) tends to reflect differences in clinical practice rather than clinical outcomes, because sequencing studies and the results of multiple individual studies seem to indicate that both regimens are equally efficacious in the first line.[17,31–45] With the optimal sequencing of these regimens remaining unclear, the decision regarding the choice of combination therapy for first- or second-line therapy is based on prior therapy, quality of life, preexisting toxicities, comorbid conditions, and clinical practice where the patient is first seen. Surgery is typically not an option in extensive metastatic disease.

In the past decade, biologic therapies targeting VEGF (bevacizumab, ziv-aflibercept, and ramucirumab) and EGFR (cetuximab and panitumumab) have been incorporated into the treatment of many cases of metastatic colorectal cancer. In addition, regorafenib, a multi-targeted, orally administered tyrosine kinase inhibitor (TKI) and trifluridine/tipiracil (TAS-102), an orally administered cytotoxic agent, have both been shown to modestly improve OS over placebo as monotherapy in the salvage setting.

TARGETING VASCULAR ENDOTHELIAL GROWTH FACTOR

Bevacizumab is a humanized monoclonal antibody that binds to the ligand of the VEGF-2 receptor, VEGF-A. The addition to bevacizumab in the first line to oxaliplatin-based regimens FOLFOX or XELOX or irinotecan-based FOLFIRI has been shown to increase progression-free survival (PFS) versus chemotherapy alone, and OS was also improved although this seems more pronounced with FOLFIRI than with oxaliplatin-based regimens.[17,33] Bevacizumab, when continued beyond progression in the second-line setting, with either FOLFOX or FOLFIRI has shown a modest survival benefit of the addition of 1.4 months versus placebo.[46]

Two newer anti-VEGF agents, ziv-aflibercept and ramucirumab, have also been shown to provide a survival benefit to the chemotherapy backbones with which they were studied. However, the differences in how they were studied is important to note in order to apply them in clinical practice. Ramucirumab, a fully human monoclonal antibody that binds to the extracellular domain of the VEGF-2 receptor, has been shown to increase survival versus placebo by 1.6 months when combined with FOLFIRI in patients that progressed on bevacizumab plus FOLFOX.[47] Ziv-aflibercept, a soluble decoy receptor that targets the ligands VEGF-A, VEGF-B, and placental growth factor (PIGF), has also been shown to increase survival versus placebo when combined with FOLFIRI in the second-line setting after progression on oxaliplatin-based therapy; however, in the patients that had previously received bevacizumab, this benefit was less pronounced (around 0.8 months).[48]

TARGETING THE EPIDERMAL GROWTH FACTOR RECEPTOR

The EGFR receptor is overexpressed in the majority of colorectal cancers, making it an attractive target for therapy. However, 56% to 63% of these tumors will possess a downstream mutation in the RAS oncogene, a predictive biomarker for a lack of response to EGFR targeted therapy.[32,40,41] Therefore, prior to consideration of EGFR therapy in any metastatic colorectal patient, analysis must be undertaken to determine RAS status, with EGFR therapy only being offered to those that are RAS wild-type.

Cetuximab is a chimeric monoclonal antibody against the extracellular domain of EGFR. It has been studied in the first line with both FOLFIRI and with oxaliplatin-based therapy and is currently approved in combination with FOLFIRI only in the first line for patients that are RAS wild-type.[32,49] It is also active as a single agent or in combination with irinotecan even in patients with irinotecan-refractory malignancies.[50] Panitumumab, a fully human monoclonal antibody also targeting the extracellular domain of EGFR, has been shown in RAS wild-type patients to improve OS in the first-line setting when combined with FOLFOX and in the second-line setting combined with FOLFIRI in patients that had progressed on an oxaliplatin and bevacizumab containing regimen.[51,52] It may also be used as monotherapy in patients that have progressed on oxaliplatin- and irinotecan-based therapy. The trials of combining cetuximab or panitumumab with bevacizumab and chemotherapy have resulted in a decrease in PFS and increased toxicity, so this combination should not be utilized.[53,54] The choice of whether cetuximab or panitumumab is chosen as the anti-EGFR agent is more a matter of local practice and differences in prescribing habits than being data driven. They have been compared to each other in the salvage setting as monotherapy and are considered equally efficacious with the main difference being a slightly higher rate of infusion reactions with cetuximab versus panitumumab (13% vs. 3%).[55] In addition, there is currently no data to support the use of one of these agents after proven progression on the other agent.

K.T. has stage IV colon cancer with metastasis to the liver and lung. The goal of therapy for K.T. is prolongation of survival. At this point, K.T.'s cancer is not curable. Because tumor cytogenetics was not performed, K.T.'s RAS status is unknown. Therefore, EGFR monoclonal antibody at this point is not considered a first-line treatment option. K.T. should receive combination chemotherapy. Standard first-line chemotherapy involves a fluoropyrimidine in combination with oxaliplatin or irinotecan. Addition of bevacizumab to this regimen will further improve response rate and survival of K.T. In this case, K.T. is scheduled to receive the FOLFIRI plus bevacizumab regimen, which is given every 2 weeks. He will receive this chemotherapy regimen until disease progression. The FOLFIRI plus bevacizumab is given as bevacizumab 5 mg/kg IV for 10 to 30 minutes, leucovorin 200 mg/m^2 IV for 2 hours, irinotecan 180 mg/m^2 IV for 90 minutes, and fluorouracil 400 mg/m^2 given as a bolus, which is then followed by 2,400 mg/m^2 infused for 46 hours.

IMMUNOTHERAPY FOR MSI-H TUMORS

Immunotherapies have broadly made their way into different areas of oncology; however, until recently, colorectal cancer patients, did not seem to benefit from these agents.[56] Two new drugs have been approved in metastatic colorectal cancer, specifically for patients with mismatch repair deficient tumors. Pembrolizumab, given as a single agent, was granted accelerated approval from the FDA on May 23, 2017 for treatment of metastatic colorectal cancer that is deficient in MMR and has progressed following treatment with a fluorpyrimidine, oxaliplation, and irinotecan; nivolumab, given as a single agent, was granted accelerated approval for this group of patients on July 31, 2017.[57,58] Approval for both was based on tumor response rate, and as a condition of accelerated approval, further studies are required to confirm the clinical benefit of these two agents for this indication.[57,58] However, while promising, patients with mismatch repair deficient colorectal cancer represent only a small subset of patients with metastatic disease (~3% of the population vs ~22% of those with stage II colon cancer and ~12% of those with stage III colon cancer).[56]

HEPATIC METASTASES

Colorectal-related metastases most commonly arise in the liver, and 20% of patients are diagnosed with synchronous liver metastases.[2] Surgical resection, if possible, offers the potential for long-term survival in colorectal patients with isolated liver metastases.[59,60] Further, because liver metastases derive most of their blood supply from the hepatic artery, direct administration of anticancer drugs into the artery can provide high drug concentrations to the area of tumor involvement and, as such, has been an area of therapeutic interest. Hepatic intra-arterial administration of floxuridine (FUDR), a fluoropyrimidine with a high first-pass metabolism, offers the ability to deliver chemotherapy to the liver metastases with virtually no systemic exposure or side effects.[61] However, the hepatobiliary toxic effects of hepatic arterial FUDR include elevations in AST, alkaline phosphatase, and bilirubin levels, and in severe cases can evoke changes similar to sclerosing cholangitis.[62] To prevent this, FUDR is infused with dexamethasone for its anti-inflammatory effect.[63] Hepatic intra-arterial therapy is usually restricted to treatment centers that have expertise for this modality. The major limitation for such treatment is that undetected metastases located elsewhere would not be exposed to the agents as they would after systemic administration. Further, there is a paucity of data related to giving FUDR via the hepatic artery in combination with systemic chemotherapy but, from the limited data available, it does seem that coadministration with systemic bevacizumab may increase the risk of biliary toxicity.[64]

Pharmacogenomics of Irinotecan and Fluorouracil

CASE 99-3, QUESTION 2: Fourteen days after receiving FOLFIRI plus bevacizumab, K.T. presented to the emergency room complaining of fever (101.2°F). On further evaluation, K.T. was identified as having febrile neutropenia with a WBC count of 1.2×10^3 cells/μL and an absolute neutrophil count of 650 cells/μL. He was admitted to the hospital for treatment. Is there an accurate method for predicting this outcome in K.T.? Can K.T. continue to receive this therapy?

Recent discoveries in the field of pharmacogenomics have identified several important genetic variations (polymorphisms) that partly account for inter-patient variability regarding the tolerability and efficacy of some drug therapies. Dihydropyrimidine dehydrogenase (DPD) is the rate-limiting enzyme responsible for the breakdown of fluorouracil to dihydrouracil and eventually to

---

fluorinated ß-alanine. The cytotoxic effects of both fluorouracil and capecitabine can only occur after conversion to active metabolites, and the amount of fluorouracil available for this conversion is determined by the extent of its breakdown.[65] DPD is subject to genetic polymorphism, which can lead to a deficiency in its activity.[66] Approximately 3% to 5% of the population will have a partial DPD deficiency, with 0.2% of the population estimated to have complete loss.[60,67] While several tests are currently available that attempt to identify this deficiency, no single test has the specificity and positive/negative predictive values to accurately predict a true lack of enzyme activity.[68] Further, most studies to date that evaluated testing for DPD deficiency prior to administration of fluorouracil-based therapy only addressed reduced toxicity but not whether dose reduction was actually necessary.[62,69,70]

Uridine diphosphate glucuronosyltransferase (UGT) enzymes are responsible for the glucuronidation of bilirubin and other endogenous substrates as well as drugs and other toxins.[71] The enzyme UGT1A1 is responsible for the glucuronidation of SN-38, the active metabolite of irinotecan. Reductions in glucuronidation and accumulation of SN-38 are associated with greater toxicity. Of the known genetic polymorphisms of UGT1A1, one polymorphism in particular (UGT1A1*28) has been associated with decreased glucuronidation and therefore prolonged exposure to SN-38.[72,73] Studies have shown that those homozygous for the UGT1A1*28 allele are at an increased risk of neutropenia.[72] Although not consistently observed among trials, severe diarrhea has also been observed with genetic polymorphisms of UGT1A1.[72] However, while the ability to test for this polymorphism is available, the low sensitivity (i.e., the ability of this test to correctly identify all patients at risk of severe neutropenia) and the lack of consensus guidelines that outline how to use the results limit its widespread use in clinical practice.[72] However, practitioners should still exercise caution when treating patients with either a known or suspected deficiency in dihydropyrimidine dehydrogenase or a known polymorphism in UGT1A1.

K.T. should receive empiric antibiotic therapy and his chemotherapy should be held until both his fever and neutropenia resolve. Because he did not experience febrile neutropenia with his previous adjuvant therapy, it is unlikely he would harbor a DPD deficiency. A dose reduction of fluorouracil could be considered. More importantly, a reduction of his irinotecan dose is warranted before resuming his chemotherapy to reduce the risk of fever and neutropenia with consecutive cycles. The FDA-approved Invader UGT1A1 molecular assay is commercially available to detect the UGT1A1*28 polymorphism. If it is known that a patient has this polymorphism, an empiric reduction in the dose of irinotecan is recommended; however, its use is not generally recommended for determining reductions of subsequent doses of irinotecan after a toxic event.

Adverse Effects of Fluorouracil, Irinotecan, and the Vascular Endothelial Growth Factor Inhibitors

CASE 99-3, QUESTION 3: K.T. was discharged from the hospital after 4 days without identification of any infection. K.T. presents to clinic to receive a second cycle of FOLFIRI plus bevacizumab. He is now more cognizant of chemotherapy's adverse effects. He states that after his first cycle of chemotherapy, he also experienced abdominal cramping followed by profuse watery bowel movements for 3 days. He reported periods of nose bleeds lasting up to 2 weeks as well, which he never had in the past. The following laboratory values were also noted:

WBC count, 4.5 × 10^3 cells/μL
Hemoglobin, 12.5 g/dL
Platelet count, 210,000 cells/μL
Serum creatinine, 1.3 mg/dL

What can be done to alleviate or avoid these symptoms? K.T. would like to know more information about the side effects of chemotherapy agents he is receiving.

The incidence of irinotecan-induced diarrhea varies depending on the dosing schedule used and its combination with other chemotherapeutic agents. Trials in metastatic colorectal cancer have reported rates of grade 3 or 4 diarrhea of 20% to 30% depending on which irinotecan-based regimen is used.[28,74] The active metabolite of irinotecan, SN-38, is capable of producing acute abdominal cramping and diarrhea, which is a cholinergic-mediated process. Administration of subcutaneous or IV atropine at doses typically lower than those used in the cardiac setting is recommended for the treatment of acute diarrhea caused by irinotecan. The occurrence of diarrhea can also be delayed; thus, the use of an oral antidiarrheal is recommended if this occurs. A regimen of oral loperamide 4 mg with the first loose bowel movement, followed by 2 mg every 2 hours during the day or 4 mg every 4 hours in the evening, is recommended until the patient is diarrhea-free for a period of 12 hours.[75] If severe diarrhea symptoms persist for more than 48 hours in spite of these measures, patients should be instructed to seek emergency medical attention. Insufficient hydration resulting from diarrhea may lead to electrolyte losses and life-threatening consequences.

The key adverse effects of fluorouracil, oxaliplatin, and irinotecan are discussed under Case 99-2, Questions 3 and 4, and Case 99-3, Question 2. Although the VEGF inhibitors (bevacizumab, ziv-aflibercept, and ramucirumab) may share some overlapping toxicities with traditional chemotherapy, the majority of their effects are unique. Although cytotoxic agents are associated with myelosuppression, antiangiogenesis agents (i.e., VEGF inhibitors) do not target proliferating cells. Hence, they do not cause this type of toxicity. All VEGF inhibitors carry the risk of grade 3 or 4 bleeding events and gastrointestinal perforation which, while severe and require immediate medical attention, are also relatively rare (<3% and <2% with bevacizumab, respectively).[76] Other adverse events deemed as VEGF inhibitor-related are arterial thrombosis, hypertension, proteinuria, and wound-healing complications.[77] Monitoring of blood pressure and the pharmacologic management of diagnosed hypertension while on VEGF-inhibitor therapy is essential. In addition, because of the wound-healing complications, the use of VEGF-inhibitors should be stopped at least 6 to 8 weeks prior to planned surgery and should not be resumed until the patient has fully healed (at least 4–6 weeks).[78,79] Finally, a rare but serious side effect of posterior reversible encephalopathy syndrome (PRES) has been reported with agents that target VEGF including bevacizumab, requiring immediate medical attention and discontinuation of therapy.[80,81]

The epistaxis K.T. is experiencing with this cycle of chemotherapy may be attributed directly or indirectly to his current regimen. Although fluorouracil and irinotecan may also cause bleeding, this is usually related to their myelosuppressive effects on platelet progenitors. Because K.T. has a platelet count of 210,000 cells/μL on his recent laboratory work, this bleeding is more likely associated with bevacizumab use.

CASE 99-3, QUESTION 4: About 10 months into his treatment, K.T. had a CT scan that suggested progression of the liver and lung masses. Cytogenetic analysis of tissue from his old tumor biopsy was requested. The cytogenetic results suggested wild-type RAS and no mutation of BRAF. What should be the best second-line treatment option for K.T.'s metastatic disease?

K.T. has not received anti-EGFR monoclonal antibody–based chemotherapy. A tumor tissue analysis now reveals that it contains wild-type RAS and negative BRAF cytogenetics. Therefore, K.T. may receive benefit from anti-EGFR monoclonal antibodies. In addition, irinotecan in combination with EGFR antibodies have synergistic activity; therefore, a regimen of irinotecan and anti-EGFR (cetuximab or panitumumab) combination would be a good choice. In many cases the fluoropyrimidine is continued as well.

Adverse Effects of Epidermal Growth Factor Receptor Inhibitors

DERMATOLOGIC REACTIONS

CASE 99-3, QUESTION 5: K.T. will receive the following combination chemotherapy regimen: FOLFIRI (dosed as before with the dose reductions for irinotecan as previously noted because of his episode of febrile neutropenia) and cetuximab at 500 mg/m^2. Each cycle is to be repeated every 2 weeks. What is the most common adverse effect KT is likely to experience with his new anti-EGFR therapy? How can this toxicity be minimized?

In addition to diarrhea, dermatologic toxicity related to EGFR therapy occurs in more than 90% of metastatic colorectal cancer patients treated with these agents. Epidermal growth factor receptor skin reactions typically occur within 7 to 10 days of therapy, and most often present as a maculopapular rash on the face or upper torso of patients.[82] The rash may cause discomfort and reduce quality of life. Both cetuximab and panitumumab have recommendations for dose reductions or the withholding of therapy based on rash severity. Collaborative efforts have been made across clinical disciplines to develop treatment strategies for EGFR-induced dermatologic toxicities based on their severity. Strategies for preventing or limiting the severity of EGFR dermatologic toxicities have also been explored, including the use of a daily regimen of skin moisturizer, sunscreen, topical 1% hydrocortisone cream, and doxycycline.[83] In addition to their antimicrobial properties, the tetracycline class of antibiotics possesses anti-inflammatory properties and anti-proliferative effects on lymphocytes, which makes it a reasonable class of agents to consider given the proposed mechanisms involved in EGFR rash development. Two studies have revealed that the use of either minocycline or doxycycline as preemptive treatment (i.e., given prior to the first dose of either cetuximab or panitumumab and continued throughout therapy) can significantly reduce the severity of the rash but not the overall incidence of occurrence.[84,85]

K.T. would most likely develop an EGFR-inhibitor rash. A strategy focused on skin moisturization and protection combined with a daily application of hydrocortisone cream and the administration of doxycycline 100 mg twice daily or another tetracycline derivative could also be considered.

INFUSION-RELATED REACTIONS

CASE 99-3, QUESTION 6: K.T. comes in for his first dose of cetuximab with FOLFIRI. Within minutes of receiving the initial cetuximab infusion, K.T. becomes hypotensive and begins having difficulty breathing. What measures should be taken as quickly as possible?

The incidence of grade 3 or 4 infusion-related reactions reported in clinical trials is less than 3.5% with cetuximab and even less for panitumumab.[50,51,86,87] Because cetuximab is a chimeric monoclonal antibody, the higher incidence of reactions is not surprising. Therefore, cetuximab administration requires premedication with diphenhydramine, whereas panitumumab does not. Although the incidence estimate for hypersensitivity is less than 5%, these reactions may be underestimated, especially in the middle southern region of the United States where a higher incidence has been observed.[88] It is not currently known why there is a greater propensity for severe hypersensitivity reactions in patients in this region of the country.

Because of the severe nature of the reaction experienced by K.T., rechallenging with cetuximab at this point would be contraindicated.

Salvage Therapy in Metastatic Colorectal Cancer

Regorafenib, a multi-kinase inhibitor targeting VEGF, as well as multiple other protein kinases (KIT, RET, BRAF, PDGFR, and FGFR) was approved in the United States for use in metastatic colon cancer. It is currently utilized as salvage therapy (i.e., in patients who have been previously treated with fluoropyrimidine-, oxaliplatin-, and irinotecan-based chemotherapy, with an anti-VEGF therapy, and, if RAS wild-type, with an anti-EGFR therapy). Regorafenib has been shown versus placebo to provide a modest survival advantage of 1.4 months in this patient population. However, toxicity and its management are very important with the most common grade 3 or higher adverse events being HFS, fatigue, diarrhea, hypertension, and rash.[89] Regorafenib has a half-life of 26 to 28 hours with two active metabolites (M2 and M5) with M5 having a half-life of 48 hours which, owing to its anti-VEGF properties, is important to consider as the same precautions apply for bleeding risk and wound healing issues as for the traditional VEGF inhibitors.

Trifluridine, a thymidine-based nucleic acid analog, combined with tipiracil hydrochloride, a thymidine phosphorylase inhibitor, is another oral agent approved in the salvage setting for metastatic colon cancer. Trifluridine is the active cytotoxic agent, and tipiracil prevents the rapid degradation of trifluridine once administered, and the combination is abbreviated as TAS-102.[90,91] It is administered at a dose of 35 mg/m^2 orally once daily on days 1 to 5 and days 8 to 12 of each 28-day cycle. Compared with placebo in the salvage setting, it has also been shown to convey a modest survival benefit of 1.8 months; however, unlike targeted therapy, TAS-102 is cytotoxic, and as such has more of the traditional chemotherapy side effects.[92] The main grade 3 or higher toxicities associated with TAS-102 were hematologic (i.e., neutropenia, anemia, and thrombocytopenia).[93]

CHEMOTHERAPY AND RADIATION FOR EARLY-STAGE RECTAL CANCER

Approximately one-third of newly diagnosed colorectal cancers originate from the rectum.[3] The differentiation between cancers of the colon and rectum lies in their location and their propensity for recurrence at or near the site of origin after treatment. If the location of B.R.'s tumor had been within 12 to 15 cm from the anal verge, he would have been diagnosed with rectal cancer (Case 99-2). The main difference between rectal cancer and colon cancer treatment lies primarily in patients with stage II or stage III disease. Unless contraindicated, radiation therapy is incorporated into the treatment plan of patients with stage II or stage III disease of the rectum. In addition, slightly different surgical techniques are used and a short course of fluorouracil or capecitabine chemotherapy is administered in combination with the radiation until it is complete. When combined with

---

chemotherapy, radiation can significantly reduce local recurrence rates.[93–95] An area of debate is the timing of chemoradiotherapy and whether it should be started before (neoadjuvant) or after surgery (adjuvant). Both strategies appear to be equally effective, so other issues are considered when choosing one modality over the other. Adjuvant chemoradiotherapy may avoid overtreatment of disease, whereas a neoadjuvant approach of chemoradiotherapy before surgery has the advantage of potentially shrinking the tumor and giving the surgeon a greater chance of obtaining negative margins, perhaps allowing for a less radical procedure and preservation of the anal sphincter. Another difference between tumors of the rectum and colon is the vascular drainage by the venous system. The colon is drained by the mesenteric veins of the hepatic portal system, whereas more distal portions of the rectum are drained by veins that empty into the inferior vena cava. This plays a role in the initial site of metastatic development for each disease. Although the liver is the most common overall site of colorectal cancer metastasis, when compared with the colon, cancers of the distal rectum are more likely to metastasize to the lungs because of the differences in their respective vasculature.

Prostate Cancer

Marina D. Kaymakcalan and Christy S. Harris

	CORE PRINCIPLES	CHAPTER CASES
1	Risk factors for the development of prostate cancer include age, family history, ethnicity, and diet.	**Case 100-1 (Questions 1, 2), Figure 100-1, Figure 100-2**
2	Screening through the use of prostate specific antigen (PSA) testing and digital rectal exams allows for early identification of prostate cancer. There is now concern that prostate cancer is being overdiagnosed.	**Case 100-1 (Question 3), Case 100-2 (Question 1), Table 100-1**
3	The PSA, Gleason score, and tumor stage can determine how aggressive the prostate cancer is and are considered prognostic factors for the risk of recurrence.	**Case 100-2 (Questions 2,3), Table 100-2, Figure 100-3**
4	Most prostate cancers are slow growing and some men may not ever develop symptoms of disease. Therefore, observation and active surveillance are options for certain men with early stage disease and shorter life expectancies.	**Case 100-2 (Question 4), Table 100-3**
5	Treatment of localized disease includes surgery, radiation, and/or androgen deprivation therapy. Androgen deprivation therapy is first line treatment for advanced prostate cancers. It lowers testosterone in the body to a castration level of ≤ 50 ng/ml. This can be accomplished through surgical (orchiectomy) or chemical (gonadotropin-releasing hormone analogs) means.	**Case100-2 (Question 5), Case 100-3 (Questions 1,2), Table 100-4, Figure 100-4**
6	Castration-resistant prostate cancer occurs when the cancer has acquired a mechanism of resistance in the presence of hormonal therapy and is no longer responding to hormonal therapy manipulation alone.	**Case 100-3 (Questions 3)**
7	Cytotoxic chemotherapy or immunotherapy may be used in metastatic disease. Metastases often occur in the bone, requiring therapy to decrease skeletal-related events.	**Case 100-4 (Questions 1,2), Table 100-5**
8	Adverse effects of prostate cancer include urinary and sexual issues but are often not a problem until the disease is advanced. Complications of therapy include cardiovascular and metabolic issues.	**Case 100-5 (Question 1), Case 100-6 (Question 1), Table 100-6**
9	Prevention of prostate cancer with finasteride or dutasteride has been studied and may be an option for select men with high risk.	**Case 100-7 (Question 1)**

INCIDENCE, PREVALENCE, AND EPIDEMIOLOGY

Prostate adenocarcinoma is the most common malignancy in American men and is the second leading cause of cancer death in men in the United States. It is a disease occurring mainly in older men with the average age of diagnosis being 66 years.[1] The incidence of prostate cancer is estimated to be 220,800 cases with 27,540 deaths in 2015,[2] which correlates to 1 chance in 7 of eventually being diagnosed with prostate cancer and about 1 chance in 38 of eventually dying of it.[1] Progress in treatment and increased public awareness has improved the 5-year overall survival to 98.9% with rates of new diagnoses falling an average of 4.3% each year over the last 10 years.[1] Because of the widespread use of screening, prostate cancer is being found in earlier stages, which allows for the possibility of earlier treatment that is less invasive with fewer adverse effects. However, the screening guidelines are changing because of what is perceived as an overdiagnosis of the cancer with a risk of overtreatment.

PATHOPHYSIOLOGY

The prostate is a walnut-shaped gland that sits directly below the bladder and is anterior to the rectum with the urethra running through the center. This location gives rise to many of the urinary, rectal, and sexual symptoms that men may experience in advanced cancer. The prostate consists of lobular glands that produce the fluid that protects and nourishes the sperm cells within the semen. This fluid is also rich in prostate-specific antigen (PSA), a glycoprotein that enhances sperm motility.[3] Cells within the prostate convert testosterone into the more potent dihydrotestosterone (DHT) by the enzyme 5-α-reductase, which stimulates growth of the cells within the prostate. Cancer can often be found confined within the capsule of the prostate if discovered early or may extend out of the capsule into the surrounding seminal vesicles and bladder neck. Eventually, systemic spread can occur via the lymphatics to involve the bone, lung, or liver.[4]

CLINICAL PRESENTATION AND DIAGNOSIS

Because of the ability to screen for prostate cancer for early identification, symptoms are rarely present at the time of diagnosis. Symptoms usually manifest after the cancer has spread beyond the prostate. At that point, the most common sign in men older than 50 years of age is bladder outlet obstruction, including hesitancy, nocturia, incomplete emptying, and diminished urinary stream. In metastatic disease, bone pain, anemia, or pancytopenia may be present.[4]

The use of routine PSA testing in men at risk for prostate cancer allows for early detection and diagnosis of prostate cancer, although rises in the serum PSA do not automatically indicate cancer. Although PSA is highly specific to the prostate, it is not specific to cancer with an overall sensitivity of ~50% to 70%.[5] Normal PSA levels in the blood are generally considered to be <4 ng/mL but begin to rise in men as they age, often in the setting of benign prostatic hypertrophy (BPH). Median PSA levels are 0.7 ng/mL in ages 40 to 49 and 0.9 ng/mL in ages 50 to 59.[6] Factors that can falsely elevate PSA levels are inflammation of the prostate, urinary retention, prostatic infection, ejaculation, or trauma.

Certain medications and supplements can affect PSA levels, which warrant careful review of a patient's medication history. The 5-α-reductase inhibitors can cause a decrease in the serum PSA by up to 50% within 6 to 12 months after initiation. Some herbal supplements, such as saw palmetto, may also falsely lower the PSA.[5] Men with PSA levels of 4 to 10 ng/mL have a 30% to 35% chance of having prostate cancer. If the level increases above 10 ng/mL, there is over a 67% risk of a prostate cancer diagnosis.[6] However, the use of PSA alone may not be adequate for screening and diagnosis as PSA elevations are not observed in up to 15% of men with prostate cancer.[1] A digital rectal exam (DRE) may be performed in conjunction with the PSA level. The placement of the prostate directly in front of the rectum allows the practitioner to feel the outside of the prostate, which should be smooth with any nodules, indurations, or asymmetry felt being suspicious for cancer.

To definitively diagnose prostate cancer, trans-rectal ultrasound (TRUS)-guided needle biopsies are used. It is important to obtain 10 or more core biopsies in a single setting as differences in pathology can be seen within different cores. Treatment will be decided by the extent and aggressiveness of the disease along with the overall health and life expectancy of the patient. Staging of prostate cancer determines the extent of the disease using the TNM (T, tumor size, N, node status, and M, sites of metastases) classification from the American Joint Committee on Cancer, although clinically it is usually referred to as local, locally advanced, and metastatic. Aggressiveness is determined by the grade and rate of growth of the cancer cells.[4,6]

OVERVIEW OF TREATMENT

Treatment modalities of prostate cancer can include surgical removal of the prostate, radiation therapy, hormonal therapy, and chemotherapy. Because prostate cancer is fueled primarily by DHT, hormonal therapy will comprise the mainstay of treatment. Only in the metastatic setting, after the failure of hormonal therapy will cytotoxic chemotherapy be utilized. As well, the option to simply observe the patient is an alternative in certain situations. Prostate cancer can be a very slow-growing disease and, if the right men are chosen, may be monitored with no treatment.

For patients diagnosed with cancer confined to the prostate, removal of the prostate, prostatectomy, or radiation to the prostate are the primary treatment options for definitive local therapy. Radiation therapies most commonly used in practice include external beam and brachytherapy. Brachytherapy consists of small pellets of radioactive material that can be placed into the prostate in small volume disease. These treatments can provide an opportunity for cure in patients with locally confined prostate cancer. Eighty percent of patients will be diagnosed in this stage and have a 5-year survival of 100%. With more advanced cancer, in which there is an increased risk of recurrence, the addition of gonadotropin-releasing hormone (GnRH) therapy to radiation may be necessary. Locally advanced cancer is diagnosed in 12% of patients and also has a 100% 5-year survival rate. Only after failure of hormonal therapy will chemotherapy be used. A number of cytotoxic agents as well as immunologic therapy are available for the treatment of castration-resistant metastatic disease. Although only 4% of patients are initially diagnosed with metastatic disease, their 5-year survival is only 28%.[7] Therapy in the different stages of prostate cancer will be discussed in more detail in the following.

RISK FACTORS

CASE 100-1

QUESTION 1: S.J. is a 50-year-old African-American male who has never been screened for prostate cancer. He has no comorbidities, does not smoke, exercises regularly, and has a diet consisting mainly of red meat 4 to 5 times a week with few vegetables and fruit. What are S.J.'s risk factors for prostate cancer?

Age

Risk factors are important in identifying those men who are most likely to develop prostate cancer and also helps identify those who will most benefit from screening. Age is the most important factor with over half of all cases occurring after the age of 65 and rarely occurs before 40 years of age. Median age at time of death is 80.[1]

Ethnicity

The risk for development of prostate cancer begins to increase after the age of 50 in white men and after age 40 in black men. In the United States, the highest risk is in African Americans with lower survival rates (Fig. 100-1). Prostate cancer also has one of the largest disparities in death rates between black and white men, which is about 2.5× higher in black men.[2] This ratio was seen in previous decades before the era of PSA testing as well. Black men tend to be diagnosed at a younger age with more advanced tumors having a 1.5-fold higher incidence of metastatic disease at presentation.[6] It is suggested that sub-Saharan ancestry may be more relevant than geographic location in a study of African and Caribbean men. Japanese men have the lowest risk and are also known to have a lower level of 5-α-reductase activity. However, it is unknown whether these differences in incidence among ethnicities are really because of genetic or environmental causes.[4]

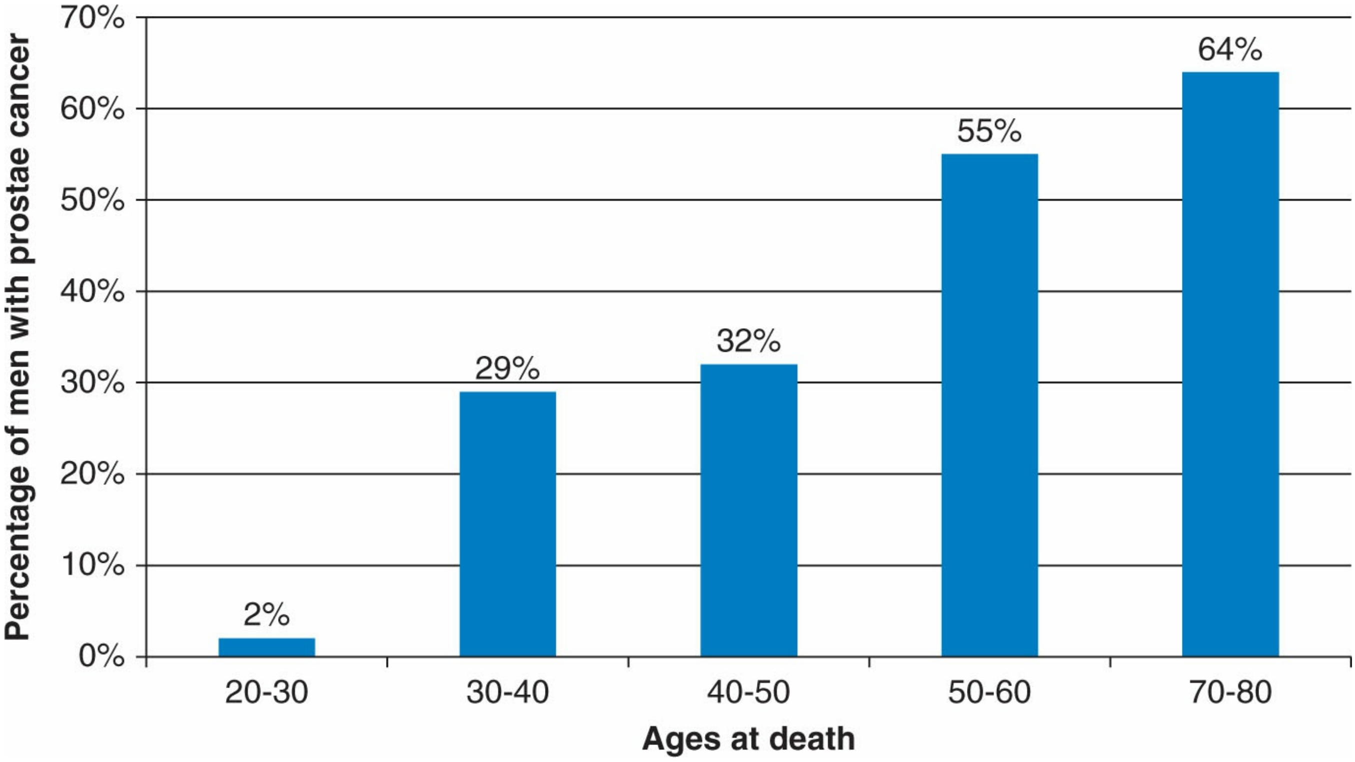

Figure 100-1 Percentage of men found to have prostate cancers at autopsy after dying of unrelated causes in the era prior to standardized PSA testing.[16]

Family History

Family history confers up to a 2.5-fold increased risk if a man's brother or father has been diagnosed by age 60.[6] If two or more first-degree relatives develop prostate cancer, then the risk is increased sevenfold to eightfold compared to the general population. Younger age at diagnosis in a family member is a higher risk than a family member who is diagnosed later in life.[1,4]

Diet and Lifestyle

Diet and lifestyle are also associated with a risk of prostate cancer. Those men having a diet with any of the following have a higher risk of developing prostate cancer: diet high in saturated fats and red meat and low intake of fruits, vegetables, tomato products, fish, or soy.[1,4] Vitamin D, calcium, lycopene, zinc, omega-3 fatty acids, a-linoleic fatty acids, selenium, vitamin E, statins, and nonsteroidal anti-inflammatory medications have been correlated with decreased risk in observational studies, but it is not sure in what way they affect the disease.[4] Several of these agents have been investigated as dietary supplements in prospective trials, but the studies did not show a benefit.

Genetic Syndromes

Germline BRCA2 mutations are associated with a twofold to sixfold increase in the risk of prostate cancer. It is not known exactly how much the BRCA1 mutation affects prostate cancer, although the two are often considered together. Cancers in men with these mutations are more aggressive, occur earlier, and are associated with a significantly reduced survival time.

Men with Lynch syndrome (germline mutations in MLH1, MSH2, MSH6, PMS2, or EPCAM) have a twofold to fivefold increase in the risk of prostate cancer. However, these cancers act similarly to those cancers without the mutation, so they are not more aggressive or occur at any earlier age.[1]

S.J. has the following risk factors for the development of prostate cancer: race and diet. Modifiable risk factors include maintaining his exercise regimen and making some changes to his diet, with less red meat and incorporating fish into his regular diet, as well as more fruits and vegetables.

CASE 100-1, QUESTION 2: S.J. has learned that his 47-year-old brother was just diagnosed with advanced prostate cancer. How has S.J.'s risk changed?

Because S.J. now has a first-degree relative who has been diagnosed with prostate cancer, especially before the age of 60, his risk has increased substantially (2.5-fold).

SCREENING

CASE 100-1, QUESTION 3: After S.J.'s brother's diagnosis, he becomes concerned and makes an appointment with his primary care office to discuss screening. Should S.J. begin routine screening for prostate cancer?

In the past 25 years, 5-year survival rates increased from 68.3% to 99.9%, attributed in part to early detection, with a 10-year survival rate of 97.8% and a 15-

year rate of 91.4%.[8] There are several guidelines for the screening of prostate cancer, including those of the American Cancer Society,[9] National Comprehensive Cancer Network (NCCN),[5] and the American Urological Association[10] (Table 100-1). Historically, men over the age of 50 were encouraged to have a PSA screening yearly. There was a steep rise in the diagnosis of prostate cancer once PSA screening was put into effect in the early 1990s; from <100 cases per age-adjusted 100,000 in 1975 and peaking at 240 cases per 100,000 in 1992, at the time of writing it is fairly constant rate of 158 cases per 100,000.[4] However, there is now some controversy among different entities regarding the appropriate recommendations for PSA screening. Prostate cancer is a relatively slow-growing cancer that may not be life threatening to some patients and potentially would not need treatment. Because it occurs primarily in older men, a number of males might not ever have symptoms of the disease that would cause them to be tested if not for routine screening.

The Prostate, Lung, Colorectal, and Ovarian (PLCO) Screening Trial randomized over 76,000 US men to strict annual PSA and DRE screening or to standard practice. It was found that prostate cancer was identified more often in the annual screening group, but that it did not change the rate of fatal disease.[11] However, a European study that randomized over 182,000 men to yearly screening or to no screening found that in the screening group, the relative reduction in risk of death was 21% at a median follow up of 11 years. To prevent one death from prostate cancer, 1,055 men would need to be screened and 37 cancers would need to be detected.[12] Therefore, it is being recognized that prostate cancer may be overdiagnosed (over-detection), especially at older ages. Overdiagnosis is typically defined as detecting a disease when it would not otherwise have shortened lifespan or resulted in adverse effects.[13] The United States Preventive Services Task Force analyzed data from several trials and concluded that for every 1,000 men between the ages of 55 and 69 who were screened, 0 to 1 death from prostate cancer would be avoided, and that 110 men would be diagnosed with prostate cancer. However, 100 to 120 men would have a false positive that would result in an unnecessary biopsy.[14] There are risks associated with any potential diagnosis, including risks during biopsy such as infection, bleeding, and dysuria, along with risks associated with unnecessary treatment, which need to be taken into account in the risk-to-benefit ratio of screening. These studies highlight the need for selective screening to avoid overdiagnosis and overtreatment while not compromising long-term survival.

Table 100-1

Prostate Cancer Screening Guidelines for Average and Elevated Risk Patients

	Average Risk	Elevated Risk

ACS,[9] 2010	≥10 year life expectancy: Informed and shared decision-making beginning at age 50 If PSA <2.5 ng/mL, repeat every 2 years If PSA ≥2.5 ng/mL, repeat annually If PSA ≥4 ng/mL, consider biopsy <10 year life expectancy: If asymptomatic, offer no screening	Higher risk (African American, family history of diagnosis <65 years of age), ≥10 year life expectancy: Informed and shared decision-making beginning at age 45 <10 yr life expectancy: If asymptomatic, offer no screening Appreciably higher risk (multiple family members diagnosed before age 65), Informed and shared decision-making beginning at age 40 <10 yr life expectancy: If asymptomatic, offer no screening
NCCN 1.2017[5]	Begin testing at age 45 in men expected to live >10 years From age 45-75: If PSA ≥ 1.0 ng/mL, repeat every 1-2 year intervals If PSA <1.0, ng/mL, repeat every 2-4 year intervals If PSA >3 ng/mL or very suspicious DRE, consider biopsy	African American and men with a family history Screening is not different than average risk but discussion with providers should occur several years earlier; consider screening every year instead of every other year
	Individualize after age 75 in select patients who are very healthy with no comorbidities: If PSA <4 ng/mL, repeat every 1-4 years If PSA ≥4 ng/mL or very suspicious DRE, consider biopsy	BRCA2 (and BRCA1); begin discussion of screening at age 40
AUA,[10] 2013	Age 55–69—shared decision-making; every 2+ years No screening ≥70 if life expectancy less than 10–15 years	High risk (African American or family history)—≤55 individualized decision
USPSTF,[14] 2012	Do not recommend routine screening with PSA	

Guidelines are consistent in their recommendation that men over the age or 70 to 75 do not need to be screened as they have not been diagnosed with cancer at this time and are more likely to die of unrelated causes before ever having any symptoms in this slow-growing cancer. Guidelines emphasize considering the life expectancy of the patient and not screening those whose expectancy is less than 10 to 15 years. For those at an elevated risk of developing prostate cancer (e.g., family, ethnicity, or other risk factors), screening may begin earlier. However, many of the guidelines are advocating that men should have a discussion with their doctor regarding any risk factors that they have and together decide whether they should undergo screening and at what age to start, depending on their risk factors, comorbidities, and personal preferences.[5,9,10] For S.J., because of his elevated risk due to his brother's diagnosis and his ethnicity, as well as his modifiable risk factors, it may be considered prudent to begin screening. However, this should be discussed with his doctor to ensure that he recognizes all of the benefits and risks of screening.

PROGNOSTIC FACTORS

CASE 100-2

QUESTION 1: C.W. is a 67-year-old man who began routine screening for prostate cancer with his primary care physician 15 years ago. His PSA history is listed below. His PSA drawn on August 5, 2012 is 6.68 ng/mL. DRE is negative. He has an excellent performance status being fully active and able to carry out all pre-disease activities without restriction. On physical exam he is well appearing with no apparent signs of distress. He has no known family history of prostate cancer. When asked about his social history, he said that he drinks socially with an average of 1 to 2 drinks every month and has never smoked or used illicit drugs. His past medical history is significant for hypercholesterolemia, hypertension, and depression.

Medications: atorvastatin, lisinopril, and sertraline; no known allergies.

PSA History:	
Date	**PSA Level (ng/mL)**
08/05/2012	6.68
09/22/2011	3.11
09/25/2010	2.52
08/29/2009	2.43
08/27/2008	2.27
09/03/2007	2.02
08/19/2006	1.98
08/15/2005	1.82
09/01/2004	1.52
08/28/2003	1.38
09/09/2002	1.25
08/20/2001	1.17

From the assessment above, what would have prompted C.W.'s primary care physician to refer the patient to an urologist?

Using prognostic factors to stratify the risk of the cancer recurring is essential to better characterize the cancer and to determine the optimal treatment. This is particularly important with a heterogeneous disease like prostate cancer. Patients with a high risk of recurrence will need more aggressive treatment, whereas those with low risk can benefit from a more conservative approach. Stage of the tumor, PSA, and Gleason score are prognostic factors that can be used by the provider to calculate the probability of a patient recurring in the next 5 to 10 years. Utilizing these factors and incorporating the patient's life expectancy will help the physician to determine the best therapies for their patient while maximizing quality of life.

LIFE EXPECTANCY

There are a number of men who will die with, not of, their prostate cancer. Autopsy data has shown that as many as 7 out of every 10 men who died of various causes had prostate cancer at time of death that was undiagnosed[15,16] (Fig. 100-2). Estimation of a patient's life expectancy can help determine the extent of benefit of potential life gained from treatment. Men with short life expectancies are at low risk of developing any symptoms of disease, or morbidity, before their demise from another unrelated event, and therefore will likely not benefit from definitive treatment. Conversely, younger men otherwise in good health are likely to need treatment as they have a longer lifetime in which to develop a recurrence of cancer that can be a cause of morbidity and mortality. Although insurance life expectancy charts (Minnesota Metropolitan or the Social Security Administration Life Insurance Tables) can be used to determine potential life expectancy, it often is a comprehensive clinical determination by the patient's healthcare team, weighing a number of factors, including their overall health, quality of life, comorbid conditions, and family history when determining a treatment plan.[4] The Social Security Administration Life Insurance Tables can be found at **www.ssa.gov/OACT/STATS/table4c6.html**.

Prostate Specific Antigen

As previously discussed, serum PSA level is used in screening for prostate cancer detection. It is also a prognostic factor used as an aid to determine treatment because a higher PSA level is associated with an increased risk of more advanced and potential progression of disease. The more prostate cancer cells there are, the more PSA is being made. Being able to determine how fast the level is rising is another way to assess the cancer's ability to potentially recur and progress. However, it is also known that not all prostate cancers will produce elevated PSA levels. It is another tool that may help the practitioner to assess the risk of recurrence in a specific patient. As mentioned previously, men with PSA levels of 4 to 10 ng/mL have a 30% to 35% chance of having prostate cancer; that risk doubles if the level increases above 10 ng/mL.[6] A number of other screening modalities have been developed in order to better define a patient's risk for prostate cancer.

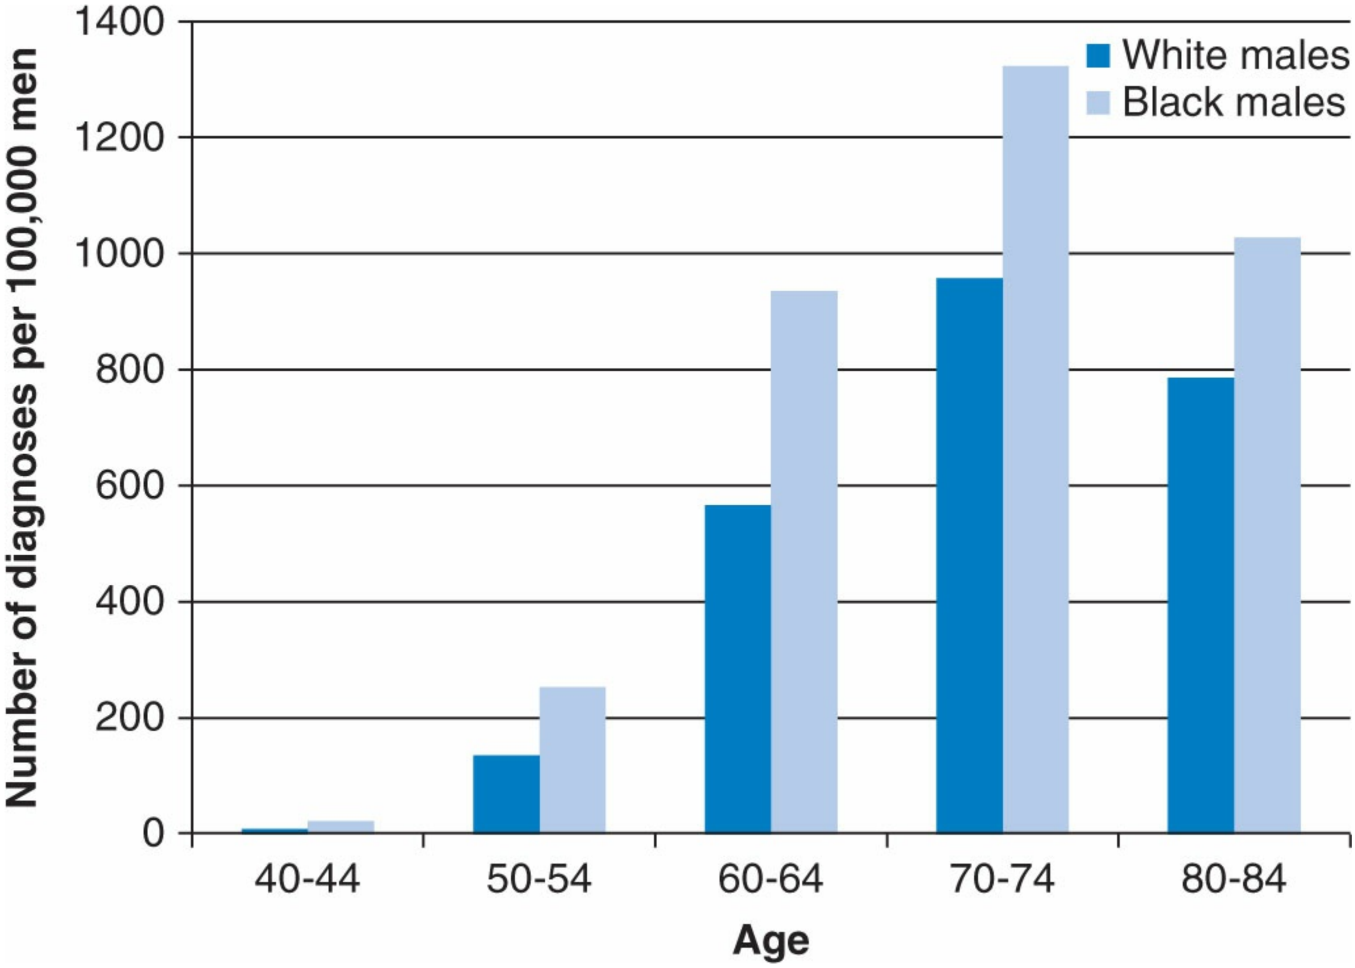

Figure 100-2 The Incidence of New Cases of Prostate Cancer by Race and Age.[4]

Observing the time over which the PSA level rises, or PSA velocity, is a way of potentially identifying those men with prostate cancer versus those with an elevated PSA because of other causes. Determining the PSA velocity may help further ascertain those men who should have a biopsy performed. Upon diagnosis, a rapid PSA velocity can also suggest more rapid progression and can serve as a guide for treatment decisions. However, it is important to know the normal PSA ranges by age and that fluctuations in levels can exist because of the laboratory controls.[4]

Because of the fact that C.W. had a PSA level of 3.21 in 2011 and 6.68 in 2012, there is concern that he may have developed prostate cancer. The Prostate Cancer Prevention Trial (PCPT) found that 15% of men with PSA ≤4.0 ng/mL and a normal DRE were diagnosed with prostate cancer. This percentage doubles with PSA levels between 4 to 10 ng/mL.[5] C.W.'s change in PSA from 2010 to 2011 and 2011 to 2012 indicated an increased PSA velocity, which can also suggest that further evaluation is necessary. The Baltimore Longitudinal Study of Aging (PLSA) trial of 980 men demonstrated an increased relative risk of prostate cancer death in men with a PSA velocity >0.35 ng/mL/year compared to those with a PSA velocity ≤0.35 ng/mL/year (p = .02).[5]

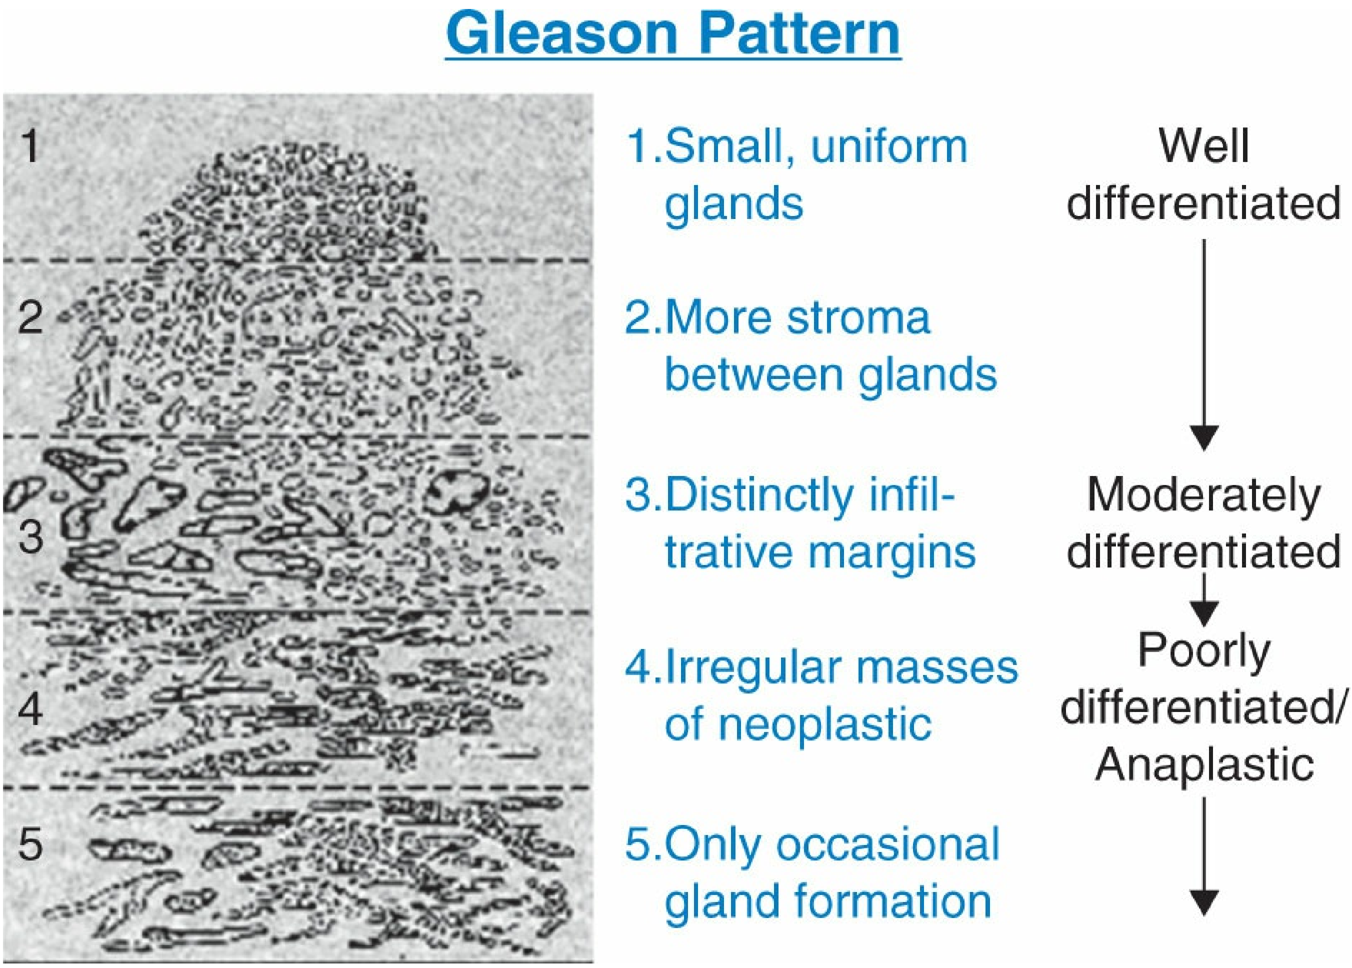
Tumor Staging

CASE 100-2, QUESTION 2: C.W. is referred to the urologist for further evaluation. What additional diagnostic procedures can be done to definitively diagnose prostate cancer? What assessments can be done from the procedure for better prognostication of the disease?

The American Joint Committee on Cancer (AJCC) developed a staging system for newly diagnosed prostate cancer. This AJCC TNM staging system classifies the extent of the tumor according to the size of the tumor (T), the extent of lymph node involvement (N), and the absence or presence of distant metastases (M). In general, if the cancer remains within the prostatic capsule, it is considered localized disease. If it has spread outside of the capsule or has invaded the adjacent structures, it is locally advanced and the cancer is considered metastatic if it has spread to other parts of the body.

Gleason Score

A Gleason score is the histologic grading of the tumor biopsy. It is calculated by adding the most common to the second most common growth patterns found in the core biopsies. This score is one of the most important factors when determining treatment and prognosis as it corresponds to how aggressive the tumor is behaving. An aggressive tumor is one that will grow faster and have a higher risk of metastasizing, increasing the likelihood of recurrence after localized treatment. There are five distinct patterns of growth from well (1) to poorly (5) differentiated with progressive loss of glandular formation (Fig. 100-3).[18] Well-differentiated cancer cells are those that are most similar to the normal prostate cells and tend to grow and spread at a slower rate than poorly differentiated tumor cells that are more aggressive. Up to 50% of prostate tumors demonstrate more than one histologic pattern.[19] By assessing several of the biopsy samples to find the most common growth patterns, the aggressive behavior of the tumor can be more accurately estimated. The added value of the first and second most common patterns can theoretically range from 2 to 10 with the majority of tumors ranging from 5 to 10. Cancer with a Gleason score of 6 or less, which is relatively well-differentiated and less aggressive, is considered low-grade. A Gleason score of 7 is considered intermediate grade cancer, and a Gleason score greater than 7 is considered poorly differentiated, high grade. For someone with a Gleason score of 2 to 4, there is a 4% to 7% chance of dying of their disease within 15 years. A man with a Gleason score of 8 to 10 has a 87% risk of dying within 15 years if untreated.[4]



Gleason Pattern
1
2
3
4
5
1.Small, uniform glands
2.More stroma between glands
3.Distinctly infil-trative margins
4.Irregular masses of neoplastic
5.Only occasional gland formation
Well differentiated
Moderately differentiated
Poorly differentiated/ Anaplastic

Figure 100-3 Gleason histologic grading of prostate cancer demonstrating progressive loss of glandular formation with increasing score. (Adapted with permission from Scher HI et al. Cancer of the Prostate. In: DeVita VT et al, eds. Cancer: Principles and Practice of Oncology. 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2015.)

Risk stratification tools that incorporate stage, PSA level, and Gleason score have been developed and validated as they identify those men who are associated with an increased risk of recurrence and worse outcomes after localized treatment. These systems group patients who are yet to receive treatment as very low, low, intermediate, high, or very high risk to be used as a basis for providers, along with life expectancy and overall health of the patient, in the selection of initial treatment (Table 100-2).[6,20]

A trans-rectal ultrasound guided needle biopsy can be done to definitively diagnose prostate cancer. The biopsy specimen can be used in conjunction with DRE results to determine the prognostic factors of clinical stage and the Gleason score.

CASE 100-2, QUESTION 3: C.W.'s biopsy revealed a Gleason 3 + 3 = 6, stage T1c (no suspected nodal or distant metastases) prostate cancer in 3 of 10 cores. Based on C.W.'s prognostic factors, what is C.W.'s risk group?

C.W. has stage T1cN0M0 prostate cancer with a Gleason score ≤6 and a PSA <10 ng/mL. With these prognostic factors and with 3 of 10 positive cores, he is considered to have low-risk prostate cancer.

TREATMENT

Observation versus Active Surveillance

CASE 100-2, QUESTION 4: C.W. consulted with a medical oncologist about his treatment options for low-risk prostate cancer. The oncologist explained that C.W. is an overall healthy patient with a long life expectancy and that his prostate cancer is relatively slow growing. What is C.W.'s conservative option for the management of his prostate cancer?

Studies have aimed to identify those select men who will have a good outcome with a very conservative approach of observation with no immediate, definitive intervention for their cancer. This is because we are now seeing what some call an overtreatment of prostate cancer. Over-screening, as discussed earlier, plays a role with some models estimating between 23% and 42% of all US screen-detected cancers are being overtreated.[6] This approach of not treating the cancer immediately has subtle distinctions according to differences in patient status.

Table 100-2

Prostate Cancer Risk Groups[6]

Risk	Stage	PSA (ng/mL)	Gleason	Other
Clinically Localized				
Very Low	T1c	<10	≤6	Fewer than three prostate biopsy cores positive, ≤ 50% cancer in each core; PSA density: <0.15 ng/mL/g
Low	T1–T2a	<10	≤6	
Intermediate	T2b–T2c	10–20	7	
High	T3a	>20	8–10	
Locally Advanced				
Very high	T3b–T4		5 > 4 cores with a score of 8–10	
Metastatic				
Metastatic	Any T, N1 or Any T, Any N, M1			

Patients are assigned a risk group according to their most severe prognostic factor. Patients with multiple adverse factors may be shifted into the next highest risk group.

Observation involves no cancer intervention, such as additional biopsies, scans, surgery or treatment but simply monitors the patient with the plan to only deliver palliative therapy if the patient becomes symptomatic. This is an option for men with low or intermediate risk prostate cancers with a life expectancy of less than 10 years due to concurrent comorbid conditions or diseases that will most likely outcompete their prostate cancer, providing no benefit from treatment.[6]

Active surveillance is different from observation as these men are actively monitored with routine PSA levels and, potentially, DREs with the expectation of intervention if it looks like the cancer is progressing with a goal of deferring side effects from treatment without missing the opportunity for cure. For this reason, it is preferred in patients with a life expectancy of less than 20 years and very low risk prostate cancer or in patients with a life expectancy greater than 10 years and low-risk prostate cancer.[6] A study of almost 1,000 men with favorable or intermediate risk prostate cancer on active surveillance were followed for a median 6.4 years (range, 0.2 to 19.8 years). They were offered treatment if their PSA doubled in less than 3 years, if their Gleason score was higher based on another biopsy or if they had clinical progression. Of those 993 study participants, 15% had died but only 15 patients (1.5%) died from prostate cancer. There were an additional 13 patients (1.3%) who developed metastases but only 4 had died at the time of analysis. At 5, 10, and 15 years, 75.7%, 63.5%, and 55% of patients, respectively, were untreated and continued surveillance.[21] In another study of over 5,500 men with low-risk and favorable intermediate-risk prostate cancer treated with brachytherapy and then active surveillance, 605 men had died, but only 5.6% of those deaths were because of prostate cancer.[22] These studies illustrate the potential to delay therapy in some men without compromising survival. The decision of observation or active surveillance should be made after a full discussion between the patient and the physician of the advantages and disadvantages of this approach (Table 100-3).

Because C.W. has low-risk prostate cancer and an excellent performance status without precluding comorbidities, giving him a long life expectancy (≥10 years), he would be eligible for active surveillance. He would not be a candidate for observation given his age and long life expectancy.

Table 100-3

Advantages and Disadvantages of Observation and Active Surveillance[6]

Advantages	Disadvantages
Avoidance of potential side effects	Chance of missed opportunity for cure
Quality of life	Risk of progression and/or metastases
Unnecessary treatment possibly avoided	Future therapy, if necessary, will be more complex with more side effects
	Nerve sparing surgery will be more difficult
	Increased anxiety
	Frequent medical exams and biopsies

Definitive Local Therapy

Treatments for early stage disease can include radiation, mainly in the form of either brachytherapy or external beam radiation therapy (EBRT) and radical prostatectomy. These localized treatments are used because the cancer is thought to still be confined to the prostate. Choice of therapy is dependent upon risk stratification, which takes into account extent of disease, pathologic stage and PSA, along with life expectancy, patient preference, and potential comorbidities that may cause complications and impact treatment outcomes. If treatment is successful and if the correct patients are selected, these local therapies can potentially provide a cure from the disease.

Surgery

Radical prostatectomy is the surgical removal of the prostate gland and possibly some surrounding tissue. It is generally recommended only for patients with clinically confined prostate cancer who have a life expectancy of 10 years or more and no comorbidities precluding their ability to undergo an operation.[6] A study using the SEER Medicare database looked at outcomes after surgery among hospitals and surgeons. In a study of 11,522 men between 1992 and 1996, it was found that postoperative complications correlated with the volume of procedures performed by the surgeon and the volume done at the institution. Postoperative morbidity was lower in very high-volume hospitals compared to low-volume hospitals (27% vs. 32%; $p = .03$) and was also lower when performed by high-volume surgeons as compared to low-volume surgeons (26% vs. 32%; $p < .001$). There was no link between surgeon/institution and death.[23] Another study found that surgeon experience was linked to a lower risk of recurrence ($p < .001$) when adjusted for tumor characteristics and year of surgery in patients who received no other therapy. Five-year probability of recurrence was 17.8% in early phase of career (10 prior operations) compared to 10.9% later on (>250 operations).[24] These findings confirm that experience is a critical factor in the success of radical prostatectomy. Surgery can be done as either an open or laparoscopic radical prostatectomy and can also include the removal of surrounding lymph nodes if there is suspicion of nodal metastases. Laparoscopic removal of the prostate is less invasive and usually a shorter hospital stay and a quicker recovery. With experienced surgeons, the outcomes of either are thought to be comparable, but long-term results are still needed.[1]

Additional information from the surgery can provide more accurate prognostic information on the grade or any extension into the surrounding tissue or lymph nodes.

This information is used to determine if further treatment is necessary. In addition to providing more accurate prognostic information, radical prostatectomy also has the benefit of being a short treatment with a hospital admission typically being 1 day. It does, however, have the risks of erectile dysfunction, urinary incontinence, and morbidities associated with any major surgery. Because of these risks, radical prostatectomy is indicated for very low risk patients with >20-year life expectancy, in low- and intermediate-risk patients with >10-year life expectancy, and in higher-risk patients without evidence of fixation of disease to adjacent tissue outside of the prostate.[6]

RADIATION THERAPY

Radiation therapy uses high-energy beams in the case of external beam (EBRT), or radioactive particles in the case of brachytherapy, to kill cancer cells. With brachytherapy, the radiation sources are placed directly into the prostate for a direct action with minimal effect to surrounding tissue. This form of radiation is given as either low dose or high dose and is indicated as monotherapy for low- risk cancers or can be given as an adjunct to EBRT in intermediate and particularly in higher-risk cancers.[6] In low-risk cancers, brachytherapy demonstrated comparable control rates to radical prostatectomy.[25] Brachytherapy has the advantage of a short 1-day course of therapy and minimal risk of incontinence and erectile dysfunction, but it can cause acute urinary retention.

Current EBRT techniques use three-dimensional conformal radiation therapy (3D-CRT) to deliver radiation under the guidance of computer-generated images of a patient’s anatomy. Intensity-modulated radiation therapy (IMRT) is the second iteration of 3D-CRT that uses various intensities of radiation according to the needs of the treatment area. Image-guided radiation therapy (IGRT) is a 3D-CRT that more accurately localizes the treatment area. Both IMRT and IGRT techniques are the standard of care for EBRT treatment that allows for higher doses of radiation to be delivered more precisely to lower the risk of adverse effects. Because of the proximity of the prostate to the bladder and rectum, treatment with EBRT can cause rectal urgency and increased bowel frequency, urinary frequency and incontinence, and erectile dysfunction. Although these symptoms are most often experienced short-term and the risk is lessened with newer techniques, they can persist for the long-term in a low percentage of patients. Unlike radical prostatectomy, EBRT avoids surgery and anesthesia complications, such as bleeding, myocardial infarction, or pulmonary embolism. External beam radiation therapy is an option for low-risk, intermediate-risk, and in higher-risk cancers. It is typically combined with a short course of ADT for intermediate risk and a longer course with ADT in higher risk cancers (see next section on androgen deprivation therapy).

Other modalities of radiation therapy, such as proton beam and stereotactic body radiation, have been used in the treatment of localized prostate cancer. However, their benefits over the current standards have not been established in the first-line setting of definitive localized treatment.[26]

There are no prospective, randomized trials to directly compare treatment outcomes of radiation versus prostatectomy in localized prostate cancer. A retrospective study of patients compared outcomes of 766 patients treated with EBRT to 888 patients treated with surgery and found no statistically significant difference in disease-free survival across all disease groups.[27] Several other retrospective studies have not found a difference between EBRT and prostatectomy.[28,29] Until prospective, randomized trials can definitively compare efficacy between these treatment options, physicians must compare the advantages and disadvantages of each treatment along with patient-specific factors to determine the most appropriate therapy.

ANDROGEN DEPRIVATION THERAPY

Androgen deprivation therapy (ADT) is the suppression of androgen production. It can be used in combination with radiation therapy for intermediate-risk patients and is used as a standard in combination with radiation in higher-risk patients. Androgen deprivation therapy can be done either through orchiectomy, because ~90% of androgens will come from the testes and called surgical castration, or by adding a GnRH analog, called medical castration. Both should decrease the body's testosterone production to castration levels, usually less than 50 ng/mL. As both methods are equally effective, most men will start GnRH therapy; however, orchiectomy can be useful for immediate decreases in testosterone when patients present with highly symptomatic disease or when adherence, cost, or availability is prohibitive. Table 100-4 includes the GnRH agonists, which include leuprolide, goserelin, histrelin, buserelin, and triptorelin as well as one GnRH antagonist, degarelix.

GnRH agonists work by binding to GnRH receptors to suppress luteinizing hormone (LH) and follicle stimulating hormone (FSH) production in the pituitary, decrease testicular testosterone and, subsequently, dihydrotestosterone. They bind to the GnRH receptors and initially cause a rise in LH and FSH and a surge in testosterone for up to a week until the continuous pituitary overstimulation eventually downregulates GnRH receptors and decreases hormone levels[30] (Fig. 100-4). This initial, transient surge in testosterone, called a tumor flare, can negatively impact patients presenting with symptoms, including bone pain and bladder obstruction. The flare can be prevented with the addition of antiandrogen therapy for a short course of at least 7 days.

Antiandrogens used in this setting are androgen receptor blockers that work by binding to androgen receptors to competitively inhibit their interaction with testosterone and dihydrotestosterone. These oral medications include flutamide, nilutamide, and bicalutamide. The combination of castration with a GnRH agonist or orchiectomy and an antiandrogen is called a combined androgen blockade (CAB). In addition to its initial use to prevent tumor flare in definitive local treatment, combined androgen blockade can also be used later in the treatment of recurrent disease.

Because GnRH antagonists directly block the receptors, there is an immediate decrease in LH and FSH production and subsequent testosterone suppression, avoiding a tumor flare and the need for antiandrogens, which may be most useful in symptomatic patients who would have experienced an increase in symptoms during this period.

Adding ADT to radiation improved overall survival in several clinical trials of men with intermediate-risk prostate cancer and is an option for some patients, particularly those thought to have characteristics of higher-risk prostate cancer.[6] These trials support the use of a short-term course of ADT of 4 to 6 months when added to radiation in intermediate-risk patients.[31–33] In high-risk or very high-risk patients, combining ADT with radiation therapy improved survival with studies favoring long-term ADT (2–3 years) over short-term (4–6 months). The addition of ADT to radiation is thought to have an additive synergistic cytotoxic effect on cancer cells that can possibly reduce the size of the prostate and the amount of radiation needed.[34] For this reason, ADT is often initiated up to 2 months prior to radiation. Androgen deprivation monotherapy, without concomitant radiation, has not been shown to be beneficial in patients with localized prostate cancer. Neoadjuvant or adjuvant ADT does not give added benefit with radical prostatectomy.

Traditionally, studies in the treatment of localized prostate cancer with radiation therapy plus ADT were done using combined androgen blockade for the entire ADT portion of treatment. Whether the addition of an antiandrogen is necessary is still unknown. Meta-analyses suggest that bicalutamide may provide an incremental relative improvement in overall survival by 5% to 20% over GnRH agonist monotherapy, but more clinical trials are needed to definitively confirm its utility in the localized treatment setting.[35,36] Antiandrogen monotherapy is less effective than medical/surgical castration and is not recommended for use in the treatment of localized prostate cancer.

Using ADT to disrupt the production of testosterone and dihydrotestosterone can cause a range of symptoms that can impact quality of life, particularly in patients using ADT for prolonged periods. These side effects include hot flashes, decreased libido, erectile dysfunction, gynecomastia, behavioral changes, and burning at injection site. Androgen deprivation therapy decreases bone mineral density after 6 months of use that can cause osteoporosis.[37] It can also cause cardiovascular and metabolic abnormalities, such as increased body fat, decreased muscle strength, and decreased insulin sensitivity leading to hyperlipidemia and hyperglycemia. The incidence of diabetes is increased up to 44% with the use of ADT.[38]

Table 100-4

Androgen Deprivation Agents

Agent	Route	Dose
GnRH Agonists		
Leuprolide (Eligard)	Subcutaneous	7.5 mg every month 22.5 mg every 3 months 30 mg every 4 months 45 mg every 6 months
Leuprolide (Lupron Depot)	Intramuscular	7.5 mg every month 22.5 mg every 3 months 30 mg every 4 months 45 mg every 6 months 3.75 mg
Triptorelin (Trelstar or Trelstar Mixject)	Intramuscular; suspension (reconstituted)	3.75 mg every 4 weeks 11.25 mg every 12 weeks 22.5 mg every 24 weeks
Goserelin (Zoladex)	Subcutaneous implant	3.6 mg every 28 days, 10.8 mg every 12 weeks
Histrelin (Vantas)	Subcutaneous implant	50 mg every 12 months
Buserelin (Suprefact)	Subcutaneous	500 mcg every 8 hours for 7 days. Maintenance 200 mcg once daily
Buserelin (Suprefac Depot)	Subcutaneous implant	6.3 mg every 2 months 9.45 mg every 3 months
GnRH Antagonist		
Degarelix (Firmagon)	Subcutaneous	Loading dose: 240 mg administered as two 120 mg injections Maintenance dose: 80 mg every 28 days (beginning 28 days after initial loading dose)
Antiandrogens		
Bicalutamide (Casodex)	Oral	50 mg once daily (with GnRH analog) 150 mg once daily (monotherapy)
Nilutamide (Nilandron)	Oral	300 mg once daily × 30 days, followed by 150 mg once daily
Flutamide (Eulexin)	Oral	250 mg three times daily

CASE 100-2, QUESTION 5: C.W. is elected to proceed with active surveillance. His medical oncologist had scheduled appointments and PSA checks every 3 months and DREs every 6 months. His results are as follows:

Date	PSA Level (ng/mL)	DRE
01/13/2013	7.16	Negative
04/27/2013	7.45	
7/12/2013	7.74	Negative

11/03/2013	8.08	
04/10/2014	8.75	Negative
10/29/2014	9.05	
01/30/2015	10.70	Negative
03/20/2015	11.19	
07/02/2015	11.70	Negative

C.W.'s PSA continued to rise; however, his overall health remained excellent and he did not have any symptoms from his disease. C.W. began to get anxious and the medical oncologist decided to do a repeat biopsy to reassess the tumor and treatment plan. The results revealed a Gleason 4 + 3 = 7 in 4 of 12 cores. What are the possible treatment options for C.W.?

C.W. now has T1cN0M0, Gleason 7, PSA 11.7 prostate cancer placing him into the intermediate-risk group. His options for definitive local treatment are radical prostatectomy or EBRT plus ADT with the possibility of adding brachytherapy. Because of the results of several trials investigating the use of ADT with radiation in intermediate- risk patient,[31–33] EBRT would be given with a short course of 4 to 6 months of ADT.

CASE 100-3

QUESTION 1: Patient H.L. is a 63-year-old male with a clinical stage T1cN0M0, PSA 9.2, Gleason 4 + 3 = 7 prostate cancer. His past medical history is unremarkable and he has an excellent performance status. He has no known allergies and is not on any medications. His labs are not clinically significant other than his PSA level. When presented with his options, H.L. decided to undergo a radical prostatectomy for definitive local treatment, which revealed a pathologic stage T2cN0M0. He was monitored after surgery and after 6 months had no symptoms from the procedure or the disease. His PSA was monitored and his nadir after surgery was 0.32 ng/mL. The medical oncologist believes that the cancer is still present but does not think there is any indication of disseminated disease. H.L. has what type of cancer progression?

Recurrence and Progression

For patients who have definitive local treatment with either radiation or surgery, about 25% to 33% of patients will experience a recurrence of their cancer. After the completion of local therapy, patients are monitored by periodically checking PSA for the detection of biochemical recurrence, which is recurrence of disease as indicated by rising PSA with no other signs or symptoms. The threshold for PSA recurrence is dependent upon the initial treatment given. Because a radical prostatectomy involves the removal of all prostate tissue, serum PSA after the procedure should become undetectable. A PSA level of ≥0.2 ng/mL following a radical prostatectomy is considered a biochemical recurrence. Risk factors for the development of a recurrence after radical prostatectomy are the Gleason score, positive surgical margins, and elevated postoperative PSA levels.[39] A biochemical recurrence after EBRT is defined as a rise in PSA level by ≥2 ng/mL above the nadir, or lowest achieved PSA, or three consecutive PSA rises above the nadir according to the American Society of Radiation Oncology (ASTRO) criteria. Risk factors for recurrence after EBRT include large volume of disease, short time to PSA recurrence, invasion of extraprostatic organs, and high Gleason score.[40] As H.L. is not symptomatic and his only evidence of disease is his PSA rise that never became undetectable post prostatectomy. He has biochemically recurrent prostate cancer.

CASE 100-3, QUESTION 2: What is the most appropriate treatment for which H.L. may be eligible?

A biochemical recurrence can indicate that a patient has either a local or metastatic recurrence. A patient thought to have local recurrence may be eligible to again receive local therapy, called local salvage therapy, providing a chance for a cure or a delay in progression. A patient with a biochemical recurrence after a radical prostatectomy with no indication of distant metastases may be a candidate for salvage radiation therapy with or without ADT. Conversely, a patient initially treated with radiation therapy may be a candidate for salvage prostatectomy. In addition to salvage prostatectomy, cryotherapy, which is a procedure that freezes cancer cells, and brachytherapy, if EBRT was first used, are also salvage therapy options post radiation therapy. Careful consideration of the characteristics of both the disease and the patient must be assessed in order to determine the appropriateness for salvage therapy.[6]

In patients with clinical features suggesting that the disease is no longer confined to the prostate, called disseminated prostate cancer, systemic therapy is indicated. As prostate cancer is hormonally driven, ADT is the initial standard treatment in recurrent prostate cancer. At this point in the disease, patients are considered castrate-sensitive as their cancer is still being suppressed by the lowering of testosterone to castrate levels with ADT. Androgen deprivation therapy is palliative, but it can control or delay symptoms and complications, improving patient quality of life.[6]

Because the benefit of ADT for biochemical recurrence is still not fully known, when to initiate ADT is still not clear. Observation until evidence of progression is an option; however, patients with rapidly progressing disease, as indicated by the presence of symptoms, an elevated PSA, or a rapid PSA velocity with a long life expectancy, should initiate ADT earlier. With long-term use of ADT, cost and the extensive side effect profile may be limiting and will impact the quality of life for some patients. Intermittent ADT, once there is response to treatment, rather than continuous administration, is an approach that can minimize side effects and improve quality of life. With this approach, patients continue ADT until maximal PSA response and then temporarily stop ADT until a set PSA threshold is reached at which point ADT is reinitiated.[41] The full benefit of intermittent ADT is still not known. A trial done by Crook and colleagues assigned 1,386 men with rising PSA after radiation therapy to either intermittent ADT or continuous ADT. The intermittent ADT approach was non-inferior in terms of overall survival (8.8 vs. 9.1 years; HR 1.02, 95% CI 0.86–1.21), but more patients in this group died from prostate cancer (120/690 vs. 94/696). The trial demonstrated an improvement in quality of life with intermittent ADT; however, more research must be done to determine the true impact on survival. This approach may be considered for well-informed patients without metastatic disease.[42] The duration of response from ADT varies, but eventually the cancer becomes resistant to ADT and most patients progress.

At this point in the disease, H.L. has recurrent prostate cancer without evidence of disseminated disease. Because it is thought that the disease is a local recurrence, he may still have an opportunity for a cure with local salvage therapy. He was initially treated with a prostatectomy, and salvage therapy should consist of EBRT with or without ADT.

CASTRATION-RESISTANT PROSTATE CANCER

CASE 100-3, Questions 3: H.L. undergoes local salvage therapy with EBRT and ADT with leuprolide. After EBRT is completed, he is monitored while continuing ADT therapy. His pertinent laboratory results are as follows:

Date	PSA Level (ng/mL)	Testosterone (ng/dL)
04/27/2014	1.56	
07/09/2014	0.36	
10/17/2014	0.31	<50
01/23/2015	0.57	
04/19/2015	1.08	<50
07/10//2015	0.74	
10/02/2015	2.45	<50

H.L. continues to be in good health other than experiencing mild depression and 3 to 4 hot flashes a day. Bone density scan results on 04/19/2015 shows osteopenia with a T-score of −1.5. Bicalutamide was added to his ADT treatment plan on 04/19/2015. How has H.L's cancer progressed? What should H.L.'s medical oncologist do next?

Castration-resistant prostate cancer (CRPC) occurs when the cancer no longer responds to ADT alone, and the cancer is progressing despite castrate levels of testosterone. This is indicated by a rising PSA or by new or progression of existing metastases. At that time, there are a number of different therapies that can be used, including chemotherapy and immunotherapy. CRPC has acquired mechanisms of resistance that upregulate androgens and/or androgen receptors, enabling the cancer to grow in the presence of ADT. This continued dependence on the androgen pathway allows for CRPC to be sensitive to additional agents that affect androgens and the inhibition of androgen receptors, despite its name suggesting tumor resistance to further androgen manipulation. A GnRH agonist or antagonist should be continued indefinitely while undergoing any other therapies to continue its inhibitory effect on testosterone and dihydrotestosterone.

If a patient has a rising PSA level while on ADT, a testosterone level should be rechecked to make sure it is below castration levels. If it is not, then ADT is not adequately blocking the production of androgens, and a change in medication or an orchiectomy is usually recommended. If the testosterone level is below 50 ng/mL, the patient is confirmed to be castrate resistant and additional systemic treatment will be necessary (Table 100-5).[6]

SECONDARY HORMONAL THERAPIES

Despite the fact that the cancer is now labeled castration resistant, many cells are still very dependent on the androgen receptor and can continue to be targeted throughout the disease. For a patient who has adequate castration levels (<50 ng/dL) while on a GnRH analog and has a significant rise in PSA level or clinical recurrence, they will typically be responsive to secondary hormonal manipulations, such as antiandrogens, antiandrogen withdrawal, ketoconazole, glucocorticoids, and estrogens. These agents can delay disease progression and postpone the need for therapies with increased toxicities; however, they have not shown a survival benefit. It is possible to use these agents sequentially prior to initiating a different approach.[6]

The addition of an antiandrogen for combined androgen blockade is a common initial treatment for CRPC patients. As mentioned earlier, there are three approved antiandrogens that are used in this setting: bicalutamide, nilutamide, and flutamide. Because of the multiple daily dosing of flutamide and the additional side effect of delayed dark vision adaptation of nilutamide, bicalutamide is typically the preferred agent. Although these agents are generally well tolerated, adverse effects can include hepatic toxicities with elevations in liver enzymes. Monitoring of liver function tests are recommended with the use of these agents. Gastrointestinal toxicities can occur with these agents, particularly flutamide. Nilutamide has the highest rate of pulmonary-associated side effects although it is rare with any of the antiandrogens.[4]

Discontinuation of an antiandrogen after progression on combined androgen blockade can result in a decline in PSA level, called “antiandrogen withdrawal syndrome.” This response can be seen in approximately 20% of patients and should be attempted prior to initiation of another treatment.[43]

Ketoconazole is an antifungal agent that is an inhibitor of adrenal androgen synthesis. The testes produce nearly 90% of testosterone in males with the remaining 10% derived from the androgens produced in the adrenal glands. The androgens are subsequently converted to testosterone and dihydrotestosterone. In the setting of prostate cancer, ketoconazole is administered orally as 400 mg three times daily under low gastric pH conditions to allow for maximal absorption along with a low-dose glucocorticoid. The PSA can be reduced by 50% or more in up to 71% of patients.[4] This drug has an increased potential for drug interactions as it is a potent inhibitor of CYP3A4. Toxicities include nausea, vomiting, rash, and fatigue and are often limiting for patients.

Table 100-5

Survival and Quality of Life Advantages with Therapies for Metastatic Castration-Resistant Prostate Cancer

Therapy	Overall Survival Advantage	Quality of Life Advantage
Abiraterone 1000 mg PO once daily Days 1–28 and Prednisone 5 mg PO twice daily Days 1–28 Repeat every 28 days	X	X
Enzalutamide 160 mg once daily Days 1–28 Repeat every 28 days	X	X
Radium-223 50 kBq/kg (1.35 microcurie/kg) Repeat every 4 weeks for 6 doses	X	X
Docetaxel 75 mg/m^2 IV Day 1 and Prednisone 5 mg twice daily Days 1–21 Repeat every 21 days	X	X
Sipuleucel-T doses about every 2 weeks Total of 3 doses	X	
Cabazitaxel 25 mg/m^2 IV Day 1 and Prednisone 10 mg daily Days 1–21 Repeat every 21 days	X	
Mitoxantrone 12 mg/m^2 IV Day 1 and Prednisone 5 mg PO twice daily Repeat every 21 days		X

PO, daily; kBq, kiloBecquerel; IV, intravenous.

Several different glucocorticoids and estrogens have historically been utilized in the treatment of prostate cancer. It is still unknown exactly how these agents act in CRPC. It is thought that estrogen can cause suppression of LH release from the pituitary to then reduce testosterone production in the testes. They may also have a direct cytotoxic effect on cancer cells. Conjugated estrogens and estramustine have also shown response rates of 24% to 42%. Glucocorticoids, such as hydrocortisone, dexamethasone, and prednisone may suppress adrenal androgen synthesis by reducing the production of adrenocorticotropic hormone (ACTH) in the pituitary. These agents have somewhat fallen out of favor given their toxicities and the increased number of options that are now available.[4]

H.L. now has castrate-resistant prostate cancer confirmed by the rise in PSA despite testosterone below castrate level. The medical oncologist had added an antiandrogen to H.L's treatment plan, which he initially responded to as indicated by his PSA, but at his next evaluation his PSA rose because of an acquired mechanism of resistance. The next step for H.L. would be to discontinue his antiandrogen for a withdrawal response.

Metastatic Disease

When metastatic disease occurs, performance status and extent of disease should be evaluated and a discussion started regarding the goals of treatment as the patient is no longer considered curable. Metastatic disease is most likely to be seen in the bones, lung, and liver. Symptoms are more common in metastatic disease and are often related to the sites of metastases. For a patient who is first diagnosed with metastatic prostate cancer, treatment begins with ADT, just as it does in earlier stages with secondary hormonal therapy used at progression or recurrence. Androgen deprivation therapy will be continued concomitantly, while other agents are used through the progression of the disease.

Once a patient is castrate resistant, men who are in good health and have asymptomatic disease may be treated with sipuleucel-T, an immunotherapy. For castrate-resistant disease that is symptomatic, cytotoxic chemotherapy would generally be considered first line. Newer antiandrogens are approved in metastatic CPRC and can be given before or after chemotherapy. Appropriate sequencing of these agents is still not known; however, patients with poor performance status, advanced age, rapidly progressing disease, or a need to delay cytotoxic chemotherapy can benefit from receiving the relatively tolerable antiandrogens sooner rather than later. A discussion regarding the benefits of each therapy, along with potential adverse effects is important in deciding if and when these therapies should be implemented.[44]

CYTOTOXIC CHEMOTHERAPY

CASE 100-4

QUESTION 1: E.S. is a 70-year-old male who has been receiving leuprolide every 3 months since December 2005 for a biochemical recurrence after radical prostatectomy in 2004. He was started on bicalutamide in March 2013 for a rising PSA of 0.47 from 0.12, which he initially responded to. However, the PSA subsequently rose to 2.16 in July 2013, at which point the bicalutamide was discontinued. His pertinent laboratory results are as follows:

Date	PSA Level (ng/mL)
07/27/2013	2.16

10/20/2013	3.01
01/10/2014	3.32
04/12/2014	3.67
07/14/2014	3.93
10/26/2014	4.42
01/14/2015	4.77
04/17/2015	5.06
07/23/2015	5.51
10/02/2015	10.79

He continued leuprolide and clinical monitoring every 3 months (pertinent laboratory findings below). He comes to the medical oncologist's office for a routine follow-up appointment and complains of increased fatigue as well as a new pain in his hip. Besides this new pain, he is otherwise in good health and exercises by walking 3 miles a day. He has no known drug allergies and is only taking lisinopril 10 mg daily for high blood pressure. The medical oncologist orders a CT scan of the chest, abdomen, and pelvis, which reveals a new pelvis mass. What would be the best treatment recommendation for E.S.?

Taxanes

Taxanes are the only class of chemotherapy that have shown an overall survival benefit in the treatment of CRPC. These agents are microtubule inhibitors, which promote assembly of microtubules and inhibit disassembly, thereby stabilizing microtubules and arresting the cell cycle. Prior to their development, chemotherapy was generally not effective, with mitoxantrone only providing a relief of symptoms.

Docetaxel

Docetaxel in combination with prednisone is considered to be first-line therapy for symptomatic, metastatic CRPC when cytotoxic chemotherapy is indicated. Docetaxel-based regimens were found to improve overall survival in two randomized phase III studies. Docetaxel plus prednisone was compared to the previous standard of care, mitoxantrone plus prednisone, which had not conferred any survival benefit but had improved quality of life. When docetaxel-based regimens were given every 3 weeks with prednisone versus mitoxantrone plus prednisone in over 1,000 men, there was an increase in overall survival of about 2 months (TAX327: 18.9 vs. 16.5 months, $p = .009$ and SWOG9916: 17.5 vs. 15.6 months, $p = .02$). Quality of life was similar in both arms of each study.[45–47] Tolerability was improved when docetaxel was switched to a lower dose every 2 weeks with less febrile neutropenia and other toxicities.[48] This every 2-week regimen may be considered in patients unable to tolerate docetaxel on an every 3-week schedule.

There is recent data to support the early use of docetaxel in men with advanced or metastatic, hormone-sensitive prostate cancer. The CHAARTED trial illustrated that in men with a high metastatic burden indicated by the presence of visceral disease or high bone burden of disease, early initiation of docetaxel plus prednisone for six cycles in addition to ADT improved survival. The median overall survival was 13.6 months longer with a combination of ADT and docetaxel over ADT alone (57.6 vs. 44 months, $p < 0.001$). The time to progression was 20.2 months compared with 11.7 months ($p < 0.001$). A subgroup analysis of men with high-volume disease had a median overall survival of 49.2 versus

---

32.2 months ($p = 0.0006$); this benefit was not seen as much in men with less disease volume. Adverse effects seen in the combination group included febrile neutropenia and neuropathy.[49]

The STAMPEDE trial demonstrated an average overall survival of 10 months longer (77 vs. 67 months) with the addition of six cycles of docetaxel than those who only received standard therapy in men with newly diagnosed advanced prostate cancer. In men with metastatic disease, the overall survival was an additional 22 months (43 vs. 65 months).[50] These studies provide evidence of a survival advantage with the early use of docetaxel that suggest a new treatment strategy of chemotherapy in the setting. Experience with its use in this setting will confirm its role in metastatic, hormone-sensitive prostate cancer.

Cabazitaxel

Cabazitaxel in combination with prednisone can be utilized after progression on docetaxel-based regimens. In a randomized phase III study of cabazitaxel plus prednisone versus mitoxantrone plus prednisone in metastatic CRPC patients who were docetaxel refractory, there was a 2.4 month improvement in overall survival ($p = .0001$), but more severe adverse effects were seen. Death occurred in 4.9% of patients (vs. 1.9% in the mitoxantrone-containing regimen), mostly because of sepsis and renal failure. Other adverse effects included febrile neutropenia, severe diarrhea, anemia, nausea, vomiting, and fatigue.[51] With the increased frequency and severity of toxicities associated with cabazitaxel, the risks versus the benefits for an individual patient should be assessed prior to use.

Mitoxantrone

Prior to the introduction of docetaxel as first-line cytotoxic chemotherapy, mitoxantrone plus prednisone was considered the only chemotherapy regimen that provided benefit in metastatic CRPC. It did not improve overall survival, but it did increase quality of life, as measured by a 29% pain response rate versus 12% with prednisone alone.[52] Because of its lack of benefit in overall and progression free survival, it has been relegated to last line therapy in which there are no other viable therapies for symptomatic relief of advanced metastatic CRPC.

IMMUNOTHERAPY

Sipuleucel-T

Sipuleucel-T is the first cancer vaccine to be approved by the FDA. Unlike vaccines that prevent infection by allowing the immune system to recognize the virus or bacteria, a cancer vaccine treats the cancer. This cancer vaccine stimulates a patient's own immune system against the prostatic acid phosphatase (PAP) antigen that is expressed in most prostate cancer tissues. Collection of a white blood cell fraction containing antigen-presenting cells are taken from the patient and then exposed to PAP-granulocyte macrophage colony-stimulating factor (PAP–GM–CSF recombinant fusion protein). The activated cells are then reinfused into the patient 3 days after collection. The infusion is repeated every 2 weeks for a total of three treatments. The randomized, double-blind, placebo-controlled phase III study was conducted in over 500 men with minimally symptomatic or asymptomatic metastatic CRPC. Median overall survival was 25.8 versus 21.7 months in the placebo group ($p = .03$). Treatment was well-tolerated with common adverse effects of mild-to-moderate chills (54.1%), pyrexia (29.3%), and headache (16%).) Unlike other treatments for metastatic CRPC, sipuleucel-T does not elicit a change in PSA level that can be used as an objective measure of response.[53]

NEXT GENERATION ANTIANDROGEN THERAPY

An increased understanding of the role of androgens in prostate cancer has clarified the concept that the androgen pathway is still active in CRPC. This has led to the development of new agents with proven efficacy in metastatic CRPC that work to inhibit androgen receptors or the enzymes needed for androgen synthesis. Phase III trials have confirmed their utility in metastatic CRPC both before and after docetaxel. Because of their tolerable toxicity profile and ease of oral administration, they can be used prior to docetaxel in patients who are ineligible to receive or unable to tolerate chemotherapy.

Abiraterone

Abiraterone is an androgen synthesis inhibitor that irreversibly inhibits CYP17 (17 alpha-hydroxylase/C17,20-lyase), an enzyme that is required for androgen biosynthesis and is expressed in prostatic, testicular, and adrenal tissue. It inhibits testosterone precursors, dehydroepiandrosterone and androstenedione. When given in combination with prednisone in men with metastatic CRPC who had progressed on docetaxel, a phase III, randomized, placebo-controlled trial found that median overall survival could be prolonged over 4 months compared to prednisone alone (15.8 vs. 11.2 months, $p < .001$).[54,55] There was also a statistically significant improvement in palliation of pain because of bone metastases, PSA response rate, and time to PSA progression.[56]

Abiraterone was studied prior to docetaxel therapy in another randomized phase III trial. Patients with asymptomatic or minimally symptomatic metastatic CRPC had a progression-free survival that was doubled compared to prednisone alone (16.5 vs. 8.3 months, $p < .001$). Progression of pain intensity was delayed from 18.4 months to 26.7 months.[57] This is a reasonable option in a patient who cannot tolerate, wishes to delay use, or chooses not to receive docetaxel.

Because of the inhibition of abiraterone on CYP17, increased mineralocorticoid production by the adrenals can occur, causing side effects such as hypertension, hypokalemia, and fluid retention and should be monitored. Concomitant use of prednisone can reduce the incidence and intensity of these side effects. The most common adverse effects associated with abiraterone include fatigue (39%) back/joint discomfort (28%–32%), and peripheral edema (28%). Diarrhea, nausea, constipation, hot flashes, and hypertension all occurred in around 22% of patients and were severe in only 4% of patients. Atrial fibrillation also occurred rarely (4%) and the most common reasons for discontinuation were liver enzyme elevations or cardiac disorders. When a patient is started on abiraterone, liver function, electrolytes (potassium and phosphorus), and blood pressure should be monitored at least monthly.[54–57]

Enzalutamide

Enzalutamide is an androgen-receptor inhibitor that inhibits androgen receptor translocation and binding to nuclear DNA to inhibit prostate cancer cell proliferation. Initial studies were done in men with metastatic CRPC who had received prior docetaxel therapy as the standard of care.

In the AFFIRM trial, men were randomized in a 2 to 1 fashion to either enzalutamide or placebo. The study was stopped early and patients on placebo were allowed to begin treatment with enzalutamide because of the results seen at the interim analysis. Median overall survival was 18.4 months versus 13.6 months in the placebo arm ($p < .001$). Quality of life was improved and there was a greater than 50% decrease in PSA level in 54% of patients ($p < .001$).[58] Adverse effects in the treatment arm versus placebo included fatigue (34% vs. 29%), diarrhea (21% vs. 18%), hot flushes (20% vs. 10%), and headache (12% vs. 6%). Seizures occurred very rarely (<1%) with enzalutamide and the incidence of cardiovascular disorders was not different.[58,59] Enzalutamide is currently the only agent that is not given in conjunction with prednisone in the metastatic CRPC setting.

When given in the first-line setting prior to any docetaxel treatment, the phase III PREVAIL trial was also halted early because of the better progression-free survival seen in the treatment arm (65% vs. 14%, $p < .001$). Overall survival was also increased (32.4 months vs. 30.2 months ($p < .001$).[60]

RADIUM-223

In patients with CRPC and symptomatic bone metastases and no known visceral metastases, radium-223 dichloride has been shown to increase median overall survival (14.9 months with radium-223 vs. 11.3 months with placebo) and to reduce pain when given every 4 weeks for six cycles. It also delayed time to first skeletal event (15.6 vs. 9.8 months, $p < .001$). It emits high-energy alpha particles that target bone metastases by binding to areas of increased bone turnover. The short-range radiation creates a localized toxic effect of double-stranded DNA breaks in these targeted areas. Adverse effects were consistently similar between the active and placebo arms, although there was a slightly higher rate of myelosuppression with radium-223. More participants in the placebo arm discontinued the study drug because of adverse events.[61]

E.S. has castrate-resistant, metastatic prostate cancer. He is symptomatic and his PSA is rapidly rising since last visit. Docetaxel is the standard of care for symptomatic, metastatic prostate cancer, and this would be the most appropriate choice for E.S. without any comorbidities or conditions that would prohibit its use.

BONE METASTASES

CASE 100-4, QUESTION 2: Now that E.S. has symptomatic bone metastases, what recommendations can be made to decrease the risk of skeletal related events?

Bone metastases occur in around 90% of men who develop metastatic prostate cancer and are a common complication in advanced disease. They may be asymptomatic but can frequently cause pain, decreased mobility, and diminished quality of life. These metastases can also cause skeletal-related events, which include pathologic fractures, need for radiation or surgery to the bone, and spinal cord compression. Prostate cancer bone metastases are primarily osteoblastic lesions, in which there is increased bone formation around tumor deposits. Additionally, there is increased osteoblastic bone resorption, or osteolysis.[4] There are several therapies proven to have benefit in bone metastases by improving symptoms, preventing complications, or improving survival.

Bisphosphonates

The only bisphosphonate shown to be of benefit in patients with CRPC and bone metastases is zoledronic acid. In a phase III study, zoledronic acid was shown to demonstrate a delay in skeletal related events, including radiation to the bone, time to pathologic fracture, and bone pain. However, the study did not show an improvement in quality of life or a decrease in the development of new metastases. It is dosed at 4 mg intravenously every 3 to 4 weeks but must be dose-reduced in renal dysfunction, and it is not recommended to use if renal clearance is <30 mL/minute. Patients should take calcium and vitamin D as necessary to prevent hypocalcemia. An uncommon but serious adverse effect of osteonecrosis of the jaw can occur with zoledronic acid use.[4]

RANKL Inhibitors

Denosumab is a monoclonal antibody for the receptor activator of nuclear factor-kB ligand (RANKL), which is involved in osteoclast-mediated bone resorption and remodeling. When compared to zoledronic acid in CRPC with bone metastases, denosumab was more effective at preventing the skeletal-related events of pathologic fractures, need for radiation or surgery to bone metastases, or spinal cord compression. Denosumab also restored bone density.[4] The serious adverse effect of concern associated with denosumab is the same as that with bisphosphonates, osteonecrosis of the jaw, and it also has a higher rate of hypocalcemia. Renal adjustment is not necessary for denosumab dosing; however, renal function should be monitored because of the increased risk of hypocalcemia in patients with renal clearance <30 mL/minute. For bone metastases occurring in patients with CRPC, denosumab is given as 120 mg subcutaneously every 4 weeks. Patients should take calcium and vitamin D as necessary to prevent hypocalcemia.[62]

Systemic Radiotherapy

Systemic radiotherapy may be used, with radium-223 delaying time to first skeletal event in symptomatic bone metastases as discussed previously. It is the only bone targeting agent with a survival benefit and can be a good choice for patients with extensive bone disease with otherwise minimal disease. Two beta-emitting radiotherapy agents that have been utilized are strontium-89 or samarium-153 in patients with painful bone metastases that is not responsive to palliative chemotherapy and pain medications. However, they have no survival benefit, and myelosuppression is a major concern that must be factored into the future plan if additional chemotherapy is to be used.

External beam radiation therapy, although not systemic radiotherapy, is an option for one or a few symptomatic sites of bone metastases. It is most often used to provide symptomatic relief.[6]

Hormonal Agents

Abiraterone was shown, in the phase III trial discussed earlier, to improve bone-related pain and delay the time to first skeletal-related event (13.3 months vs. 16.7 months).[56,58] The PREVAIL study of enzalutamide prior to docetaxel therapy also showed an increase in time to first skeletal-related event.[60]

E.S. should start taking calcium and vitamin D supplementation and can add weight bearing exercises to his daily walking. In addition, his medical oncologist can recommend either zoledronic acid every 3 to 4 weeks or denosumab every 4 weeks.

Adverse Effects of Prostate Cancer Therapy

Because of the large number of men who are diagnosed with prostate cancer, as well as the continuously increasing numbers of those who live a considerable amount of time after therapy, the adverse effects of cancer therapy should remain a consideration for the remainder of the patient's life. It should be recognized that these effects include both short- and long-term issues. Patients should be aware of these potential adverse effects and their management strategies in a discussion with their physician. Guidelines from the American Cancer Society are now available for the primary care physician regarding long-term survivorship of patients with a prior diagnosis of prostate cancer.[8]

Androgen Deprivation Therapy

The loss of the majority of testosterone with the use of ADT in a male can instigate symptoms much as loss of estrogen does in the postmenopausal female. The large number of men living after a diagnosis of cancer should be aware of the long-term adverse effects of this therapy. The American Society of Clinical Oncologists (ASCO) survivorship guidelines recognize these problems and give recommendations for their monitoring. These include health promotion, screening for secondary cancers, rectal and urinary symptoms, cardiovascular and metabolic effects, anemia, bone health, sexual dysfunction, and vasomotor symptoms.[63]

CASE 100-5

QUESTION 1: P.L. is a 63-year-old male who has been on ADT therapy for just over a year and is experiencing hot flashes and mild depression. He also had a bone mineral density scan, indicating ADT-induced osteopenia. What can P.L.'s medical oncologist offer him to alleviate some of the side effects and complications he is experiencing from ADT treatment?

VASOMOTOR SYMPTOMS

Vasomotor symptoms will bother most men for the duration of their treatment with ADT. Hot flashes are characterized by an intense heat sensation, flushing and diaphoresis, involving the face and trunk and may also include anxiety and palpitations. These effects can vary in frequency, intensity, and duration. The mechanism may be because of a withdrawal of androgens, disrupting the equilibrium of the norepinephrine and serotonin neurotransmitters. Data has been taken from women as well as men in the efficacy of these agents because most therapies have seen similar efficacy in both men and women. These agents include, among others, estrogens, gabapentin, pregabalin, and venlafaxine.[63]

Gabapentin has been one of the most studied drugs for the treatment of hot flashes in men. Gabapentin at doses of up to 900 mg/day in men on ADT showed a significant reduction in hot flashes. Titration recommendations are to start at 300 mg daily and increase at increments of 300 mg to achieve the final dose. Pregabalin has shown some benefit in women at doses of 150 to 300 mg/day and has not been studied in men but may be a reasonable option starting at doses of 75 mg twice daily.

Serotonin and serotonin–norepinephrine reuptake inhibitors have also shown benefit in men on ADT, although no placebo-controlled, randomized trials have been done to date. Venlafaxine at doses of 75 mg/day has been the most extensively studied from this drug class. Paroxetine has also been studied in men on ADT. The use of other agents in these classes have also been reported.

Estrogens have also been used to treat hot flashes. Diethylstilbestrol and transdermal estrogen have resulted in good responses. Thrombotic events were not seen but gynecomastia occurred in a number of men. Megestrol and medroxyprogesterone have also been studied and one trial revealed a better response with medroxyprogesterone than with venlafaxine. However, there is concern that it might stimulate prostate cancer growth, similar to what is seen with an androgen receptor antagonist and the agent should be stopped if cancer growth does occur.

Alternative therapies have also been used to treat hot flashes. Acupuncture has shown some promise in small studies. Soy and herbal products have also been used; however, randomized controlled studies must be done to determine the true benefit of these therapies.[64]

CARDIOVASCULAR AND METABOLIC ADVERSE EFFECTS

There is concern of an association between ADT and risk of mortality from cardiovascular disease. However, this has not been consistently seen in clinical trials. Congestive heart failure and myocardial infarction have been identified as a risk highest in those who already have a risk of cardiovascular disease. A meta-analysis of studies with non-metastatic and non-CRPC did not find a significant difference in cardiovascular death in those men treated with ADT versus those who were not. The American Heart Association advisory panel concluded that links remain controversial and do not recommend periodic cardiac testing, but screening for cardiovascular risk factors should occur and monitoring of blood pressure, lipid profiles, and serum glucose should be routine, especially in those men who receive more than 6 months of ADT.[65]

Androgen deprivation has been shown to increase the risk of obesity, decrease lean muscle mass, decrease insulin sensitivity, increase high-density lipoprotein levels, and increase subcutaneous fat accumulation. Screening for diabetes and hypercholesterolemia is necessary, particularly with long-term use of ADT.[8,66–71]

SEXUAL ADVERSE EFFECTS

Loss of libido and erectile dysfunction are expected adverse effects of ADT, occurring in up to 85% of men treated with ADT. The impact of ADT therapy may be delayed with full effect occurring up to 2 years later.[72] Recovery from erectile dysfunction will usually occur after cessation of therapy. However, for patients on long-term therapy, there should be open dialog between the healthcare team and the patient regarding options available to help in mitigating these effects.[8] Other factors that may be contributing to erectile dysfunction should also be considered, including a history of diabetes or cardiovascular disease as well as whether the patient has had a previous prostatectomy. There is no consensus regarding the best therapy for this adverse effect. Phosphodiesterase inhibitors can be tried as 44% of patients reported a benefit in one study.[72]

PSYCHOLOGIC/COGNITIVE ADVERSE EFFECTS

Psychosocial adverse effects such as distress, depression, and cognitive impairment may occur. It has been estimated that up to 30% experience distress, 25% have increased anxiety, and almost 10% have a major depressive disorder. Low testosterone levels can affect mood in some men, causing depression and short temper. Routine assessment is crucial to identifying those patients experiencing these effects that can have a major impact on survivorship and quality of life with referral for behavioral intervention considered, as necessary.[8,73,74]

BONE HEALTH ADVERSE EFFECTS

Patients treated with ADT are more susceptible to decreased bone mineral density and bone fractures. In a study looking retrospectively at men diagnosed with prostate cancer from 1992 to 1997, those men who received ADT therapy were compared to those who did not and were found to have a higher incidence of fractures (19.4% vs. 12.6%, $p < .001$). Androgen deprivation therapy increases bone turnover and decreases bone mineral density with a 21% to 54% relative increase in fracture risk. Rapid loss of bone mineral density is seen within the first 6 to 12 months.[75]

The Prostate Cancer Survival Guidelines of the American Society of Clinical Oncologists (ASCO) suggest that all men who have received ADT should be assessed for the risk of fracture, using a baseline dual energy x-ray absorptiometry (DEXA) scan and calculation of a FRAX (fracture risk assessment) score.[8] For those men who are determined to be high risk, there are a number of options. Alendronate 70 mg weekly, zoledronic acid 5 mg annually, or denosumab 60 mg every 6 months are available for use in this setting.[6]

Osteonecrosis of the jaw is considered to be the most serious adverse effect of the agents used to improve bone health. Patients are recommended to undergo a baseline dental evaluation prior to the start of a bisphosphonate or denosumab with any invasive dental surgery done and completely healed before these agents are started. Good oral hygiene should also be stressed.

P.L.'s medical oncologist can offer P.L. an antidepressant. Gabapentin, venlafaxine, estrogens, and acupuncture have been shown to have some benefit for vasomotor symptoms, such as hot flashes. If P.L. is interested in being treated for both his depression and hot flashes, venlafaxine may be a good option as it can treat both side effects at the appropriate dose. As for P.L’s osteopenia,

weight-bearing exercises, supplementation of vitamin D and calcium, and the addition of yearly zoledronic acid or biyearly denosumab can be given to prevent complications that can arise from bone loss.

Radiation Effects

SEXUAL SIDE EFFECTS

CASE 100-6

QUESTION 1: K.A. has been recently diagnosed with prostate cancer after a biopsy. The results revealed a Gleason 4 + 3 = 7 in 5 of 12 cores. He discusses his options for definitive local treatment with the medical oncologist, radiation oncologist, and urologist. He decides to undergo radiation, and the radiation oncologist plans to treat him with EBRT in conjunction with 6 months of ADT. What side effects from treatment can C.W. expect? What concerns will the medical oncologist have regarding side effects and his history (PMH, FH, and SH)?

Erectile dysfunction is the most commonly seen sexual adverse effect of radiation but can include decreased volume of ejaculate, absence of ejaculate, decreased intensity of orgasm, and decreased libido. Erectile dysfunction 3 or more years after EBRT occurs in 36% to 68% of patients and 50% to 60% of men have some extent of erectile dysfunction with brachytherapy. With radical prostatectomy, erectile dysfunction is seen soon after surgery but may improve over time. This is the opposite of what is seen with radiation, where it is more of a slow decline.

In one study, 80% of patients receiving radiation therapy responded well to sildenafil. It was seen that 74% of patients in another study continued to respond after 4 years. Additional factors that may contribute to erectile dysfunction should be considered, such as coronary artery disease and diabetes as well as patient age. Some patients will not respond and should be referred to an urologist or sexual health expert to evaluate other options for treatment.[4,72]

EXTERNAL BEAM RADIATION THERAPY

Radiation treatment for definitive local treatment is typically 4 to 6 weeks long with acute symptoms usually occurring around the third week and resolving within days to weeks after completion of treatment. Symptoms such as diarrhea can be treated with standard agents (e.g., loperamide, diphenoxylate/atropine). Internal or external hemorrhoids can become inflamed and sitz baths and hydrocortisone suppositories can help alleviate symptoms. Also, acute urinary symptoms may occur with agents such as phenazopyridine and alpha-blockers such as tamsulosin providing benefit.

Late rectal toxicities from radiation therapy can occur 12 to 18 months after completion of EBRT and persist for several years, although developing adverse effects after 5 years is rare. These adverse effects can include rectal bleeding, mucous discharge, and mild incontinence of stool. Rectal bleeding can be controlled with increased fiber in the diet, steroid suppositories, and sitz baths with rectal ulcers and fistulas occurring in less than 1% of patients.

Late urinary toxicities consist of chronic urethritis in 10% to 15% of patients and urethral strictures in 2% to 3%.[4]

BRACHYTHERAPY

Brachytherapy allows for the radiation of small areas of the prostate, which decreases some of the adverse effects of EBRT. In low-dose brachytherapy, acute urinary retention is known to occur in 6% to 15%, although better identification of risk factors for its development have decreased the incidence to ~6% in recent years. Transient urinary effects that occur include radiation-induced urethritis or prostatitis, urinary frequency, urgency, and dysuria. Symptoms will peak about 1 to 3 months after brachytherapy is placed and gradually resolve over the subsequent couple of months. Alpha-blockers such as tamsulosin help relieve some of these symptoms.[4]

C.W. may experience some of the common symptoms from EBRT, which include diarrhea and hemorrhoids. Other urinary and rectal symptoms include rectal urgency, increased urinary and bowel frequency, and erectile dysfunction may also occur. Androgen deprivation therapy can cause many side effects as listed in Table 100-6. The most common adverse effects include loss of libido, erectile dysfunction, hot flashes, weight gain, and muscle loss. Because C.W. already has hypercholesterolemia and suffers from depression, which can be impacted by the use of ADT, C.W.'s medical oncologist must closely monitor for changes in these comorbidities and be proactive about treating them if needed.

PREVENTION

CASE 100-7

QUESTION 1: A.G. is a 42-year-old, African-American male who has come to his doctor's office to discuss potential ways to decrease his risk of prostate cancer. His father was diagnosed with prostate cancer at the age of 49, and his brother has just been diagnosed at the age of 45. Beyond lifestyle and diet modifications, what should A.G.'s physician discuss with him about the use of 5-α-reductase inhibitors?

Because of the large number of men who develop prostate cancer, interest has turned to the possibility of prevention. There are modifiable risk factors that can be addressed, but there is also interest in the potential of drugs or supplements that can at least lower the risk or possibly prevent the occurrence of prostate cancer.

The largest trials to date have involved the 5-α-reductase inhibitors, finasteride and dutasteride. Finasteride is a competitive inhibitor of type II 5-α-reductase that blocks the conversion of testosterone to DHT in prostatic cells. In the Prostate Cancer Prevention Trial (PCPT), over 18,000 men aged 55 or older were included if they had a baseline PSA of ≤ 3 and a normal DRE. They were randomized to finasteride 5 mg daily or placebo and had annual DREs and PSA measurements. At 7-years follow-up, a 24.8% reduction in the prevalence of prostate cancer was seen for those men on finasteride. In the finasteride cohort, there were 803 cancers of the 4,368 men; the placebo cohort had 1,147 cancers in 4,692 men. There were more reports of sexual side effects but were less likely to have lower urinary tract symptoms, which can be attributed to finasteride's mechanism of action and it use for BPH. However, for those men on finasteride, there was a higher proportion of cancers considered to be high grade (Gleason score of 7 or more) with 280 high grade tumors diagnosed in the finasteride group and 237 on placebo.[76] There was concern that these cancers would be more aggressive. The risk was considered too high and few considered its use for prevention. At 18 years from the start of the trial, a post hoc analysis of survival was assessed again to see whether there was an increased risk of death in the finasteride group because of the higher grade cancers diagnosed. The 10-year survival rates in men with low-grade cancers was 83% with finasteride and 80.9% in placebo group ($p = 0.46$), and in high-grade cancers survival was 73% in the finasteride group versus 73.6% in placebo group. Updated data at 15 years found that prostate cancer had been diagnosed in 10.5% versus 14.9% of finasteride and placebo patients, respectively ($p < 0.001$). In the finasteride cohort, 3.5% were found to be high grade and 3% were high grade in the placebo arm ($p = 0.05$). At 15 years, the survival was 78% in the finasteride arm and 78.2% in the placebo arm. The hazard ratio for death in the finasteride arm was 1.02 ($p = 0.46$). The difference in the risk of death was not significant between the two groups. Overall, finasteride reduced the risk of prostate cancer by about one-third.[77]

Table 100-6

Adverse Effects of Androgen Deprivation, Approximate Frequency, and Potential Therapeutic Options for Amelioration

Effect	Approximate Frequency	Potential Corrective Actions
Libido loss	Universal	None known
Erectile dysfunction	Universal	None known
Hot flashes	50%–80%	Venlafaxine, estrogens, progestins
Muscle loss	Common, duration-dependent	Exercise
Weight gain	Common	Exercise/diet
Facial/body hair loss	Very common	None known

Fatigue	Not defined	Exercise
Emotional liability	Not defined	None known
Depression	0%–30%	Various antidepressants
Cognitive dysfunction	Not defined	None known
Gynecomastia	Up to 20%	Preemptive radiation
Breast tenderness	Not defined	Aromatase inhibitors
Osteoporosis	Common, duration-dependent	Exercise/bisphosphonates
Anemia	5%–13%	Erythropoietin not recommended
Hyperlipidemia	10%	Diet, statins
Diabetes	0.8%/year increase	Exercise, oral agents
Myocardial infarction	0.25%/year increase	Treatment of risk factors
Coronary heart disease	1%/year increase	Treatment of risk factors

A number of events are poorly defined in frequency as a consequence of a lack of controlled studies, quantitative assessments, and/or agreed on definitions.

Adapted from Scher HI et al. Cancer of the Prostate. In: DeVita VT et al, eds. Cancer: Principles and Practice of Oncology. 10th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2015, with permission.

Dutasteride, a type I and II 5-α-reductase inhibitor, was studied in a 4-year randomized, double-blind, placebo-controlled trial in which men were given either dutasteride 0.5 mg daily or placebo. These men were between the ages of 50 and 75 with a PSA between 2.5 and 10 ng/mL and one negative prostate biopsy within 6 months. There were 6,729 men who participated and cancer was found in 659 of 3,305 men in the dutasteride arm and 858 of 3,424 men diagnosed in the placebo arm. This was a relative risk reduction of 22.8% over the 4-year period ($p < 0.001$). The difference between those with a high-grade tumor was not significant between the two groups. Erectile dysfunction was seen in 9% and 5.7% of men in the dutasteride and placebo arms, respectively ($p < 0.001$). Decreased libido was also seen (3.3% vs. 1.6%), although the symptoms of BPH were less in the dutasteride group. Less than 5% of men discontinued the study drug because of drug-related adverse events.[78]

The SELECT trial assessed the use of selenium and vitamin E in the prevention of prostate cancer. Research has indicated that reactive oxygen species may be associated with the onset and progression of various malignancies, including prostate cancer. This was a phase III, randomized, double-blind, placebo-controlled trial to assess the efficacy of selenium 200 mcg daily and vitamin E 400 IU daily, either alone or in combination. Over 35,000 men were included in this study who had a normal DRE and a PSA level <4 ng/mL. At a median of 5.46 years, no difference was seen among the groups.[79]

S.J,'s physician should explain that the 5-α-reductase inhibitors did show a significant decrease in the incidence of prostate cancer, but that it is still not clear what impact they have on prostate cancer survival and may have a negative impact on the incidence of high-grade cancers. In addition, there are side effects that patients may experience with these medications, such as erectile dysfunction and decreased libido.

SURVIVORSHIP

Because of the large numbers of prostate cancer diagnoses as well as the generally slow growth of the tumor, there are a large number of men who are living with or after a diagnosis of prostate cancer. They account for about 20% of all cancer survivors. It is recognized that physical and psychosocial effects can occur long after treatment is complete. The American Cancer Society created guidelines, last updated in 2014 and endorsed by ASCO in 2015, for the primary care physician to monitor the health of prostate cancer survivors.[8,64]

Quality of life should be assessed at baseline and monitored at least annually using one of the validated surveys for this purpose, 5-item Sexual Health Inventory for Men or International Index of Erectile Function.[8] These are beneficial for identifying side effect burden or other adverse effects that are of concern to the patient.

Healthy Lifestyle

Guidelines include an emphasis on reminding patients of the benefit of achieving and maintaining a healthy weight, getting enough physical exercise, and eating a diet that is high in fruits, vegetables, and whole grains. For those patients with residual bowel problems that impact absorption, they should be referred to a registered dietitian. Guidelines also include cautions on avoiding alcohol or

limiting it to no more than 2 drinks a day as well as tobacco use and offering cessation counseling if necessary. Smoking increases the chance of recurrence as well as second cancers.

Obesity is associated with increased prostate cancer–specific mortality and biochemical recurrence. Body mass index and healthy food choices along with physical activity should be addressed and encouraged by the primary care physician.

Physical activity has been shown to improve cancer-specific and overall survival, help speed up recovery from short-term effects of therapy, and prevent some long-term effects. Exercise can improve fatigue, anxiety, depressive symptoms, self-esteem, happiness, and quality of life. Patients should be encouraged to engage in at least 150 minutes of physical activity per week.[8]

Surveillance

Once treatment is complete, the PSA should be monitored every 6 to 12 months for the first 5 years and then monitored annually. An annual DRE is also appropriate, especially as some patients will not have a PSA elevation in the setting of cancer. As well, those patients who have received pelvic radiation are at an increased risk of bladder and colorectal cancers. They should have routine screening and any signs of hematuria and rectal bleeding or pain should be referred back to their treating radiation oncologist for evaluation.[4]

101

Hematopoietic Cell Transplantation

Valerie Relias

CORE PRINCIPLES		CHAPTER CASES
1	Hematopoietic cell transplantation (HCT) is a life-saving medical procedure involving the infusion of hematopoietic stem cells into a patient, the HCT recipient, to treat malignant and nonmalignant diseases and/or restore normal hematopoiesis and lymphopoiesis.	**Case 101-1 (Question 1),** **Case 101-2 (Question 1)**
2	In autologous HCT, the donor and recipient are the same individual, eliminating the need for pretransplantation and posttransplantation immunosuppression. Autologous hematopoietic cells must be obtained (i.e., harvested) before the myeloablative preparative regimen is administered and subsequently stored for administration after the preparative regimen.	**Case 101-1 (Questions 2, 3)**
3	Post-transplantation pharmacotherapy for autologous HCT includes hematopoietic growth factors to stimulate the proliferation of committed progenitor cells and to accelerate hematopoietic recovery.	**Case 101-1 (Question 6),** **Case 101-2 (Question 8)**
4	Common complications after autologous HCT are infections and organ failure, which occur in less than 5% of patients. The most common cause of death after autologous HCT is recurrence of the primary disease.	**Case 101-1 (Question 5)**
5	Allogeneic HCT involves the transplantation of hematopoietic stem cells obtained from a donor's bone marrow, peripheral blood progenitor cells (PBPCs), or umbilical cord blood to a patient. The donor for an allogeneic HCT may be an unrelated or related individual. Histocompatibility determination between donors and recipients must be performed through human leukocyte antigen (HLA) typing. The preparative regimen is, in part, determined by the degree of mismatch between the donor and the recipient.	**Case 101-2 (Questions 2, 3)**
6	The function of the preparative regimens for autologous HCT is to eradicate residual malignancy. The function of the preparative regimen in allogeneic HCT is to eradicate the residual malignancy, but also to provide immunosuppression, allowing the transplanted stem cells to grow and create a graft-vs.-tumor effect.	**Case 101-1 (Question 4)**
7	Choice of preparative regimens for HCT depends on factors such as underlying disease, degree of HLA matching, stem cell source, patient age, and comorbid conditions. Preparative regimens differ in intensity	**Case 101-2 (Questions 5, 6)**

	and are distinguished as myeloablative or nonmyeloablative.	
8	Post-transplantation immunosuppressive therapy is necessary for allogeneic HCT to prevent both graft rejection and acute and/or chronic graft-vs.-host disease (aGVHD/cGVHD). Some immunosuppressants require therapeutic drug monitoring to ensure effectiveness while minimizing toxicity.	**Case 101-2 (Question 7), Case 101-4 (Question 1), Case 101-5 (Questions 1–9)**

10	Opportunistic infections are a major cause of morbidity and mortality after myeloablative and nonmyeloablative HCT. The primary pathogens vary based on the time post-transplant and include bacterial, fungal, and viral species.	**Case 101-6 (Questions 1–3), Case 101-7 (Questions 1–5)**
11	Long-term complications of HCT include cGVHD, endocrine dysfunction, and secondary cancers.	**Case 101-5 (Questions 7–9), Case 101-8 (Question 1)**

OVERVIEW

Worldwide, more than 32,000 autologous and 25,000 allogeneic hematopoietic cell transplantations (HCTs) are performed annually.[1] The rationale behind the use of HCT is based on the steep dose response of chemotherapy; however, with increasing doses of chemotherapy, bone marrow suppression becomes a dose-limiting side effect. The administration of HCT provides recovery of the bone marrow.

Hematopoietic stem cell transplant is a procedure that involves the infusion of hematopoietic stems cells into patients who have received high doses of chemotherapy and/or radiation. Variations of this procedure depend on the donor of these stem cells, self- versus nonself, and the source of the stem cells. Autologous stem cell transplants are ones in which the patient serves as the donor of hematopoietic stem cells whereas, in allogeneic transplants, the donor is another related individual such as a sibling, or an unrelated donor. The source of the hematopoietic stem cells may be from peripheral blood progenitor cells (PBPCs), bone marrow (BM), or umbilical cord blood.

The type of HCT performed depends on a number of factors, including type and status of the disease, patient age, performance status, and organ function and, if allogeneic transplant is needed, the availability of a compatible donor. Characteristics of autologous and allogeneic transplantation, with either myeloablative or nonmyeloablative preparative regimens, are compared in Table

101-1.[2] Many diseases are treated with autologous or allogeneic HCT and are listed in Table 101-2.[2] Modifications to the basic schema for HCT are necessary based on the immunologic source (i.e., allogeneic or autologous) and the anatomic source (i.e., bone marrow, PBPCs, or umbilical cord blood) of the hematopoietic stem cells infused.

Hematopoietic cell transplantation (HCT) may be the only treatment available to many patients; however, it is associated with considerable morbidity and mortality, with approximately 40% of advanced cancer patients who undergo HCT dying of its complications.[2] The basic schema for HCT is illustrated in Figure 101-1. A combination of chemotherapy and/or radiation administered before infusion of the hematopoietic stem cells is referred to as the preparative or conditioning regimen.[2] The days leading up to the infusion of the hematopoietic stem cells are counted in the negative (i.e., −3, −2, −1), the day of HCT infusion is termed day 0, and the days following the transplant are counted in the positive (+1, +2, etc.). Although the preparative regimen may use the same agents that are used in conventional chemotherapy regimens, the doses are higher. The purpose of the preparative regimen is to eradicate the residual malignancy and, in the setting of an allogeneic HCT, to suppress the recipient's immune system.[2] Only myeloablative preparative regimens are used for autologous HCT; however, myeloablative, reduced-intensity or nonmyeloablative preparative regimens may be used with allogeneic HCT. Myeloablative preparative regimens involve administration of near-lethal doses of chemotherapy and/or radiation, which ablate the bone marrow; this may be followed by a 1- to 2-day rest. After completion of the preparative regimen, the HCT takes place. Myeloablative preparative regimens have significant regimen-related toxicity and morbidity and thus are usually limited to healthy, younger (i.e., usually younger than 60 years) patients.[3] Alternatively, reduced-intensity or nonmyeloablative transplants are performed with the hope of curing more cancer patients without the complication of preparative-related toxicity. Nonmyeloablative regimens make use of the graft-versus-tumor (GVT) effect allowing for donor lymphocyte-induced tumor eradication (see graft-vs.-tumor section). For most chemotherapy-based preparative regimens, a rest period is necessary to allow for elimination of toxic metabolites from the chemotherapy that could damage infused cells. After chemotherapy and/or radiation, a period of pancytopenia lasts until the infused hematopoietic stem cells re-establish functional hematopoiesis. Engraftment, when functional hematopoiesis is established, is commonly defined as the point at which a patient can maintain a sustained absolute neutrophil count (ANC) of more than 500 cells/μL and a sustained platelet count of at least 20,000/μL lasting three consecutive days without transfusions.[4] Graft rejection occurs when the patient cannot maintain functional hematopoiesis and may occur after autologous or allogeneic HCT.

AUTOLOGOUS HEMATOPOIETIC STEM CELL TRANSPLANTATION

The defining characteristic of autologous HCT is that the donor and the recipient are the same individual, making post-transplantation immunosuppression unnecessary. Autologous hematopoietic stem cells must be obtained (i.e., harvested) before the myeloablative preparative regimen is administered and subsequently stored for administration after the preparative regimen. Essentially, these hematopoietic stem cells are administered as a rescue intervention to re-establish bone marrow function and avoid long-lasting, life-threatening marrow aplasia that results from the myeloablative preparative regimen.[5] Incomplete tumor eradication by the high-intensity treatment prior to transplant remains the main cause of relapse after transplant.[6]

Table 101-1

Comparison of Types of Hematopoietic Cell Transplants

	Myeloablative		Nonmyeloablative
Risk[a]	**Autologous**	**Allogeneic**	**Allogeneic**
Relapse after HCT	+++	+	+
Rejection	–	+	++
Delayed engraftment	++	+	+
GVHD	–	+	++
Infection	+	++ to +++[b]	++ to +++[b]
Transplant-related morbidity	+	+++	++
Transplant-related mortality	+	++	+
Cost of procedure	++	+++	++ to +++

[a] Risk varies depending on underlying disease, patient characteristics, and previous medical history.

[b] Risk of infection increases with intensity and duration of immunosuppression and/or chronic GVHD.

GVHD, graft-versus-host disease; HCT, hematopoietic cell transplants.

Table 101-2

Diseases Commonly Treated with Hematopoietic Cell Transplantation (HCT)

Allogeneic
Nonmalignant
Aplastic anemia

Thalassemia major
Severe combined immunodeficiency disease
Wiskott–Aldrich syndrome
Fanconi anemia
Inborn errors of metabolism
Malignant
AML
Acute lymphoblastic leukemia
Chronic myeloid leukemia
Myelodysplastic syndrome
Myeloproliferative disorders
NHL
Hodgkin disease
Chronic lymphocytic leukemia
Multiple myeloma
Juvenile myelomonocytic leukemia
Autologous
Malignant
NHL
Multiple myeloma
AML
Hodgkin disease
Neuroblastoma
Germ-cell tumors
Other diseases
Autoimmune disorders
Amyloidosis

Timing of HCT relative to diagnosis varies with disease.

AML, acute myelogenous leukemia; NHL, non-Hodgkin lymphoma.

Indications for Autologous Hematopoietic Cell Transplantation

CASE 101-1

QUESTION 1: P.J., a 46-year-old man, has diffuse large B-cell non-Hodgkin lymphoma (NHL) in first relapse after a complete remission of 1 year. An 80% reduction in measurable disease is noted after two cycles of dexamethasone, high-dose cytarabine, and cisplatin (DHAP) salvage chemotherapy. P.J.'s bone marrow biopsy and lumbar puncture are negative for malignant cells. Is a myeloablative preparative regimen with autologous HCT indicated for P.J.?

Autologous HCT is used to treat a variety of malignancies (Table 101-2). NHL and multiple myeloma are the most common indications for this procedure and represent more than two-thirds of all autologous HCT.[2] Nearly all patients who undergo autologous HCT have failed standard chemotherapy regimens; therefore, their hematopoietic stem cells have been exposed to prior chemotherapy leading to less abundant and viable stem cells.

The primary use of autologous HCT is in diseases that have aggressive features but are still chemotherapy-sensitive.[7] In a randomized, controlled trial,[8] autologous bone marrow transplant (BMT), compared with conventional chemotherapy with DHAP, resulted in a 5-year event-free survival of 46% versus 12%, respectively ($p = 0.001$). Overall 5-year survival was 53% in the BMT group and 32% in the conventional chemotherapy patients ($p = 0.038$).[8]

Whereas HCT is delayed until relapse after primary treatment in NHL, in some malignancies, autologous HCT is indicated as primary therapy to improve overall survival and progression-free survival.[7,9–10]

Prospective studies comparing preparative regimens, stem cell mobilization techniques, and stem cell source (i.e., BMT vs. PBPCT) are not available; however, autologous PBPCT has become the preferred source of stem cells, most likely owing to the improved outcomes with PBPCT in other disease settings.[11] PBPCs, defined as cells that express the CD34 antigen (e.g., $CD34^+$), are continuously circulating in the blood; however, their numbers are too low to easily collect the amount needed in transplant. Mobilization refers to the techniques used to move the stem cells out of the bone marrow compartment, increasing their numbers in circulation. Mobilization can be accomplished using growth factors or chemotherapy (see Mobilization and Collection of Autologous Peripheral Blood Progenitor Cells section).

P.J. has minimal residual disease that has demonstrated chemotherapy sensitivity (i.e., he had an 80% response to chemotherapy). His long-term prognosis will be improved with autologous PBPCT rather than with further conventional chemotherapy, as described previously. Thus, autologous PBPCT is indicated, owing to the greater likelihood that higher-dose chemotherapy may eradicate his tumor.

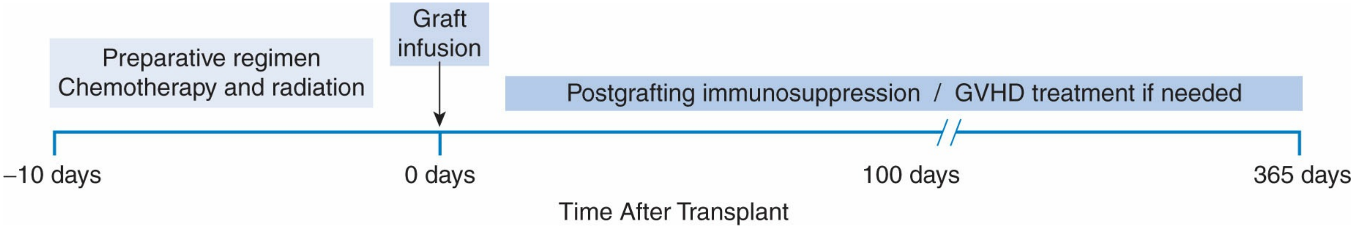

Figure 101-1 Basic schema for hematopoietic stem cell transplantation. Day 0 = bone marrow, peripheral blood progenitor cell (PBPC), or umbilical cord blood infusion. Postgraft immunosuppression or graft-versus-host disease (GVHD) prophylaxis for allogeneic grafts only.

Harvesting Autologous Hematopoietic Stem Cells

CASE 101-1, QUESTION 2: What is the best way to harvest and preserve harvested hematopoietic stem cells for P.J.?

PBPCs have essentially replaced bone marrow as the source of stem cells at many HCT centers, accounting for 98% of autologous transplants in adults from 2004 to 2008.[1] PBPCs result in more rapid engraftment than bone marrow and fewer days of neutropenia.[12] Collection of PBPCs occurs before administering the preparative regimen; thus, autologous hematopoietic stem cells must be cryopreserved.[2] Hematopoietic stem cells are frozen below −120°C and used within a few weeks; although, when frozen, they are viable for years.[2] Dimethyl sulfoxide (DMSO) is the cryopreservative commonly used to protect hematopoietic stem cells from damage during freezing and thawing. Infusion of hematopoietic stem cells stored in DMSO can be associated with toxicities due to the DMSO itself. During infusion, DMSO is associated with skin flushing, nausea, diarrhea, dyspnea, hypotension, arrhythmias and, rarely, anaphylactic reactions.[13] The presence of undetectable tumor cells in the transplanted cells contributes to relapse of hematologic cancers; unfortunately, purging the grafts of tumor cells does not improve survival.[2]

Relative to bone marrow harvest, collection of PBPCs requires less invasive collection methods and contains up to 5 times more hematopoietic stem cells. This results in a PBPC HCT having more rapid neutrophil and platelet recovery (i.e., a shorter duration of neutropenia or thrombocytopenia), fewer platelet transfusions, fewer days of intravenous antibiotics, and a shorter duration of hospitalization compared to a bone marrow HCT. Thus, the shift to the use of PBPCs instead of bone marrow for autologous HCT is primarily because of the more rapid engraftment and less invasive collection methods.[11] Therefore, it would be best for P.J. to undergo pheresis for PBPC collection. These cells would be bathed in DMSO and frozen at –120°C.

Mobilization and Collection of Autologous Peripheral Blood Progenitor Cells

CASE 101-1, QUESTION 3: For PBPC mobilization, P.J. received one dose of cyclophosphamide 4 g/m^2 IV on day 1, followed by filgrastim 10 mcg/kg/day subcutaneously (SC) beginning on day 2 and continuing through completion of pheresis. Twelve days after receiving cyclophosphamide, P.J.'s white blood cell count recovered to 3,000 cells/μL and pheresis was begun. An adequate number of PBPCs is collected after two pheresis sessions. P.J.'s cells are processed and stored. What was the rationale for administering filgrastim and cyclophosphamide? What determines the duration of pheresis?

Normally, low numbers of PBPCs are found in the peripheral circulation; therefore, it is necessary to "mobilize" PBPC from the marrow compartment into the systemic circulation. Mobilization leads to a collection of sufficient numbers of autologous PBPCs in most patients, although a minority of patients may still have poor mobilization.[11] Multiple methods can be used to mobilize PBPCs. Hematopoietic growth factors alone or in combination with myelosuppressive chemotherapy are used to mobilize PBPCs.[11] After administration of the mobilizing agent(s), the patient undergoes pheresis, an outpatient procedure similar to dialysis in order to collect PBPCs.[12]

Granulocyte–macrophage colony-stimulating factor (GM-CSF, sargramostim) and granulocyte colony-stimulating factor (G-CSF, filgrastim) are both hematopoietic growth factors and are used as mobilizing agents for PBPC collection.[11,14] Both reliably mobilize PBPCs, with filgrastim providing a higher PBPC yield.[11] The most frequently used filgrastim doses for autologous PBPC mobilization are in the range of 10 to 24 mcg/kg/day subcutaneously.[11,14] PBPC yield is higher when pheresis is started at day 5 (vs. day 6), with the optimal yield being around 10 hours after filgrastim administration.[11]

Myelosuppressive chemotherapy stimulates stem cell and progenitor cell proliferation. The combination of chemotherapy with filgrastim enhances PBPC mobilization relative to filgrastim alone. A benefit of using chemotherapy is that it also treats the underlying malignancy.[11] Examples of PBPC mobilization chemotherapy regimens include single-agent cyclophosphamide or melphalan. No mobilization chemotherapy regimen is clearly superior, which has led to incorporating PBPC mobilization into a cycle of disease-specific chemotherapy, such as using a single cycle of R-ICE (rituximab, ifosfamide, carboplatin, etoposide) therapy as the mobilization regimen for a NHL patient whose disease is responsive to R-ICE treatment.[11] By administering chemotherapy to the patient, the body's repair mechanism accelerates the cell division of stem cells and releases them into the circulation. This is a delicate balance, because the more the chemotherapy that is given to mobilize the stem cells the greater the potential for damage to the stem cells and a decreased yield at collection. Stem cell toxic agents, such as carmustine, should be avoided because they lower the quantity and quality of PBPCs. The hematopoietic growth factor is initiated 24 to 72 hours after completion of chemotherapy. Pheresis begins when the peripheral WBC count recovers to greater than 1 to 3 × 10^3 cells/μL.[11]

Certain patients fail to mobilize sufficient PBPC due to extensive prior therapy or therapy with marrow toxic agents. In these patients, plerixafor, an inhibitor of the CXCR4 chemokine receptor, can be used. Plerixafor was approved by the US Food and Drug Administration (FDA) in 2008 for use in stem cell mobilization in conjunction with filgrastim. It is known that CD34 is an adhesion molecule involved in promoting adherence of hematopoietic stem cells to the bone marrow microenvironment. Stromal cell-derived factor-1 (SDF-1) is a chemo-attractant agent for hematopoietic stem cells; its presence in circulation causes rapid migration of these stem cells to the peripheral blood.[11] Inhibition of the CXCR4 by plerixafor blocks the ligand SDF-1 from binding to the CXCR4 receptor, thus releasing CD34$^+$ cells from the bone marrow. In two randomized studies, 59% of NHL patients and 72% of multiple myeloma patients had sufficient CD34$^+$ cell collection for autologous transplant using plerixafor and filgrastim in four or fewer pheresis sessions, compared to 24% and 34%, respectively, in those using filgrastim alone.[15] Plerixafor is administered to the patient approximately 10 to 18 hours prior to each pheresis beginning four days after initiation of daily filgrastim 10 mcg/kg. Pheresis is continued daily until the target number of PBPCs per kilogram of the recipients' weight is obtained.[11] Typically, 1 to 2 large volume pheresis sessions are needed to collect adequate numbers of CD34$^+$ cells.[16] For adult recipients, the number of cells infused that are CD34$^+$ is the most reliable indicator of an adequate PBPC collection and predictor of durable engraftment.[11] A variety of different thresholds have been identified as the minimal number of CD34$^+$ cells needed for an autologous PBPCT to produce rapid and complete (i.e., white blood cells, red blood cell, platelet) engraftment in adults. The minimum threshold range has varied from 1 to 3 $\times 10^6$ CD34$^+$ cells/kg of recipient weight, with more rapid platelet and neutrophil engraftment occurring with greater than or equal to 5 to 8 $\times 10^6$ CD34$^+$ cells/kg of recipient weight.[11]

There are a number of factors that can affect the yield of CD34$^+$ cells, including the timing and amount of myelosuppressive treatments received prior to mobilization; both chemotherapy and radiation negatively impact mobilization. The type of chemotherapy, number of different regimens, and overall duration of chemotherapy treatment affect the ability to collect stem cells. Additionally, hypocellular marrow and refractory disease can lead to a poor PBPC harvest.[11] There is a paucity of information regarding the parameters associated with engraftment in children undergoing an autologous PBPCT.[17] After pheresis, the cells are cryopreserved, stored, thawed, and infused into the patient as described in the Harvesting Autologous Hematopoietic Stem Cells section. Because P.J. has been in remission for a year after initial treatment for his disease, he received no radiation treatment, and his salvage therapy did not contain alkylating agents, his cell collection can be expected to be good and of short duration.

Myeloablative Preparative Regimens

CASE 101-1, QUESTION 4: What are the goals and characteristics of agents used for myeloablative preparative regimens in patients like P.J.?

The primary goal of P.J.'s high-dose, myeloablative preparative regimen followed by autologous transplant is to eradicate residual malignancy that is not treatable with standard chemotherapy. With autologous HCT, there is no need for immunosuppression because the donor and recipient are genetically identical.[2] Combination chemotherapy with multiple alkylating agents constitutes the most common high-dose regimens before autologous HCT. Alkylating agents are used because they exhibit a steep dose–response curve for various malignancies to overcome resistance to treatment, and are characterized by dose-limiting bone marrow suppression.[18] Ideally, combinations of antineoplastics should have nonhematologic toxicities that do not overlap and that are not life-threatening. Examples of common myeloablative regimens are illustrated in Table 101-3.[19–23] The early and late toxicities to myeloablative regimens are listed in Table 101-4.[2–4]

Table 101-3

Representative Myeloablative Preparative Regimens Used in Hematopoietic Stem Cell Transplantation

Type of HCT	Disease State	Regimen	Dose/Schedule
Allogeneic[75]	Hematologic malignancies[a]	CY/TBI	CY 60 mg/kg/day IV on 2 consecutive days before TBI 1,000–1,575 rads fractionated for 1–7 days
Autologous[92,93]	Acute and chronic leukemias	BU/CY	BU adult 1 mg/kg/dose PO or 0.8 mg/kg/dose IV every 6 hours for 16 doses BU children <12 kg 1.1 mg/kg/dose IV every 6 hours for 16 doses CY 50 mg/kg/day IV daily for 4 days or 60 mg/kg/day IV daily for 2 days after BU
Autologous[23]	Non-Hodgkin lymphoma, Hodgkin disease	BEAM (carmustine/etoposide/cytarabine/melphalan)	Carmustine 300 mg/m^2/day IV, 1 dose etoposide 200 mg/m^2/day BID IV for 3 days Cytarabine 200

			mg/m^2/day IV BID for 4 days
			Melphalan 140 mg/m^2 1 dose

[a] Includes acute myelogenous leukemia (AML), acute lymphocytic leukemia, chronic myelogenous leukemia, non-Hodgkin lymphoma, and Hodgkin disease.

BID, twice a day; BU, busulfan; CY, cyclophosphamide; IV, intravenously; PO, orally; TBI, total body irradiation.

Table 101-4

Common Toxicities Associated with Myeloablative Allogeneic Hematopoietic Stem Cell Transplantation

Early Post-transplant (<100 days)	Late Post-transplant (>100 days)
Febrile neutropenia	Increased susceptibility to infections
Nausea, vomiting, diarrhea Mucositis Veno-occlusive disease (VOD) Renal dysfunction Cardiotoxicity	Endocrine disorders (hypothyroidism, hemorrhagic cystitis, infertility, growth retardation) Neurocognitive changes
Pneumonitis	Secondary malignant neoplasms
Graft rejection	Chronic GVHD
Acute GVHD	Cataracts

GVHD, graft-versus-host disease.

Complications of Autologous Hematopoietic Cell Transplantation

CASE 101-1, QUESTION 5: What complications must be anticipated as a consequence of autologous HCT? How can these be minimized? How can treatment be provided in an outpatient setting?

The most common cause of death after autologous HCT is relapse of the primary disease. The most common toxicities seen during autologous HCT are the result of the pancytopenia induced by high-dose chemotherapy. Because autologous HCT is not complicated by profound immunosuppression or GVHD, supportive-care strategies differ from allogeneic HCT. Isolation and use of laminar air flow rooms are unnecessary. The use of autologous PBSCT is associated with shorter periods of neutropenia and less need for clinical resources; thus, some HCT centers have developed programs that incorporate outpatient care into

---

the initial recovery. These outpatient programs also offer cost savings to the payer for health services.[24,25] Successful outpatient care during autologous HCT requires careful development and implementation of the necessary supportive-care strategies to prevent or minimize infection, chemotherapy-induced nausea and vomiting, infection, pain, and transfusion requirements. It is also necessary to develop admission criteria for patients with more severe complications.

Use of prophylactic oral antibiotics and once-daily IV antibiotics to prevent or treat febrile neutropenia has facilitated outpatient care and prevented many patients from being hospitalized.[26]

In addition, outpatient care during autologous HCT demands that HCT centers have appropriate resources, facilities, and staff to provide 24-hour patient care coverage. Patients undergoing outpatient care must meet eligibility criteria, including the availability of caregivers 24 hours a day and housing within close proximity to the HCT center.

Hematopoietic Growth Factors After Autologous Peripheral Blood Progenitor Cell Infusion

CASE 101-1, QUESTION 6: Ten days after the collection of PBSC, P.J. is admitted for his autologous HCT. He receives a myeloablative preparative regimen with cyclophosphamide, carmustine, and etoposide with an autologous PBPC graft. An order is written to begin filgrastim 5 mcg/kg/day subcutaneously, beginning on day 0 and continuing until the ANC has recovered to 500 cells/μL for two consecutive days. What is the rationale for filgrastim in P.J. after the transplant procedure?

Autologous HCTs, regardless of the stem cell source, are associated with profound aplasia due to the myeloablative preparative regimen (Table 101-3). Aplasia typically lasts 14 to 21 days after an autologous BMT and 10 to 14 days after an autologous PBPCT.[21] During this period of pancytopenia, patients are at high risk for complications such as bleeding and infection. In order to lessen the complications of pancytopenia, hematopoietic growth factors, such as filgrastim and sargramostim, may be used. These drugs exert their effects by stimulating the proliferation of committed progenitor cells. The benefits of the hematopoietic growth factor have been shown in several large multicenter, randomized, double-blind, placebo-controlled trials.[27–29] The majority of the trials suggest hematopoietic growth factor administration is associated with a shorter time to neutrophil engraftment (by 4–7 days), less infectious complications, shorter hospitalization after autologous BMT, and therefore decreased resource utilization.[27,28,30] However, the use of these agents does not affect overall survival.[27,29]

Although studies in the autologous PBPCT setting note more rapid neutrophil recovery after hematopoietic growth factor use, others report no difference in infection rates and minimal decreases in associated resource use such as the duration of hospitalization.[28,30–32] Although clinical practice guidelines for hematopoietic growth factors support their use after autologous transplant, pharmacoeconomic analyses are needed to further evaluate the true benefit of hematopoietic growth factors after autologous PBPCT.

Filgrastim is preferred for accelerating neutrophil engraftment in clinical practice. The reason most commonly cited is the desire to avoid febrile reactions associated with sargramostim, which complicates interpretation of febrile neutropenia. Although sargramostim or filgrastim theoretically may stimulate proliferation of leukemia myeloblasts, no evidence to date suggests that the incidence of leukemia relapse is higher in patients who receive these hematopoietic growth factors after autologous or allogeneic HCT.[33,34]

Although both filgrastim and sargramostim successfully hasten neutrophil recovery, neither agent stimulates platelet production or augments platelet recovery.[27,28] At this time, there is no established role for erythropoietin stimulating agents or platelet growth factors in the care of these patients. In summary, P.J. is undergoing autologous PBPCT for the treatment of a lymphoid malignancy. Thus, either sargramostim or filgrastim is an acceptable option for accelerating engraftment. Whether the addition of either agent will reduce infection and improve other clinically relevant outcomes is debatable.[14] A complete blood cell (CBC) count with differential should be obtained daily. Filgrastim should be continued until neutrophil recovery is achieved.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Allogeneic HCT involves the transplantation of hematopoietic stem cells obtained from a donor's bone marrow, PBPCs, or umbilical cord blood to a patient. Fifty-one percent (51%) of all transplants performed in North America in 2008 used unrelated donors.[1] Thus, to understand the application of and complications after allogeneic HCT, a working knowledge of immunology and the major histocompatibility complex (MHC) and human leukocyte antigen (HLA) in humans is necessary.

Indications for Allogeneic Hematopoietic Stem Cell Transplantation

CASE 101-2

QUESTION 1: B.S., a 22-year-old man, has acute myelogenous leukemia (AML) in first remission after induction chemotherapy with standard doses of cytarabine and daunorubicin and consolidation with high-dose cytarabine. B.S. has poor risk cytogenetics, with abnormalities of 11q23 and inversion 3. Thus, he will receive an allogeneic HCT as part of postremission therapy. Typing performed on family members has identified a fully HLA-matched sibling donor. B.S. returns to the clinic today for a pretransplantation workup. At this time, his physical examination is noncontributory. All laboratory values are within normal limits. A bone marrow biopsy reveals less than 5% blasts. B.S. has a normal electrocardiogram and cardiac wall motion study. His renal, hepatic, and pulmonary function tests are normal. Is an allogeneic HCT indicated for B.S.?

The primary indications for allogeneic HCT include treatment of otherwise fatal diseases of the bone marrow or immune system (Table 101-2). The optimal role and timing of allogeneic HCT, in contrast to other therapies, remains controversial,[35] especially because treatment options for AML have increased. The National Comprehensive Cancer Network treatment guidelines for AML include the use of allogeneic HCT. A matched sibling or alternative donor (e.g., matched unrelated donor [MUD]) HCT is recommended as part of postremission therapy in patients with preceding hematologic disease (e.g., myelodysplasia, secondary AML) or poor risk cytogenetics, as in the case of B.S.[36] Current research efforts focus on the use of reduced-intensity preparative regimens and the utility of HCT relative to novel targeted agents in the hope of improving the outcome of allogeneic HCT.[36] B.S. is eligible for allogeneic HCT by virtue of his cytogenetics and the availability of a histocompatible donor. In addition, he meets age and organ function eligibility requirements and is in complete remission with minimal residual disease.

Histocompatibility

CASE 101-2, QUESTION 2: Why is histocompatibility important in selection of the donor in patients like B.S. who undergo an allogeneic HCT?

Because the tissue transplanted in allogeneic HCT is immunologically active, there is potential for bidirectional graft rejection.[2] In the first scenario, cytotoxic T cells and natural killer (NK) cells belonging to the host (recipient) recognize MHC antigens of the graft (donor hematopoietic stem cells) and elicit a graft rejection response. This results in ineffective hematopoiesis (i.e., inadequate ANC and/or platelet counts) post-transplant. In the second scenario, immunologically active cells in the graft recognize host MHC antigens and elicit an immune response, referred to as GVHD. Therefore, an essential first step for patients eligible for HCT is finding an HLA-compatible graft with an acceptable risk of rejection and GVHD.

Determination of histocompatibility between potential donors and the patient is completed before allogeneic HCT.[37] Initially, HLA typing is performed using tissue (buccal swab) and blood samples. Compatibility at class I MHC antigens (HLA-A, HLA-B, and HLA-C) is determined through serologic and DNA-based testing methods.[38,39] Currently, most clinical and research laboratories are also performing molecular DNA typing.[38–47] A donor–recipient pair with different HLA antigens (i.e., “antigen mismatched”) always has different alleles, whereas pairs with the same allele always have the same antigen and are termed “matched.” However, some pairs have the same HLA antigen but different alleles and are thus “allele mismatched.” (See Chapter 34, Kidney and Liver Transplantation, for additional discussion of histocompatibility.)

Graft rejection is least likely to occur with a syngeneic donor, meaning that the recipient and host are identical (monozygotic) twins. Identical twins occur spontaneously in nature in approximately 1 in 100 births; thus, it is unlikely that a patient would have a syngeneic donor. In those patients without a syngeneic donor, initial HLA typing is conducted on family members because the likelihood of a complete histocompatibility match between unrelated individuals is remote. Siblings are the most likely to be histocompatible within a family; however, only 25% of potential HCT recipients will have an HLA-identical sibling.[38]

Lack of an HLA-matched sibling donor can be a barrier to allogeneic HCT. Alternative sources of allogeneic hematopoietic stem cells, such as related donors mismatched at one or more HLA loci, or MUDs, are used.[40] Establishment of the National Marrow Donor Program has helped increase the pool of potential donors for allogeneic HCT.[40] Through this program, an HLA-matched unrelated volunteer donor might be identified. Recipients of an unrelated graft are more likely to experience graft failure and acute GVHD relative to recipients of a matched sibling donor.[41] Thus, work is ongoing to identify factors that predict graft failure or GVHD to improve the availability and safety of unrelated donor transplants (see Graft Rejection section).[42]

The preparative regimen and/or GVHD prophylaxis may be altered based on the mismatch between the donor and the recipient. The risk of graft failure decreases with better matches, and although mismatching in a single HLA allele does not appear to impact overall survival, mismatching in more than one allele significantly impairs overall survival. The most important alleles to match are the HLA class I antigens (HLA-A, HLA-B, HLA-C) and the HLA class II antigens (HLA-DRB1, HLA-DPB1, HLA-DQB1).[43–45] This field is continually evolving with current data suggesting that mismatches at HLA-DPB1confer an increased risk of mortality.[46]

Eligibility criteria for allogeneic HCT vary between institutions. Having a matched sibling donor is no longer a requirement for allogeneic HCT, because improved immunosuppressive regimens and the National Marrow Donor Program have allowed an increase in the use of unrelated or related matched or mismatched HCT.[41] Potential donors also include haploidentical donors, who are a parent, sibling, or child of a parent with only one identical HLA haplotype. Hematopoietic cell transplant with a haploidentical donor was initially associated with high rates of graft failure and GVHD, but recent technologic advances have improved outcomes. Haploidentical HCT involves another alloreactive mechanism involving NK cells, which may be associated with reduced relapse rates in AML patients.[2]

Normal renal, hepatic, pulmonary, and cardiac functions are necessary for eligibility at most centers. Historically, patients older than 55 years were excluded from allogeneic HCT because they were more likely to succumb to transplantation-related complications. However, many centers are now considering patients up to 65 years old and basing their selection criteria on physiologic rather than biologic age.

Harvesting, Preparing, and Transplanting Allogeneic Hematopoietic Stem Cells

CASE 101-2, QUESTION 3: What methods can be used to harvest hematopoietic stem cells from B.S.'s histocompatible sibling and prepare them for transplant? Are there any advantages to the use of bone marrow, PBPCs, or umbilical cord blood as a source for hematopoietic stem cells?

The method of harvesting allogeneic hematopoietic stem cells varies according to the site of harvest (i.e., bone marrow, peripheral blood, or umbilical cord blood). ABO incompatibility increases the complexity of HCT, but is not an obstacle to HCT. The hematopoietic stem cells may need additional processing to reduce the RBCs infused with the HCT product if the donor and recipient are ABO-incompatible, which occurs in 30% to 40% of sibling donor HCTs and is higher in unrelated donor HCT.[47] Various strategies post-transplant used to manage blood support for ABO-incompatible HCT recipients include the infusion of donor-type fresh frozen plasma to provide a noncellular source of A or B antigens, as well as transfusing-type volume reduced RBCs and platelets or O RBCs to minimize the risk of immune-mediated hemolytic anemia and thrombotic microangiopathic syndromes.[47]

BONE MARROW

Harvesting bone marrow entails a surgical procedure in which marrow is obtained from the iliac crests. Allogeneic bone marrow is obtained from the donor under local or general anesthesia on day 0 of BMT.[2] The number of nucleated marrow cells harvested varies depending on disease being treated, conditioning regimen, and preinfusion manipulation, and is usually 1 to 3 × 10^8 infused cells/kg of recipient weight.[17] These cells are obtained through multiple aspirations of marrow from the posterior iliac crests. The marrow is then processed to remove fat or marrow emboli and is usually immediately infused intravenously into the patient. If immediate transplant is not possible, the bone marrow is frozen until it can be infused. Once infused into circulation, through the mechanism of the chemokine SDF-1/CXCR4 receptor, the stem cells migrate to the bone marrow compartment where they will eventually reside.

PERIPHERAL BLOOD PROGENITOR CELLS

As mentioned earlier, hematopoietic stem cells continuously detach, enter the circulation, and return to the marrow; thus, the peripheral blood is a convenient source of hematopoietic stem cells. The number of PBPCs is estimated by using the cell surface molecule CD34 as a surrogate marker. The number of circulating $CD34^+$ cells in blood is increased by mobilizing them from the marrow. The most commonly used regimen to mobilize allogeneic (healthy) donors is a 4- to 5-day course of filgrastim 10 to 16 mcg/kg/day subcutaneously, followed by pheresis on the fourth or fifth day when peripheral blood levels of $CD34^+$ cells peak.[9] An adequate number of hematopoietic stem cells is usually obtained with one to two pheresis collections. The optimal number of $CD34^+$ required is 4 to 10 × 10^6 cells/kg of recipient body weight for a HLA-identical sibling donor transplant with haploidentical transplants requiring greater numbers.[10,48,49] Higher cell doses have been associated with not only more rapid engraftment but also fewer fungal infections and improved overall survival.[50] Hematopoietic stem cells obtained from the peripheral blood are processed like bone marrow-derived stem cells and may be infused immediately into the recipient or frozen for future use. Compared to bone marrow, PBPC infusions are associated with quicker neutrophil and platelet engraftment.[2] In patients with a hematologic malignancy and a matched sibling donor, PBPCT is also associated with lower relapse rates and increased disease-free survival rates.[51] However, PBPC grafts contain more T cells than do bone marrow grafts.[2] Therefore, PBPCT has a similar incidence of acute GVHD, but an approximately 20% higher incidence of extensive stage and overall chronic GVHD.[51]

UMBILICAL CORD BLOOD

Blood from the umbilical cord and the placenta is rich in hematopoietic stem cells but limited in volume.[52] Thus, umbilical cord blood offers an alternative stem cell source to those patients who do not have a suitable related donor. After consent is obtained, the cord blood cells are obtained in the delivery room after birth, typically after the delivery of the placenta.[53]

The cord blood is then processed, and, if it matches certain pre-established criteria (e.g., minimum nucleated cell content, sterility), a sample is sent for HLA typing and cryopreserved for future use. An estimated 20,000 HCTs with cord blood donors have been performed with more than 300,000 cord blood units banked worldwide. It is unknown how long cryopreserved cord blood is viable.[54]

HCT with an unrelated cord blood donor has several potential advantages over unrelated marrow or PBPC donors.[52] Specifically, (a) cord blood is readily available, which leads to a more rapid time to HCT; (b) lack of stem cell exposure to the thymus allows for greater degrees of HLA disparity as compared to bone marrow or PBPC[53]; and (c) despite the less-stringent HLA matching, mismatched cord blood cells are less likely to cause GVHD while still maintaining GVT activity. The less-stringent HLA requirements increase the likelihood of identifying a suitable allogeneic donor, which is particularly beneficial for minority populations who are underrepresented in adult registries and often lack matched stem cell sources. Outcomes in umbilical cord blood recipients are improved with fewer HLA mismatches and greater numbers of $CD34^+$ cells.[55] However, the limited number of hematopoietic stem cells in cord blood is a disadvantage in particular when considering adult patients.[56] In order to overcome the cell dose limitation and improve engraftment, researchers have been studying infusing two cord blood units,[57] coinfusing a cord blood unit with highly purified $CD34^+$ cells from haploidentical donors,[58] and ex vivo expansion of cord blood progenitors,[59] delivery of the cord blood unit directly into the bone marrow space,[60–62] and priming of cord blood with agents that may facilitate homing to the bone marrow.[63]

As an adequate cell dose is critical for engraftment after cord blood transplantation and the cell dose of a single cord blood unit is limited, progress in the field of cord blood transplantation for the treatment of adults has been slower.[56] However, recent data showed that when a single cord blood unit with an adequate cell dose is available, the outcomes of adults with leukemia are similar to those receiving unrelated bone marrow or peripheral blood grafts.[64]

Moreover, for those adults with leukemia who do not have a single cord blood unit with a suitable cell dose, the use of two partially matched cord blood units to compose the graft also provides outcomes similar to that of related and unrelated donors.[65] These data associated with the promising outcomes when using umbilical cord blood in the context of reduced-intensity conditioning have significantly increased the utilization of cord blood as a source of hematopoietic progenitors for the treatment of adult patients.[66,67]

In summary, the utilization of cord blood as a source of hematopoietic stem cells for transplantation has substantially expanded in the last decade. Novel methodologies to improve engraftment, promote immune reconstitution, and improve outcomes after cord blood transplantation are under investigation and are likely to further extend its availability to patients who require a potentially curative allogeneic transplant but lack a suitable related donor.

Therefore, it is most reasonable to harvest PBPCs from B.S.'s sibling to use for his myeloablative HCT because his sibling is fully HLA-matched. A PBPC transplant is preferred to BMT due to the expectations of increased speed of neutrophil and platelet engraftment and disease-free survival rate and lower relapse rate.

Graft-versus-Tumor Effect

CASE 101-2, QUESTION 4: B.S. will receive an allogeneic HCT from his histocompatible sibling with the hope of inducing GVT effect to help in treating his malignancy. What is the GVT effect? Which tumors are most responsive to this effect?

Graft-vs.-tumor refers to the phenomenon where the donor's cytotoxic T lymphocytes suppress or eliminate the recipient's malignancy. Initial clinical evidence of a GVT effect came from the observation that patients with GVHD had lower relapse rates compared with those who did not.[68,69] This suggested a GVT effect due to the donor lymphocytes. Lymphocyte involvement in GVT was further supported by the effectiveness of donor lymphocyte infusions in treating patients who experienced relapse of their malignancies after allogeneic HCT.[70,71] Eradication of the recurrent malignancy is due to either specific targeting of the tumor antigens or to GVHD, which may affect cancer cells preferentially. Different illnesses vary in their responsiveness to donor lymphocyte infusions, with chronic myelogenous leukemia (CML) and acute leukemias being the most and least responsive, respectively.[72] Patients with certain solid tumors (e.g., renal cell carcinoma) also appear to benefit from a GVT effect.[73] These data are the platform on which the use of reduced-intensity and nonmyeloablative preparative regimens are based.

Preparative Regimens for Allogeneic Hematopoietic Stem Cell Transplantation

MYELOABLATIVE PREPARATIVE REGIMENS

CASE 101-2, QUESTION 5: What is the rationale for using myeloablative preparative regimens for patients like B.S. who are to receive an allogeneic HCT? What types of regimens are used, and what is recommended for B.S.?

p. 2108

p. 2109

The combination of chemotherapy and/or radiation used in allogeneic HCT is referred to as the preparative or conditioning regimen. The rationale for high-dose myeloablative preparative regimens is similar to that discussed in the Autologous Hematopoietic Stem Cell Transplantation section. Infusion of hematopoietic stem cells restores hematopoiesis induced by dose-limiting myelosuppression of chemotherapy, maximizing the potential value of the steep dose–response curve to alkylating agents and radiation[18], and suppressing the host immune system. The preparative regimen is also designed to eradicate immunologically active host tissues (lymphoid tissue and macrophages) and to prevent or minimize the development of host-versus-graft reactions (i.e., graft rejection). Conversely, patients undergoing syngeneic transplantation do not require immunosuppressive preparative regimens before HCT because the donor and the patient are genetically identical; thus, there is no potential for host-versus-graft reactions. Therefore, preparative regimens are tailored to the primary disease and to HLA compatibility between the recipient–donor pair.

Examples of common preparative regimens for allogeneic HCT are shown in

Table 101-3.[8,20,74] Table 101-4 lists the common toxicities associated with myeloablative allogeneic HCT. Most allogeneic preparative regimens for the treatment of hematologic malignancies contain cyclophosphamide, radiation, or both. The combination of cyclophosphamide and total body irradiation (TBI) was one of the first preparative regimens used, and it is still used widely today. This regimen is immunosuppressive and has inherent activity against hematologic malignancies (e.g., leukemias, lymphomas). TBI is myeloablative and immunosuppressive, does not have cross-resistance to chemotherapy, and reaches sites not affected by chemotherapy (e.g., the central nervous system).[2] The toxicity of TBI and the scarcity of facilities for its delivery have led to the development of radiation-free preparative regimens. Modifications of the cyclophosphamide–TBI (CY/TBI) preparative regimen include replacing TBI with other agents such as busulfan and adding other chemotherapeutic or monoclonal agents such as alemtuzumab to the existing regimen. These measures are designed to minimize the long-term toxicities associated with TBI (e.g., growth retardation in children, cataracts) or to provide additional antitumor activity. The long-term outcomes of busulfan/cyclophosphamide (BU/CY) and CY/TBI in patients with AML and CML have been compared in a meta-analysis of four clinical trials. [75] Equivalent rates of long-term complications were present between the two preparative regimens, except for a greater risk of cataracts with CY/TBI and alopecia with BU/CY. Overall and disease-free survival rates were similar in patients with CML although there was a trend for improved disease-free survival with CY/TBI in AML patients. In the case of a mismatched allogeneic HCT with an increased chance of graft rejection, antithymocyte globulin (ATG) may also be added to the preparative regimen to further immunosuppress the recipient.

Based on these data, the CY/TBI preparative regimen is preferred for B.S. because he has AML with poor cytogenetics and has a matched sibling available. Because of the high relapse rates seen in AML, myeloablative allogeneic transplant is indicated in first remission for patients less than 60 years old with good performance status due to the decrease in likelihood of achieving a complete response to reinduction chemotherapy and the expected reduced duration of a second remission.

REDUCED-INTENSITY OR NONMYELOABLATIVE PREPARATIVE REGIMENS

CASE 101-2, QUESTION 6: Describe the rationale for nonmyeloablative preparative regimens. Is B.S. a candidate for such a regimen?

The regimen-related toxicity of a myeloablative preparative regimen (Table 101-4) limits the use of allogeneic HCT to younger patients who have minimal comorbidities. Because many patients with hematologic malignancies are older and have comorbidities, myeloablative HCT cannot be offered to a substantial portion of them.[76] The observation that patients with GVHD have less relapses and an improved understanding of the GVT effect led to the development of strongly immunosuppressive but not myeloablative (i.e., a reduced-intensity or nonmyeloablative) preparative regimens.[2] Currently, reduced-intensity preparative regimens account for 30% of allogeneic transplants.[77] More than 60% of patients receiving reduced-intensity preparative regimens are older than 50 years.[1,77]

There is a wide spectrum of reduced-intensity preparative regimens, with the nonmyeloablative regimens causing the least amount of myelosuppression. In general, more intensive preparative regimens are required for engraftment in the setting of unrelated donor or HLA-mismatched related HCT.[78] Reduced-intensity regimens do not completely eliminate the host's normal hematologic and malignant cells and therefore depend on the GVT effect to eradicate remaining cancer. The newly transplanted donor cells slowly replace host hematopoiesis, and elicit GVT effects.[73] After engraftment, mixed chimerism is generally present. Chimerism can be defined as the ability to detect both donor-derived and recipient-derived hematopoietic cells; both donor and patient cells coexist together for a period of time in the patient. If the graft is rejected, typically only recipient cells are present. After a reduced-intensity preparative regimen, mixed chimerism (defined as 5%–95% donor T cells present in the peripheral blood) between the host and recipient develops, allowing for a GVT effect as the primary form of therapy. Chimerism is evaluated to monitor disease response and engraftment post-transplant. Chimerism is assessed within T cells and granulocytes in the peripheral blood and bone marrow using conventional (e.g., using sex chromosomes for opposite sex donors) and molecular (e.g., variable number of tandem repeats for same sex donors) methods. The methods used to characterize chimerism after HCT are reviewed elsewhere.[79–81] A few months after HCT, donor lymphocytes can be infused (called a "donor lymphocyte infusion") to augment the GVT activity.[2] The use of donor lymphocyte infusions is dependent on the availability of the donor and is highly center specific. The challenge is to maximize the GVT effect while minimizing the risk of GVHD. Therefore, GVHD prophylaxis, although different from that used with myeloablative regimens, is still necessary. Although reduced-intensity preparative regimens have led to lower treatment-related mortality rates, they may be offset by higher relapse rates.[2,82] The safety and efficacy of these regimens have led to their wider application to nonmalignant conditions.[2] Because most of the data for reduced-intensity preparative regimens are derived from older patients or those with comorbid conditions, they cannot be compared with data for myeloablative preparative regimens.[82] It is unclear if reduced-intensity preparative regimens improve long-term survival of patients with malignant or nonmalignant diseases who are younger or without comorbid conditions. Prospective controlled trials are needed with stratification based on comorbidities, disease characteristics, pretransplant therapy, and hematopoietic stem cell source.[82]

There is a paucity of data regarding the optimal source of hematopoietic stem cells after reduced-intensity preparative regimens. Most case series have combined data from PBPC and marrow grafts. But some data suggest that, compared to bone marrow grafts, PBPC is associated with quicker engraftment, earlier T-cell chimerism, longer progression-free survival, and a lower risk of graft rejection.[83,84]

B.S. is young and healthy enough to receive a myeloablative allogeneic HCT. Presently, reduced-intensity HCT is only indicated

---

as first-line therapy for patients ineligible for myleoablative regimens due to age, extensive prior treatments, or other contraindications. It is not an option for B.S.

Post-transplantation Immunosuppressive Therapy

CASE 101-2, QUESTION 7: What is the rationale for immunosuppressive therapy after an allogeneic HCT? What is recommended for B.S.?

After infusion of hematopoietic stem cells, immunosuppressive therapy is administered to prevent or minimize GVHD. Patients receiving syngeneic transplants or a T-cell-depleted histocompatible allogeneic transplant generally do not receive post-transplantation immunosuppressive therapy. In syngeneic transplantation, the donor and the patient are genetically identical, and GVHD should not be elicited. In T-cell-depleted transplantation, the volume of donor T cells infused into the patient is usually insufficient to elicit significant GVHD.[70,85] Numerous immunosuppressive agents given alone or in combination have been evaluated for the prevention of GVHD. Commonly used regimens after myeloablative HCT include cyclosporine or tacrolimus administered with a short course of low-dose methotrexate.[86] Graft-versus-host disease (GVHD) prophylaxis varies in reduced-intensity protocols and can be found in Table 101-5.[87] Corticosteroids may also be used to prevent GVHD, but they are more commonly used to treat GVHD. In allogeneic HCT recipients without GVHD, immunosuppressive therapy is slowly tapered and discontinued over the course of 6 months to 1 year. Over time, the immunologically active tissue between host and recipient become tolerant of one another and cease recognizing the other as foreign, negating the need for immunosuppression. In contrast, solid organ transplant recipients usually continue immunosuppressive therapy for the duration of the recipient’s life.

In patients without a matched related or unrelated donor who undergo HCT with a haploidentical donor, the use of cyclophosphamide posthematopoietic stem cell infusion may be used. The cyclophosphamide is typically given approximately 4 days after HCT. It has been shown that the cyclophosphamide does not affect the hematopoietic stem cells but does exert its effect on alloreactive T cells, thereby reducing the risk of GVHD development.[88] Current trials are ongoing to assess the usefulness of this approach.

Table 101-5

Common Reduced-Intensity Preparative or Nonmyeloablative Regimens and Post-grafting Immunosuppresion[102]

Preparative Regimens	Postgraft Immunosuppression
Fludarabine 30 mg/m^2/day IV on 3 consecutive days (−4, −3, −2), TBI 2 Gy as single fraction on day 0	Cyclosporine 6.25 mg/kg PO BID, days –3 to day +100 with taper from day +100 to +180
Fludarabine 25 mg/m^2/day IV for 5 days and melphalan 90 mg/m^2/d IV for 2 days	Mycophenolate mofetil 15 mg/kg PO BID or TID, day +0 to +40 with taper from day +40 to +90
Fludarabine 25–30 mg/m^2/day IV for 3–5 days, busulfan ≤9 mg/kg/total dose	Tacrolimus to maintain trough blood concentration of 5–10 ng/mL with methotrexate 5 mg/m^2/day IV days +1, +3, +6, +11

BID, 2 times a day; IV, intravenous; PO, orally; TBI, total body irradiation; TID, 3 times a day.

B.S. is receiving a myeloablative preparative regimen with allogeneic transplant and will receive cyclosporine administered for 6 months, followed by a taper, with a short course of methotrexate 15 mg/m^2 on day +1 and 10 mg/m^2 on day +3, +6, and +11 for post-transplant immunosuppression. This combination regimen will lower the risk of GVHD. Assuming B.S. does not experience any serious complications, he will likely be immunosuppressant free by 9 months post-transplant. The cyclosporine will require therapeutic drug monitoring.

Comparison of Supportive-Care Strategies Between Autologous and Allogeneic Myeloablative Hematopoietic Stem Cell Transplantation

CASE 101-2, QUESTION 8: How do supportive-care strategies used for myeloablative preparative regimens with an autologous graft differ from an allogeneic graft? What supportive care will B.S. likely require?

Supportive-care strategies common to patients receiving a myeloablative preparative regimen, regardless of whether they have received an autologous or allogeneic HCT, include use of indwelling central venous catheters; blood product support; and pharmacologic management of chemotherapy-induced nausea and vomiting, mucositis, and pain. These similarities are a function of the side effects of a myeloablative preparative regimen.

Because of the different needs for immunosuppression with an autologous and allogeneic HCT, the supportive care differs. Allogeneic HCT patients experience an initial period of pancytopenia followed by a more prolonged period of immunosuppression, which substantially increases the risk of bacterial infections, but more importantly, fungal, viral, and other opportunistic infections.[4] The risk of infection increases as additional immunosuppressive therapy is incorporated to prevent or treat GVHD. Supportive strategies designed to minimize infection during immunosuppression are essential after allogeneic HCT (see Infectious Complications section).

B.S. received a myeloablative allogeneic transplant; therefore, he will have a central venous catheter inserted at admission. He will most likely require multiple RBC and platelet transfusions until engraftment occurs. He is at increased risk of infection because he will be immunosuppressed for months after the transplant. Also, if he were to develop GVHD, additional supportive care would be required. GVHD prophylaxis with cyclosporine and methotrexate will place him at risk for additional drug-related toxicities that will require monitoring. Had he received an autologous transplant the duration of neutropenia would be less, no immunosuppressive medications would be required, and the risk of developing complications from GVHD would have been avoided.

Comparison of Supportive-Care Strategies Between Allogeneic Myeloablative and Nonmyeloablative Hematopoietic Cell Transplantation

CASE 101-2, QUESTION 9: How do supportive-care strategies used for myeloablative and nonmyeloablative preparative regimens with an allogeneic graft differ?

A direct comparison of the toxicities between a myeloablative and nonmyeloablative preparative regimen is difficult because the latter is offered only to patients who are not candidates for myeloablative allogeneic HCT. The preparative regimens differ substantially in terms of the chemotherapy agents used (Tables 101-3 and 101-5) and the degree of myelosuppression. Nonmyeloablative HCT may have a different time pattern for infectious complications but there is a similar incidence and severity of acute GVHD. This makes comparisons between the preparative regimens challenging because of the differences in the pre-HCT health of the recipients.[78] Clinical research is focusing on designing optimal preparative regimens with acceptable efficacy and toxicity. Thus, as compared to myeloablative HCT, the preparative regimens and immunosuppression used after hematopoietic stem cell infusion are more variable for reduced-intensity and nonmyeloablative HCT.

COMPLICATIONS ASSOCIATED WITH

HEMATOPOIETIC CELL TRANSPLANTATION

CASE 101-3

QUESTION 1: K.M. is a 36-year-old woman with CML in accelerated phase. After her initial diagnosis, a successful search for an unrelated 6/6 HLA-matched allogeneic donor was conducted. K.M. is being admitted for myeloablative allogeneic PBPCT. Orders for K.M.'s preparative regimen are written as follows: busulfan, 16 mg/kg total dose to be administered over 4 days (1 mg/kg/dose orally [PO] every 6 hours for 16 doses, days −7, −6, −5, and −4). Cyclophosphamide 60 mg/kg/day IV to be administered on days −3 and −2. Day −1 is a "rest" day, followed by infusion of PBPC on day 0. What toxicities associated with myeloablative preparative regimen should be anticipated in K.M.? Are they similar to those anticipated after standard-dose chemotherapy?

Myelosuppression is a frequent dose-limiting toxicity for chemotherapy when administered in conventional doses used to treat cancer. However, because myelosuppression is circumvented with hematopoietic rescue in the case of patients receiving HCT, the dose-limiting toxicities of these myeloablative preparative regimens are nonhematologic (i.e., extramedullary) in nature. The toxicities vary with the preparative regimen used. Most patients undergoing HCT experience toxicities commonly associated with chemotherapy, such as alopecia, mucositis, chemotherapy-induced nausea and vomiting, infertility, and pulmonary toxicity (see Chapter 94, Adverse Effects of Chemotherapy and Targeted Agents). However, these drug-related toxicities are magnified in the HCT population.

Table 101-4 depicts a range of toxicities that can occur after myeloablative preparative regimen for HCT, and Figure 101-2 depicts the time course for complications after HCT. Selected toxicities are discussed in the following sections.

Busulfan Seizures

CASE 101-3, QUESTION 2: In addition to her preparative regimen, the following supportive-care agents and monitoring parameters are prescribed for K.M.: on the day of admission (day −8), administer levetiracetam 500 mg PO twice daily from days −8 to −3. Busulfan pharmacokinetic blood sampling is to occur after dose 1 to a target busulfan concentration at steady state (C_{SS}) greater than 900 ng/mL. Begin normal saline hydration 3,000 mL/m^2/day 4 hours before cyclophosphamide and continue for 24 hours after the last cyclophosphamide dose. Mesna is to be given concurrently with cyclophosphamide as 10% of the cyclophosphamide dose administered intravenously 30 minutes before starting the cyclophosphamide dose, then as 100% of cyclophosphamide dose administered as a continuous IV infusion for 24 hours after each dose of cyclophosphamide. Beginning on day −5, weigh patient twice daily, check fluid input and urinary output every 4 hours, and monitor urine for RBCs daily until 24 hours after the last cyclophosphamide dose. If urine output drops below 300 mL for 2 hours, administer an IV bolus of 250 mL normal saline and give furosemide 10 mg/m^2, not to exceed 20 mg IV. What is the rationale for these supportive-care therapies and monitoring parameters prescribed for K.M. as they relate to busulfan therapy?

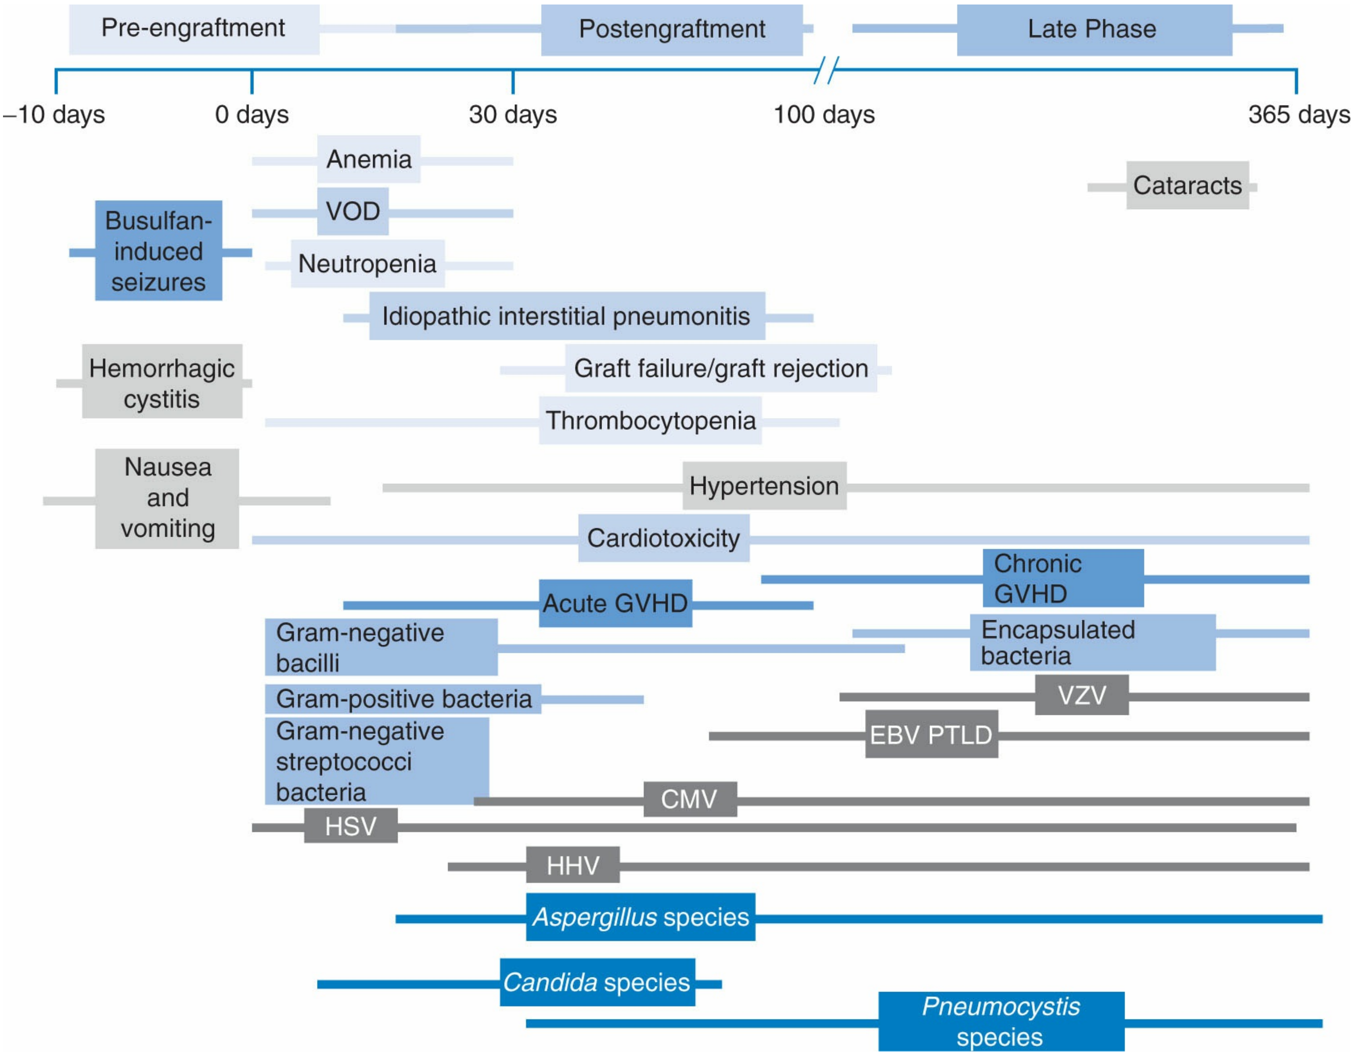

Figure 101-2 Complications after hematopoietic stem cell transplantation (HCT) by time for patients undergoing myeloablative allogeneic HCT only. CMV, cytomegalovirus; EBV, Epstein-Barr virus; GVHD, graft-versus-host disease; HHV, human herpes virus; HSV, herpes simplex virus; PTLD, post-transplantation lymphoproliferative disease; VOD, veno-occlusive disease; VZV, varicella-zoster virus.

Seizures occur in approximately 10% of patients receiving high-dose busulfan in HCT preparative regimens. Busulfan is highly lipophilic and readily crosses the blood–brain barrier with an average cerebrospinal fluid:plasma ratio of 1 or higher. Seizures are probably a direct neurotoxic effect[89]; therefore, seizure prophylaxis is used. Many HCT centers have moved from phenytoin to levetiracetam for seizure prophylaxis, although benzodiazepines (e.g., lorazepam or clonazepam) also have been used.[90] Seizure prophylaxis is started at least 12 hours before the first busulfan dose and is usually discontinued 24 to 48 hours after administering the last busulfan dose. Seizures can occur despite the use of seizure prophylaxis, but they usually do not result in permanent neurologic deficits.

Adaptive Dosing of Busulfan

CASE 101-3, QUESTION 3: What dosing strategies can be used to minimize busulfan toxicities?

Intravenous busulfan is commonly used in combination with cyclophosphamide as a preparative regimen before allogeneic HCT for CML. The FDA-approved dose is 0.8 mg/kg IV every 6 hours for 16 doses, which is similar to the oral busulfan dose of 1 mg/kg, assuming a fraction absorbed of 90%.[91] Intravenous busulfan, at 0.8 mg/kg of actual body weight, produces an average AUC of 1,200 µM/minute, within a wide range of 900 to 1,500 µM/minute in 80% of patients.[92] Higher AUC values (>1,500 µM/minute) have been associated with an increased risk of developing veno-occlusive disease (VOD) of the liver; therefore, monitoring of busulfan AUC is warranted. Target AUCs are commonly between 900 and 1,350 µM/minute after the first dose. This minimizes the risk of VOD and graft failure and minimizes the risk of disease recurrence.[93] (See Case 101-3, Questions 7–9 for information on VOD.)

To minimize adverse events from IV busulfan, an AUC is obtained with the first dose of busulfan to analyze K.M.'s exposure. Samples are drawn at the end of the 2-hour infusion, then 1, 2, and 4 hours after the first sample. Many centers are not capable of analyzing IV busulfan levels; therefore, prior arrangements must be made for timely analysis of these samples in order to adjust the dose after the second or third dose, if needed. K.M.'s AUC comes back 12 hours later at 1,225 µM/minute and, therefore, her dose is not changed. Had the AUC been greater than 1,350 µM/minute; her dose could have been adjusted using the following formula:

$$\text{Adjusted dose (mg)} = \text{Actual Dose (mg)} \times \text{Target AUC } (\mu\text{M/min}) / \text{Actual AUC } (\mu\text{M/min}) \qquad \text{(Eq. 101-1)}$$

Hemorrhagic Cystitis

CASE 101-3, QUESTION 4: What is the rationale for these supportive-care therapies and monitoring parameters prescribed for K.M. as they relate to cyclophosphamide therapy?

In HCT patients receiving cyclophosphamide, moderate-to-severe hemorrhagic cystitis occurs in 4% to 20% of patients receiving hydration alone.[94] Development of hemorrhagic cystitis is thought to be due to the bladder toxin acrolein, a metabolite of cyclophosphamide.[95] The chemoprotectant mesna donates free thiol groups which bind acrolein and reduce its toxicity. The American Society of Clinical Oncology (ASCO) Guidelines for the Use of Chemotherapy and Radiotherapy Protectants recommends the use of mesna plus saline diuresis or forced saline diuresis to lower the incidence of urothelial toxicity with high-dose cyclophosphamide in the setting of HCT.[96] It is important to note that hematuria or hemorrhagic cystitis can occur despite the use of any of these methods.

The optimal mesna dose with high-dose cyclophosphamide in preparation for myeloablative HCT is unknown. A variety of different regimens have been used, including intermittent bolus dosing (mesna dose 20%–40% of cyclophosphamide dose, administered for up to five doses) or continuous infusion regimens (mesna dose 80%–160% of cyclophosphamide dose).[94,97,98] Mesna should be continued for 24 to 48 hours after the last cyclophosphamide dose, such that mesna is present within the bladder at the same time as the urotoxic metabolite acrolein. After IV administration of mesna, most of it (i.e., 60%–100%) is excreted within the urine over the course of 4 hours.[99] Cyclophosphamide has an average half-life of 7 hours after administration of 60 mg/kg,[100] and acrolein may be present within the urine for 24 to 48 hours after cyclophosphamide administration.[101]

Thus, K.M. is receiving hydration with normal saline and mesna, administered as a continuous infusion, to minimize her risk of hemorrhagic cystitis due to cyclophosphamide. K.M. should be monitored for any RBCs present in the urine, along with her urinary output, to allow for rapid intervention if hemorrhagic cystitis occurs.

Chemotherapy-Induced Gastrointestinal Effects

CASE 101-3, QUESTION 5: What other end-organ toxicities must be watched for? Should any medications be ordered for K.M. to prevent and treat the gastrointestinal (GI) effects associated with myeloablative therapy?

The high doses of chemotherapy in preparative regimens cause most patients to be nauseated and anorexic until day +10 to +15. Chemotherapy-induced nausea and vomiting in HCT recipients can be due to highly emetogenic chemotherapy agents (see Chapter 22, Nausea and Vomiting), TBI administration, and poor control of nausea and vomiting prior to HCT. Thus, patients such as K.M. who are undergoing a myeloablative HCT should be given prophylaxis with a serotonin antagonist plus a corticosteroid.[102]

American Society of Clinical Oncology guidelines state that the use of the neurokinin receptor-1 antagonist, aprepitant, should be considered, although evidence to support its use in HCT patients is lacking.[102] Because aprepitant is a moderate inhibitor of cytochrome P-450 3A4, it may theoretically interact with the preparative regimen, especially cyclophosphamide. Well-controlled studies evaluating its efficacy, along with its potential for causing drug interactions, are needed.[102] Some data suggest that the serotonin antagonist ondansetron may increase cyclophosphamide clearance in patients undergoing a myeloablative HCT.[103,104] However, further work is needed to identify the clinical implications of this finding because, to date, cyclophosphamide concentrations have not been consistently associated with clinical outcomes in patients undergoing a myeloablative HCT.[19,91]

Most patients receiving a myeloablative preparative regimen may also experience mucositis due to its effects on rapidly dividing cells of the oral epithelium. The use of methotrexate as GVHD prophylaxis also contributes to mucositis.[105] Oral mucositis may also contribute to the development of nausea and anorexia.

In severe cases, parenteral opioid analgesics for pain relief[106] and total parenteral nutrition (TPN) may be needed. Because mucositis can be worsened by superinfection, good oral hygiene should be practiced. Soft toothbrushes should be used and replaced often.[107] Oral mucositis can be decreased with the use of recombinant human keratinocyte growth factor palifermin. The Multinational Association of Supportive Care in Cancer and International Society for Oral Oncology Guidelines recommend palifermin to prevent mucositis for patients with hematologic malignancies receiving myeloablative chemotherapy and TBI with autologous HCT. Palifermin 60 mcg/kg/day is given for 3 days immediately prior to administering the preparative regimen and for 3 days after infusion of the hematopoietic stem cell graft (i.e., days 0, +1, +2).[108] In these patients, palifermin lowered the incidence and average duration of clinically meaningful oral mucositis. The incidence of blood-borne infections and the use of parenteral opioids were also diminished in patients using palifermin.[108]

Myelosuppression and Growth Factor Use

CASE 101-3, QUESTION 6: An order is written to begin filgrastim on day +5 and to continue administration until the ANC has recovered to 500/μL for 2 consecutive days. Is this therapy appropriate for K.M.?

The use of hematopoietic growth factors after infusion of allogeneic PBPC is controversial and is not recommended by ASCO Guidelines.[14] Administration of hematopoietic growth factors after allogeneic graft infusion decreases the duration of neutropenia, but has not been demonstrated to decrease cost, length of hospitalization, or antibiotic use. Hematopoietic growth factor administration may increase the incidence of severe GVHD and lower survival.[109] K.M. is receiving an allogeneic PBPC graft and thus should not receive filgrastim.

Sinusoidal Obstructive Syndrome (SOS)/Veno-Occlusive Disease of the Liver

CASE 101-3, QUESTION 7: K.M.’s pretransplantation admission laboratory values are within normal limits. Her weight on admission is 80 kg. During the first 5 days after marrow infusion, K.M.’s weight begins to increase by approximately 0.5 kg/day, her inputs exceed her outputs by about 500 to 1,000 mL/day, and she is mildly febrile with an axillary temperature of 38°C. Blood and urine cultures are all negative. On day +6, her weight is 85 kg. Laboratory values on day +7 are significant for the following:

Total bilirubin, 1.5 mg/dL
Aspartate aminotransferase (AST), 40 units/L
Alkaline phosphatase, 120 units/L

By day +10, K.M. is complaining of mid-epigastric, right upper quadrant pain, and a liver that is tender to palpation. During the next few days, K.M. begins to look icteric. Her liver function tests continue to rise slowly, until day +18 when they reach the following peak values:

Total bilirubin, 5 mg/dL
AST, 150 units/L
Alkaline phosphatase, 180 units/L

On day +18, K.M.'s weight is 90 kg. "Rule out SOS of the liver" is included on her problem list in the medical record. What is SOS?

Sinusoidal obstructive syndrome (SOS), formerly known as VOD, is a syndrome consisting of fluid retention, right upper quadrant pain, and hyperbilirubinemia. In severe cases, it results in renal failure, encephalopathy, multiorgan failure, and ultimately may result in death. The incidence of SOS/VOD varies depending on the definition used to diagnose the syndrome; however, it is most commonly associated with high-dose chemotherapy with HCT. It has been reported to occur in 5% to 55% of patients undergoing myeloablative HCT.[110,111] The major risk factor for the development of SOS/VOD is high-dose chemotherapy associated with myeloablative transplants. Preparative regimens including busulfan, cyclophosphamide, and/or TBI greater than 13.2 Gy have been associated with higher SOS/VOD rates.[19,112] Patient-specific factors such as older age, impaired performance status, and advanced disease have also been reported to increase SOS/VOD risk.

Although the exact pathophysiology underlying the development of SOS/VOD is not fully understood, it is known that damage to the sinusoidal endothelial cells in the liver is the initial insult which initiates the process. Damage continues and leads to sloughing of the endothelial lining of the sinusoids ultimately resulting in embolism and obstruction of sinusoidal flow.[113] This obstruction of flow within the liver contributes to postsinusoidal portal hypertension and worsening liver dysfunction, usually manifested by increased bilirubin and ascites.

CLINICAL PRESENTATION AND DIAGNOSIS

CASE 101-3, QUESTION 8: What signs and symptoms in K.M. are consistent with a diagnosis of SOS/VOD?

The initial signs and symptoms of SOS/VOD can occur anytime within the first 15 to 30 days post-transplant. Insidious weight gain exceeding 5% of baseline may be one of the first manifestations of impending SOS/VOD, occurring in more than 90% of patients within 3 to 6 days after marrow infusion.[111] Weight gain is caused by sodium and water retention, as evidenced by decreased renal sodium excretion. New onset of transfusion refractory thrombocytopenia may also be an early sign of impending SOS/VOD. Hyperbilirubinemia, which also occurs in virtually all patients, follows the onset of weight gain and usually appears within 10 days after hematopoietic stem cell infusion. Other liver function test abnormalities usually occur after hyperbilirubinemia and include elevations in AST and alkaline phosphatase. Ascites, right upper quadrant pain, and encephalopathy lag behind changes in liver function tests and develop within 10 to 15 days after infusion of hematopoietic stem cells.[111]

Although liver biopsy is the gold standard for diagnosis of SOS/VOD, its use is limited due to the risk of bleeding during the procedure. Other noninvasive criteria have been developed to help diagnosis SOS/VOD after HCT. Two sets of clinical criteria call for an evaluation of hyperbilirubinemia, ascites/weight gain, and right upper quadrant pain not attributable to other causes such as medications, acute GVHD, or infection.[111,114] Along with these criteria, ultrasound may be useful in determining whether there is reversed hepatic venous flow and to confirm ascites and/or hepatomegaly.

CASE 101-3, QUESTION 9: What is the likelihood that K.M. will recover from her SOS/VOD? How should she be treated?

There is no standard treatment for SOS/VOD although many patients with SOS/VOD (70%–85%) spontaneously recover. Preventive measures look to control patient risk factors, and pharmacologic prevention strategies have also been used. Patient-specific risk factors are often not reversible; however, selection of appropriate

---

preparative regimens such as nonmyeloablative regimens, avoidance of concomitant hepatotoxic drugs, use of fractionated TBI, and the use of adaptive busulfan dosing may reduce risk. Preventive medications have also been investigated. The use of prophylactic heparin has shown varied results in clinical trials; therefore, its use is still controversial.[115] The data for the use of ursodeoxycholic acid are also inconclusive. However, some trials have shown a benefit in reducing the incidence of SOS/VOD with its use. According to one trial, patients who received ursodeoxycholic acid were shown to have decreased hepatotoxicity, less acute GVHD, and better survival.[116]

Other treatments consist of supportive-care measures such as management of sodium and water balance, and paracentesis, in severe cases, for ascites that is associated with pain and pulmonary compromise.[105] Volume expanders such as albumin and colloids may be used to maintain intravascular volume, spironolactone may be used to minimize extravascular fluid accumulation, and protein restriction and lactulose may be used if encephalopathy develops. Unfortunately, improved outcomes with these measures have not been confirmed. In patients with severe SOS/VOD and multiorgan failure, available treatment options are limited. Thrombolytic therapy with recombinant human tissue plasminogen activator and heparin have had mixed results in terms of efficacy and can cause fatal intracerebral or pulmonary bleeding.[105] Defibrotide, an investigational drug, has shown promising results in the treatment of SOS/VOD.[117–119] Defibrotide, a ribonucleotide, has antithrombotic, anti-ischemic, and thrombolytic activity without producing significant systemic anticoagulation. In a compassionate use trial of 88 patients with severe SOS/VOD and associated organ dysfunction, 36% of patients had complete resolution of SOS/VOD and 35% survived past day 100 after HCT.[119]

Although the use of defibrotide in treating SOS/VOD appears to be effective, little is known about whether prophylactic defibrotide could be beneficial in high-risk patients. Corbacioglu et al. explored this question in children with malignant infantile osteopetrosis undergoing stem cell transplantation. Previously 7/11 or 63.6% (n = 20) of the children in their center between 1996 and 2001 experienced SOS/VOD. Defibrotide prophylaxis was initiated in nine consecutive patients between 2001 and 2005 and in this group 1/9 (11.1%) was diagnosed with moderate SOS/VOD, suggesting a significant benefit from prophylactic defibrotide. To further explore this question, a US National Institutes of Health-sponsored prospective randomized trial has been undertaken to answer the question as to whether prophylactic defibrotide is superior to therapeutic defibrotide in children at high risk for experiencing SOS/VOD during stem cell transplantation.[120]

Because K.M. does not meet the criteria for severe SOS/VOD, she should be managed conservatively with fluid restriction and spironolactone for fluid diuresis. Her signs and symptoms should resolve during the next 2 weeks. Because she has mild SOS/VOD, she is likely to recover completely without sequelae.

Graft Rejection

CASE 101-4

QUESTION 1: E.R. is a 65-year-old woman diagnosed with myelodysplastic syndrome. Past medical history is significant for type I diabetes and renal dysfunction. After her initial diagnosis, a search for a completely HLA-matched unrelated donor was conducted. A donor was found in the National Marrow Donor Registry and E.R. will receive a nonmyeloablative allogeneic HCT using bone marrow from an unrelated male donor. E.R.'s preparative regimen is as follows: fludarabine 30 mg/m^2/day on days −4, −3 and −2 and 2 Gy TBI on the day of marrow infusion with post-transplant cyclosporine and mycophenolate mofetil. It is now day +28 and E.R.'s CBC shows the following:

WBC count, 500 cells/μL
Differential, no granulocytes or monocytes detected
Platelets, 100,000/μL
Hematocrit (Hct), 30%
Donor T-cell chimerism is <5%. What is E.R. experiencing and how should she be treated?

Reduced-intensity regimens typically consist of fludarabine in combination with an alkylating agent or low-dose TBI (Fig. 101-3). With the nonmyeloablative fludarabine/TBI regimen, there is minimal neutropenia, thrombocytopenia, and other nonhematologic toxicities.[2] Engraftment is usually evident within the first 30 days in patients receiving a nonmyeloablative preparative regimen; however, rejection can occur after initial engraftment.[121] Mixed chimerism, a state where both host and donor cells coexist, generally develops after nonmyeloablative HCT. E.R. has low donor T-cell chimerism on day +28, placing her at high risk of graft rejection.

Graft rejection occurs particularly after nonmyeloablative allogeneic HCT. A delicate balance exists between host and donor effector cells. This is established with myelosuppressive chemotherapy and immunosuppressants to decrease the risk of excessive host-versus-graft effects that could lead to graft rejection. The incidence of graft rejection is higher in patients with aplastic anemia and in patients undergoing HCT with histoincompatible marrow or T-cell-depleted marrow. There are limited therapeutic options for the treatment of graft rejection. A second HCT is the most definitive therapy, assuming donor cells are available, although the toxicities are formidable.[122] In patients receiving myeloablative allogeneic HCT, graft rejection is best managed with immunosuppressants such as ATG. In patients receiving a reduced-intensity regimen, graft rejection may require a second HCT.

E.R. received nonmyeloablative conditioning, and thus, she should have mixed chimerism post-transplant; however, she has fewer than 5% donor T cells. Current research is focusing on quantitative chimerism monitoring, specifically evaluating the percent donor chimerism, which may be used as a tool with which to base clinical interventions.[80] Donor chimerism is evaluated in different cell types (e.g., T cells, NK cells, granulocytes) although the cell type most predictive of outcome is not known. The changes in the percent donor chimerism over time post-transplant, termed "engraftment kinetics," are influenced by several factors such as type of HCT conditioning, stem cell source, and intensity of postgrafting immunosuppression.[80,123] A balance between the recipient's and donor's cells is needed to maximize the GVT effect, which lowers the risk of relapse while minimizing the risk of GVHD.[80,123] Based on E.R.'s state of chimerism, she will not benefit from the GVT effect due to the lack of the donor's cytotoxic T lymphocytes that suppress the recipient's malignancy.

E.R. is at high risk of graft rejection and therefore may not benefit from the transplant. A trial of discontinuing cyclosporine and mycophenolate mofetil, in an attempt to shift the balance toward donor graft growth and away from recipient T-cell growth, is an option. E.R.'s T-cell chimerism should be monitored periodically and hematopoietic function should be monitored with daily CBC and a bone marrow biopsy as clinically indicated.

GRAFT-VERSUS-HOST DISEASE

Graft-versus-host disease is caused by activation of donor lymphocytes, leading to immune-mediated damage to the recipient. Histocompatibility differences between donor and recipient necessitate post-transplantation immunosuppression after allogeneic HCT because considerable morbidity and mortality are associated with graft rejection and GVHD. Therefore, immunosuppression or GVHD prophylaxis is used after allogeneic HCT. However, because allogeneic transplantation offers the potential for a GVT effect in which immune effector cells from the donor recognize and eliminate residual tumor in the recipient, research is focusing on immune suppression manipulations that allow sufficient GVT effects while not increasing the risk of graft rejection and GVHD.[124]

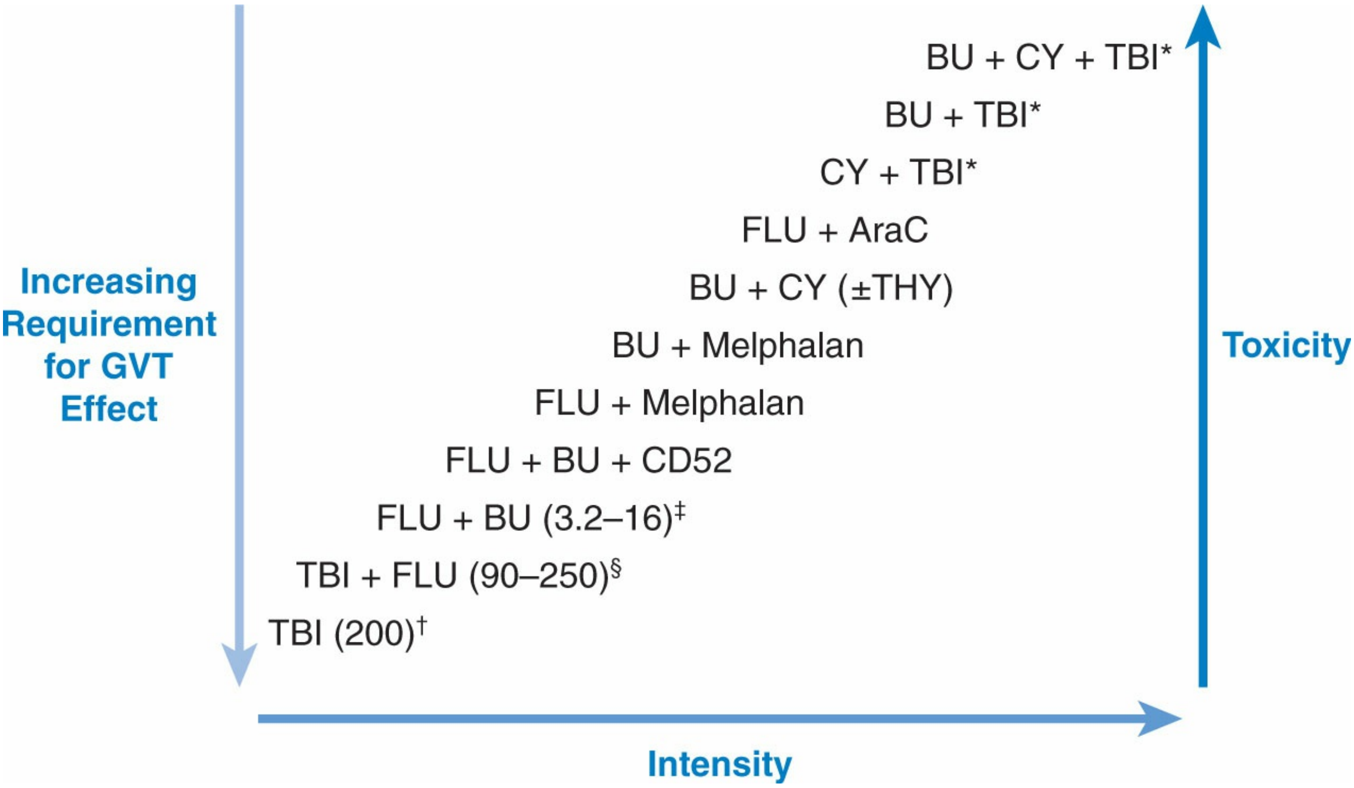

Figure 101-3 Partial spectrum of preparative regimens of various intensities, their impact on toxicity, and their dependence on graft-versus-tumor (GVT) effects for success of hematopoietic stem cell transplantation. AraC, cytarabine; BU, busulfan; CD52, anti-CD52 antibody (alemtuzumab); CY, cyclophosphamide; FLU, fludarabine; TBI, total body irradiation; THY, thymoglobulin. *TBI >1,200 cGy; †200 cGy; ‡3.2 to 16 mg/kg; §90 to 250 mg/m^2. (Adapted from Deeg HJ et al. Optimization of allogeneic transplant conditioning: not the time for dogma. Leukemia. 2006;20:1701, with permission.)

Graft-versus-host disease is the most important complication of allogeneic HCT and limits the use of this lifesaving treatment in patients without histocompatible donors.[2,125] GVHD can occur after allogeneic HCT, regardless of the preparative regimen used. The pathophysiology of GVHD is not completely understood, but the current view of its development is described by a three-step process, including (a) the preparative regimen causing tissue damage and release of inflammatory cytokines into the circulation; (b) recipient and donor antigen presenting cells and inflammatory cytokines triggering activation of donor-derived T cells; and (c) activated donor T cells mediating cytotoxicity through a variety of mechanisms, which leads to tissue damage characteristic of acute GVHD (aGVHD).[126]

Graft-versus-host disease has traditionally been divided into two forms (i.e., acute or chronic) based on time points and clinical manifestations. Acute GVHD, defined as occurring during the first 100 days post-transplant, damages the skin, GI tract, and liver.[2] In contrast, chronic GVHD (cGVHD) may affect almost any organ system, closely resembles several autoimmune diseases, and occurs after day 100. With the introduction of nonmyeloablative HCT, the time course of GVHD has shifted and a late-onset aGVHD occurring after day 100 is possible; however, in these individuals, acute and chronic GVHD symptoms may both be present. As such, consensus criteria developed by The National Institutes of Health have classified GVHD based on clinical manifestations and not time after HCT.[127]

The majority of the data regarding the prevention and treatment of GVHD have been obtained after myeloablative preparative regimens. Therefore, the subsequent section refers only to trials conducted in recipients of a myeloablative allogeneic HCT.

Acute Graft-versus-Host Disease

RISK FACTORS

CASE 101-5

QUESTION 1: M.P., a 22-year-old, 70-kg man, undergoes a one-antigen mismatched allogeneic HCT from his sister for the diagnosis of Philadelphia chromosome-positive (Ph^+) AML. After a myeloablative preparative regimen of CY/TBI, the following immunosuppressive regimen is ordered: cyclosporine 2.5 mg/kg every 12 hours from day –3 until tolerating oral medications, then switch to cyclosporine 4 mg/kg PO every 12 hours until day +50. Methotrexate 15 mg/m^2 IV on day +1, then 10 mg/m^2 on days +3, +6, and +11. What factors are associated with an increased risk of acute GVHD?

The single most important factor associated with the development of GVHD is the degree of histocompatibility between donor and recipient.[2] Clinically relevant grade II–IV acute GVHD occurs in 20% to 50% of HLA-matched sibling grafts and 50% to 80% of HLA-mismatched sibling or HLA-identical unrelated donors.[128] The onset of aGVHD is earlier and severity is increased in mismatched grafts relative to matched grafts, and also in MUDs relative to matched sibling donors.[41,129] Other factors that increase the risk of experiencing aGVHD include increasing recipient (and possibly donor) age, greater intensity of the preparative regimen, use of PBPC rather than bone marrow, and donor/recipient sex mismatch.[126] Umbilical cord transplants have a lower risk of aGVHD.[130–132]

M.P. is receiving allogeneic bone marrow from a female sibling donor that is mismatched at one HLA antigen. These two factors increase his risk of exhibiting aGVHD. Therefore good immunosuppressive therapy is critical in preventing its development.

CLINICAL PRESENTATION

CASE 101-5, QUESTION 2: On day +14, the time at which engraftment has occurred, M.P. is noted to have a diffuse maculopapular rash on his arms, hands, and front trunk. He does not have diarrhea, and his liver function tests are within normal limits. At the onset of his rash, M.P.'s empiric antibiotics are changed from cefepime to meropenem. Despite the change in antibiotics, M.P.'s rash persists. How is M.P.'s presentation consistent with acute GVHD?

The primary targets of immune-mediated destruction of host tissue by donor lymphocytes in aGVHD are the skin followed by the GI tract (diarrhea) and the liver.[128,133] Acute GVHD of the skin, the most common site of aGVHD, usually manifests as a diffuse maculopapular, pruritic rash that starts on the palms of the hands, soles of the feet, or the face. In more severe cases, skin aGVHD can progress to a generalized total body erythroderma, bullous formation, and skin desquamation.

The earliest symptoms of aGVHD of the GI tract are usually loss of appetite followed by nausea and vomiting.[105] Abdominal pain and watery or bloody diarrhea also occur, which can result in electrolyte abnormalities, dehydration, or ileus in severe cases. Liver GVHD usually follows skin and/or GI GVHD. Clinical symptoms of liver GVHD include a gradual rise in total bilirubin, alkaline phosphatase, and hepatic transaminases.[105] Acute GVHD is usually not evident until the time of engraftment, when donor lymphoid elements begin to proliferate. The skin is usually the first organ to be involved. The onset of liver or GI GVHD usually lags behind the onset of skin GVHD by approximately 1 week and infrequently occurs without skin GVHD.

Table 101-6

Modified Glucksberg Grading of Acute Graft-versus-Host Disease

Organ Stage	Skin[a]	Liver	Intestinal Tract[b]
1	Maculopapular rash <25% of body surface	Bilirubin 2–2.9 mg/dL	500–1,000 mL/day diarrhea or biopsy-proven upper GI involvement
2	Maculopapular rash 25%–50% body surface	Bilirubin 3–6 mg/dL	1,000–1,500 mL/day diarrhea
3	Maculopapular rash >50% body surface	Bilirubin 6.1–15 mg/dL	1,500–2,000 mL/day diarrhea

4	Generalized erythroderma with bullae	Bilirubin >15 mg/dL	>2,000 mL/day diarrhea or severe abdominal pain with or without ileus

[a] Extent of rash determined by "rule of nines."

[b] Diarrhea volume applies to adults.

Source: Cutler C, Antin JH. Manifestations and treatment of acute graft-versus-host disease. In: Blume KG et al, eds. Thomas' Hematopoietic Cell Transplantation. 4th ed. Malden, MA: Blackwell; 2009:1291.

Acute GVHD must be distinguished accurately from other causes of skin, liver, or GI toxicity in the HCT patient. For example, a maculopapular rash, which may occur as a manifestation of an allergic reaction to antibiotics, usually begins on the trunk or upper extremities and is rarely present on the palms of the hands or soles of the feet. Diarrhea can be caused by chemotherapy, radiation, infection, or antibiotic therapy.[105] However, diarrhea caused by the preparative regimen is rarely bloody and usually resolves within 3 to 7 days after discontinuation of drugs and radiation. Diarrhea caused by infectious agents such as Clostridium difficile or cytomegalovirus (CMV) should be distinguished from GVHD. Liver GVHD must be distinguished primarily from SOS/VOD and, to a lesser extent, hepatitis induced by drugs, blood products, or parenteral nutrition. Although liver function test abnormalities between these syndromes are similar, liver GVHD is rarely associated with insidious weight gain or right upper quadrant pain.[105] A tissue biopsy of the affected organ in conjunction with clinical evidence is the only way to definitively diagnose aGVHD, though biopsy of the gut or liver is rarely done due to the increased risks associated with thrombocytopenia early in the post-transplant phase. Acute GVHD is associated with characteristic histologic changes to affected organs. A staging system based on clinical criteria is used to grade aGVHD. The severity of organ involvement is determined first (Table 101-6), and then an overall grade is established based on number and extent of involved organs (Table 101-7).

Table 101-7

Modified Glucksberg versus International Bone Marrow Transplant Registry Overall Grading of Acute Graft-versus-Host Disease Severity

Organ Stage	Skin	Liver	Gut
Glucksberg Grading			
I—Mild	Stage 1–2	None	None
II—Moderate	Stage 3 or	Stage 1 or	Stage 1
III—Severe		Stage 2–3 or	Stage 2–4
IV—Life-threatening	Stage 4 or	Stage 4	—
IBMTR Grading			
A—Mild	Stage 1	None	None
B—Moderate	Stage 2	Stage 1 or 2	Stage 1 or 2
C—Severe	Stage 3	Stage 3	Stage 3

D—Life-threatening	Stage 4	Stage 4	Stage 4

IBMTR, International Blood and Marrow Transplant Registry.

M.P. developed a rash at the time of engraftment that could have been consistent with either an antibiotic-induced rash or aGVHD. Although it was appropriate to change antibiotics, the fact that M.P.'s rash did not improve is suggestive of aGVHD. M.P.'s rash is present on 36% of his body, but because there are no signs of GI or liver involvement at this time, M.P. is likely to have grade I aGVHD (Tables 101-6 and Table 101-7).

IMMUNOSUPPRESSIVE PROPHYLAXIS

CASE 101-5, QUESTION 3: Why did M.P. receive prophylactic immunosuppressive therapy with cyclosporine and methotrexate?

Graft-versus-host disease is a leading cause of morbidity and mortality after allogeneic HCT. Without immunosuppression, serious aGVHD would occur in almost every allogeneic HCT recipient.[2] The most common method used to minimize GVHD risk is to administer prophylactic immunosuppressive therapies and most patients receive multi-drug GVHD prophylaxis.

Historically, aGVHD was prevented with single-drug therapy using ATG, cyclophosphamide, methotrexate, or cyclosporine.[134–136] ATG binds nonspecifically to mononuclear cells and depletes hematopoietic progenitor cells in addition to lymphocytes. Consequently, ATG is generally avoided as a prophylactic agent due to the risk of graft failure.[134] The risk of GVHD is greatly reduced by two-drug combination immunosuppression (Table 101-8). Although the most widely published regimen is short-course methotrexate plus cyclosporine,[136] there is no consensus with regard to the most effective regimen. Several randomized clinical trials have compared tacrolimus and short-course methotrexate with cyclosporine plus short-course methotrexate in patients undergoing allogeneic HCT using HLA-matched siblings[137,138] and unrelated donors.[86] Recipients of matched sibling grafts treated with tacrolimus had a lower incidence of grade II to IV aGVHD but a similar incidence of cGVHD.[137] Overall survival was lower in the tacrolimus group as a result of more toxic deaths in patients with advanced stage disease; however, a higher number of advanced stage disease patients in the tacrolimus/methotrexate group make the results of this trial somewhat difficult to interpret.[137]

Table 101-8

Combination Immunosuppression Regimens for Prophylaxis of Acute Graft-versus-Host Disease in Myeloablative Transplant[137]

Drug	Dosing Examples
Cyclosporine/short-term methotrexate	1.5 mg/kg IV or 4 mg/kg (Neoral) PO every 12 hours, days −1 to +50, then taper 5% per week and discontinue by day +180
	Methotrexate 10 mg/m^2 IV, days +3, +6, +11
Tacrolimus/short term	Tacrolimus 0.03 mg/kg/d continuous IV infusion or 0.12 mg/kg/d PO BID
Methotrexate[136]	Methotrexate 15 mg/m^2 IV day +1; 10 mg/m^2 IV, days +3, +6, +11
Cyclosporine/methotrexate/prednisone	Cyclosporine 5 mg/kg/d IV continuous infusion, days –2 to +3, then 3–3.75 mg/kg IV until day +35; then 7 mg/kg/d (Neoral) PO, dose adjusted to cyclosporine concentrations (via radioimmunoassay) of 200–400 ng/mL. Taper by 20% every 2 weeks; then discontinue by day +180
	Methotrexate 15 mg/m^2 IV day +1; 10 mg/m^2 IV days +3, +6
	Methylprednisolone 0.5 mg/kg/day IV day +7 until day +14; then 1 mg/kg/d IV until day +28; then prednisone 0.8 mg/kg/day PO until day +42; then taper slowly and discontinue by day +180

BID, twice a day; IV, intravenous; PO, orally.

Subsequently, the International Blood and Marrow Transplant Registry conducted a matched control study, which suggested that the survival difference between the two arms of tacrolimus plus short-course methotrexate and cyclosporine plus short-course methotrexate was in fact due to the imbalance in the underlying risk factors.[138] In patients receiving HLA-matched or slightly mismatched unrelated grafts, those given tacrolimus had a lower incidence of grade II to IV aGVHD, a similar incidence of cGVHD, and similar disease-free and overall survival rates.[86] Both regimens are currently used in allogeneic HCT after myeloablative preparative regimens.

More recently, the use of mycophenolate mofetil has been studied in allogeneic transplants with myeloablative conditioning used in combination with cyclosporine. It appears to have a similar incidence of aGVHD and 100-day survival as methotrexate/cyclosporine, yet significantly less severe mucositis and more rapid neutrophil engraftment than the methotrexate/cyclosporine arm.[139,140] Mycophenolate mofetil is now commonly used in clinical practice in combination with cyclosporine or tacrolimus.

M.P. received acute GVHD prophylaxis with a two-drug regimen of short-course methotrexate and cyclosporine, the most common regimen for myeloablative allogeneic conditioning regimens. Using two drugs with different mechanisms of immunosuppression, one blocking the activation of T cells (cyclosporine) and the other (methotrexate) blocking the division and clonal expansion of activated T cells, is more effective in decreasing the likelihood of GVHD than one of these agents alone.

CASE 101-5, QUESTION 4: What principles are used in dosing medications used for acute GVHD prophylaxis?

Although the various combination immunosuppressive regimens vary slightly by drug, dose, and combination, several guidelines are consistent throughout all regimens. First, methotrexate used for prophylaxis of aGVHD is withheld or given in reduced doses if mucositis is severe or the patient experiences excessive fluid retention.[136,141] Fluid retention sites act as a depot for methotrexate accumulation, increasing duration of exposure. Methotrexate for GVHD prophylaxis can delay engraftment, increase the incidence and severity of mucositis, and cause liver function test elevations. The methotrexate dose is reduced in the setting of renal or liver impairment.[136,142]

The calcineurin inhibitors (i.e., cyclosporine, tacrolimus) should be initiated before or immediately after donor cell infusion (day −3 to 0) when used for GVHD prophylaxis. This schedule is recommended because of the known mechanism of action of these agents, which entails blocking the proliferation of cytotoxic T cells by inhibiting production of helper T-cell-derived interleukin-2 (IL-2). Administering cyclosporine before the donor cell infusion allows inhibition of IL-2 secretion to occur before a rejection response has been initiated.

Cyclosporine is usually administered intravenously until the GI toxicity from a myeloablative preparative regimen has resolved (e.g., for 7–21 days).[136] This is because GI effects of the preparative regimen (e.g., chemotherapy-induced nausea and vomiting, diarrhea) and GVHD affect the oral absorption of microemulsion cyclosporine and may result in inconsistent blood concentrations.[143] Most centers use the microemulsion oral formulation (Neoral) or other new generic microemulsion formulations that have improved bioavailability. With the microemulsion oral formulation, an IV to PO dosing ratio of 1:2 or 1:3 is appropriate. The most common ratio used when converting tacrolimus from IV to oral is 1:4. Empiric dose adjustments may be required when patients are receiving concomitant medications (e.g., voriconazole) that affect cytochrome CYP3A4 or P-glycoprotein, which are involved in the metabolism and transport of the calcineurin inhibitors. Thus, careful monitoring for drug interactions with the calcineurin inhibitors is warranted.[144]

The dose of cyclosporine or tacrolimus is adjusted based on serum drug levels and the serum creatinine (SCr) concentration. Although the calcineurin inhibitors do not contribute to myelosuppression, common adverse effects to these agents include electrolyte abnormalities, neurotoxicity, hypertension, and/or nephrotoxicity.[89]

Tapering schedules for GVHD prophylaxis vary widely among institutions. The general goal is to keep calcineurin inhibitor

doses stable until day +50 and then slowly taper with the intent of discontinuing all immunosuppressive agents by 6 months after HCT. By this time, immunologic tolerance has developed, and patients no longer require immunosuppressive therapy. This can only be accomplished if the patient is not experiencing GVHD.

ADAPTIVE DOSING OF CALCINEURIN INHIBITORS

CASE 101-5, QUESTION 5: On day +18, a cyclosporine concentration is measured right before the morning dose (trough) and is reported as 392 ng/mL. Why are cyclosporine concentrations being obtained for M.P.?

The role of pharmacokinetic monitoring of the calcineurin inhibitors in HCT patients is not well defined but is commonly performed because of the established pharmacodynamic associations within solid organ transplant recipients. It is standard practice for HCT centers to adjust cyclosporine or tacrolimus doses based on trough blood concentrations.[145] An association between cyclosporine concentrations and aGVHD was not found in early studies; however, other studies have suggested that cyclosporine trough concentrations for 12-hour dosing of 200 to 400 ng/mL in adult patients minimize the risk of aGVHD and the risk of cyclosporine-induced nephrotoxicity.[146–148] For continuously infused cyclosporine, higher target blood concentrations of 300 to 500 ng/mL have been required to prevent GVHD in order to provide an equivalent AUC of exposure to intermittent dosing.[149,150] It is important to note that cyclosporine-induced nephrotoxicity may occur despite low or normal concentrations of cyclosporine and may be a consequence of other drug- or disease-related factors known to influence the development of nephrotoxicity. Additionally, recent studies suggest that trough concentrations do not correlate well with exposure to cyclosporine and that a peak level is better correlated to the $AUC_{(0–12)}$. A peak concentration of greater than 800 ng/mL may be required to prevent GVHD. Despite this, the data are limited and the routine use of peaks for therapeutic drug monitoring is not recommended.[151] Desired tacrolimus trough concentrations are 5 to 15 ng/mL. Tacrolimus concentrations greater than 20 ng/mL have been associated with increased risk of toxicity, primarily nephrotoxicity.[145,152] Adjustments in tacrolimus dosing for increased SCr should be made in a manner similar to that described for cyclosporine.

It is reasonable to adjust M.P.'s doses to maintain cyclosporine trough concentrations between 200 and 400 ng/mL, as in all patients undergoing allogeneic HCT with a myeloablative preparative regimen. Recommendations for dose adjustments should be based on cyclosporine concentrations and SCr level. No standard dosage adjustment schedule exists, but most centers adopt their own standardized approach. M.P. has a normal SCr, and his cyclosporine trough is 392 ng/mL. Therefore, his cyclosporine dose should be maintained and the trough repeated in a few days. It may be repeated sooner if an interacting drug is added or discontinued, or if there are toxicity concerns.

TREATMENT OF ESTABLISHED ACUTE GRAFT-VERSUS-HOST

DISEASE

CASE 101-5, QUESTION 6: In the third week post-transplant, M.P. experiences a pruritic rash on his shoulders and neck which spreads to the palms of his hands and looks like a sunburn. On day +19, the suspicion of acute skin GVHD is confirmed by biopsy. On the same day, M.P. develops diarrhea (1,000 mL over 24 hours) and is noted to have a bilirubin of 2.8 mg/dL. He is started on methylprednisolone 1 mg/kg IV every 12 hours. What is the rationale for methylprednisolone therapy in M.P.?

Preventing the development of aGVHD is the most effective way to treat this HCT complication. In patients who develop aGVHD, first-line treatment is a corticosteroid added to their current immune suppression regimen.[126] For this reason, aGVHD and its treatment cause profound immunodeficiency.[2,153] The combination of aGVHD and infectious complications is the leading cause of mortality for allogeneic HCT patients.

The route of corticosteroid administration is determined by the severity of the aGVHD. Those patients with only skin involvement of less than 50% of their body surface area may be treated with topical steroid creams, whereas involvement of other organs, or stage 3 or 4 skin disease, requires systemic corticosteroids. A complete response occurs in up to 25% to 40% of patients, with a lower likelihood of response in more severe cases of aGVHD.[126,153] Patients with mild-to-moderate (grades I–III) aGVHD who respond to initial therapy have a significantly better survival advantage than patients with severe aGVHD who do not respond to initial therapy. Patients who do not respond to corticosteroid therapy or have ongoing severe GVHD usually die from a combination of GVHD and infectious complications.[154]

Corticosteroids used in the treatment of aGVHD are generally tapered based on response. There is no consensus on the optimal method for tapering the corticosteroids,[153] and the tapering rate depends on the patient. Patients who experience aGVHD or who experience flares of existing GVHD during a tapering trial will have their dosages increased or tapered more slowly as tolerated.

Because M.P. had objective evidence of established aGVHD, he was given systemic IV corticosteroids. This was appropriate because single-agent corticosteroids are considered the therapy of choice for established aGVHD.[153] Corticosteroids indirectly halt the progression of immune-mediated destruction of host tissues by blocking macrophage-derived interleukin-1 secretion. Interleukin-1 is a primary stimulus for helper T-cell-induced secretion of IL-2, which in turn is responsible for stimulating proliferation of cytotoxic T lymphocytes. The recommended dosage of methylprednisolone for the treatment of established aGVHD is 1 to 2 mg/kg/day, given intravenously or orally in divided doses, followed by a tapering schedule that is determined by response.[154,155] Trials that compared higher doses of corticosteroids (i.e., 10 mg/kg/day) to 2 mg/kg/day as initial treatment of aGVHD showed no advantage.[156] Monitoring for rash, diarrhea, and bilirubin levels to asses aGVHD response should occur daily.[126] M.P. was receiving cyclosporine for

GVHD prophylaxis at the time the aGVHD developed. Although the cyclosporine was not effective in preventing the aGVHD, it is typical for patients to remain on their prophylactic immune suppressants.

A significant portion of patients do not respond to corticosteroids, and they are said to have steroid-refractory GVHD.[126] If aGVHD symptoms worsen during 3 days of treatment and if the skin does not improve by 5 days, it is unlikely that a response will be achieved in a timely manner, and secondary therapy should be considered.[126] Patients with steroid-refractory aGVHD have a poorer prognosis. A variety of medications are being studied for “salvage” or secondary therapy. The salvage therapy depends on the organs affected. For example, phototherapy is used as salvage therapy for skin GVHD, and nonabsorbable corticosteroids are used for GI GVHD. Other options for salvage therapy include ATG, denileukin diftitox, and TNF-α blockers (e.g., infliximab, etanercept).[126,157] The most effective dose, timing, or combination of these salvage therapies is still unknown.

M.P. should be evaluated for response to methylprednisolone after 4 to 7 days. If his aGVHD has improved or stabilized, he should be continued on therapy at this dose for a total of 14 days. If M.P. responds to therapy, his methylprednisolone dose should be tapered slowly over a minimum of 1 month, and he should be monitored for any evidence of recurrent GVHD. If the GVHD

flares during his steroid taper as evidenced by worsening skin reactions, increased bilirubin, or increased diarrhea volume, the dose should be increased again until his disease is stable; the subsequent taper should be initiated at a slower rate. If M.P. fails to respond to first-line therapy with methylprednisolone, he should receive salvage therapy.

Chronic Graft-versus-Host Disease

CLINICAL PRESENTATION

CASE 101-5, QUESTION 7: M.P. was successfully treated for his aGVHD, is no longer taking corticosteroids, and is currently tapering off his cyclosporine. On day +200, M.P. comes to clinic for follow-up after a 2-week vacation in Florida. On examination, M.P. is found to have a mild skin rash on his arms and legs, hyperpigmentation of the tissue surrounding the eyes, and white plaque-like lesions in his mouth. He is also complaining of dry eyes. Laboratory tests reveal an increased alkaline phosphatase and total bilirubin concentration. What is the most likely cause of M.P.’s findings?

Chronic GVHD (cGVHD), the most common late complication of allogeneic HCT, occurs in 20% to 70% of patients surviving more than 100 days.[158] Chronic GVHD is a major cause of nonrelapse morbidity and mortality.[2] Risk factors for cGVHD include recipient, donor, and transplant factors. Nonmodifiable recipient risk factors include older age, certain diagnoses (e.g., CML), and lack of an HLA-matched donor. Modifiable factors that may lower the risk of cGVHD include selecting a younger donor, avoiding a multiparous female donor, using umbilical cord blood or a bone marrow graft rather than PBPC, and limiting the $CD34^+$ and T-cell dose infused.[158] Development of aGVHD is a major predictor of cGVHD; 70% to 80% of those with grade II to IV aGVHD go on to develop cGVHD.[158]

Chronic GVHD is not a continuation of aGVHD. Traditionally, the boundary between the two was based on time, but now they are classified based on different clinical symptoms.[158] Signs and symptoms of cGVHD in various organ systems are listed in Table 101-9.

A consensus guideline for the diagnosis and scoring of cGVHD has been published.[127] The diagnosis of cGVHD requires (a) being distinct from aGVHD, (b) having at least one diagnostic clinical sign of cGVHD or at least one distinctive manifestation confirmed by pertinent biopsy or other relevant tests, and (c) exclusion of other possible diagnoses. The clinical scoring system uses a numerical value of 0 to 3, with more severe symptoms having a higher number. A global score is calculated by including the number of organs involved and the severity within each affected organ. The global score reflects the expected effect of cGVHD on the patient's performance status and can be used to evaluate whether treatment with systemic immunosuppression is required. The grading and prognosis of cGVHD can define and predict high-risk patient groups.[159]

Table 101-9

Selected Signs and Symptoms of Chronic Graft-versus-Host Disease

Affected Organ	Diagnostic	Distinctive	Other Features[a]	Seen With Both Acute and Chronic GVHD
Eyes		New-onset dry, gritty, or painful eyes[b]	Photophobia	
		Cicatricial conjunctivitis Keratoconjunctivitis sicca[b]	Periorbital hyperpigmentation	
		Confluent areas of punctuate keratopathy, tear formation, dry eyes, burning, photophobia	Erythema of the eyelids with edema	
Gastrointestinal tract	Esophageal web		Pancreatic insufficiency	Anorexia
	Stricture or stenosis in the upper- to mid-			Nausea Vomiting

	third of the esophagus[c]			Diarrhea Weight loss Failure to thrive (infants and children)
Liver				Total bilirubin, alkaline phosphatase >2 × upper limit of normal[c]
Lung	Bronchiolitis obliterans diagnosed with lung biopsy	Bronchiolitis obliterans diagnosed with pulmonary function tests and radiology[b]		Bronchiolitis obliterans organizing pneumonia
Skin	Poikiloderma	Depigmentation	Seat impairment ichthyosis	Erythema
	Lichen planus-like features		Keratosis pilaris	Maculopapular rash Pruritus
	Sclerotic features		Hypopigmentation	
	Morphea-like features		Hyperpigmentation	
	Lichen sclerosus-like features			

Signs and symptoms for hematopoietic and immune differences, as well as for nails; scalp and body hair; mouth; genitalia; muscles, fascia, and joints; and other organs, are also described by Filipovich et al.[152]

[a] Part of chronic GVHD symptomatology if the diagnosis is confirmed.

[b] Diagnosis of chronic GVHD requires biopsy or radiology confirmation (or Schirmer test for eyes).

[c] Infection, drug effects, malignancy, or other causes must be excluded.

GVHD, graft-versus-host disease.

The signs and symptoms of cGVHD in M.P. include a rash in sun-exposed areas of the skin, hyperpigmentation of tissues surrounding his eyes, white plaque-like lesions in the mouth, dry mucous membranes, and increased alkaline phosphatase and total bilirubin levels. These symptoms appeared after a period of complete resolution of aGVHD and during a taper of the cyclosporine. Thus, M.P. has moderate-involvement, quiescent cGVHD.[127]

PHARMACOLOGIC MANAGEMENT

CASE 101-5, QUESTION 8: M.P. is started on prednisone 1 mg/kg PO daily for the treatment of his chronic GVHD. His cyclosporine taper is stopped, and the dosage is raised to therapeutic concentrations. Is this therapy rational? What other agents are available to treat cGVHD?

There is no specific prophylactic therapy for cGVHD, and the optimal treatment remains controversial. The mainstay of therapy for cGVHD is long-term immunosuppressive therapy. Survival for patients with cGVHD is improved by extended corticosteroid therapy, although there are multiple long-term adverse effects associated with the corticosteroids.[158,160] A typical regimen is prednisone 1 mg/kg/day, administered orally in divided doses for 14 days and then converted slowly to alternate-day therapy by increasing the "on-day" and decreasing the "off-day" dose until a total of 1 mg/kg/day on alternate days is administered.[160] Alternate-day therapy is preferred to minimize adrenocortical suppression. Once therapy is initiated, 1 to 2 months may pass before an improvement in clinical symptoms is noted. Therapy is usually continued for 9 to 12 months and then slowly tapered after signs and symptoms of cGVHD have resolved. The median duration of treatment has been reported to be 23 months.[161] If cGVHD worsens during the tapering or after discontinuation of prednisone, immunosuppressive therapy is restarted. Other potential approaches for patients with refractory cGVHD include mycophenolate mofetil, daclizumab, sirolimus, pentostatin, and extracorporeal photophoresis.[160]

When immunosuppressive therapy is administered for long periods, the patient must be monitored closely for chronic toxicity. Cushingoid effects, aseptic necrosis of the joints, and diabetes can develop with long-term corticosteroid use. Other severe complications include a high incidence of infection with encapsulated organisms and atypical pathogens such as Pneumocystis jiroveci (P. jiroveci) pneumonia, CMV, and herpes zoster.

It is reasonable to start M.P. on single-agent prednisone for cGVHD treatment at 1 mg/kg daily for 2 weeks and then convert to every other day as described.

ADJUVANT THERAPIES

CASE 101-5, QUESTION 9: Suggest some adjuvant therapies that should be instituted in a patient like M.P. with chronic GVHD.

Patients who are being treated for cGVHD should receive trimethoprim–sulfamethoxazole for prophylaxis of P. jiroveci and encapsulated organisms, such as Streptococcus pneumoniae and Haemophilus influenzae. Ensuring optimal prophylactic antibiotics in cGVHD patients is critical because infection is the primary cause of death during treatment.[161] Artificial tears and saliva may improve lubrication and decrease the occurrence of cracking and fissures in mucous membranes. Newer therapies such as cyclosporine ophthalmic emulsion and autologous serum tears have provided relief for chronic ocular GVHD.[162] If nutritional intake is poor, consultation with a clinical nutritionist and use of oral nutritional supplementation may be advisable. Patients should be instructed to apply sunscreens to exposed areas whenever prolonged sun exposure is anticipated. Liver function abnormalities have been improved by up to 30% with the use of ursodiol as bile acid displacement therapy.[163–165] Calcium supplements, estrogen replacement, or other anti-osteoporosis agents should be considered in women or other patients at risk for fracture or bone loss while receiving prolonged regimens with immunosuppressant therapy.[166] Patient education regarding the gradual resolution of symptoms such as skin sclerosis, fatigue and muscle weakness, anticipated duration of therapy, and importance of compliance with oral immunosuppressive therapy is essential.

INFECTIOUS COMPLICATIONS

Opportunistic infections are a major cause of morbidity and mortality after myeloablative and nonmyeloablative HCT. There are three general periods of infectious risk (Fig. 101-2). During the early period pre-engraftment, particularly for patients undergoing myeloablative HCT, the primary pathogens are aerobic bacteria, Candida spp., and herpes simplex virus (HSV). Chemotherapy-induced mucosal damage creates a portal of entry into the bloodstream for many organisms, such as viridans group Streptococcus, Candida, and aerobic gram-negative bacteria. Catheter-associated infections have become the leading cause of bacteremia, most notably in the early post-transplant period.[159,161] The routine use of antiviral prophylaxis has decreased the incidence of HSV. Respiratory viruses such as respiratory syncytial virus (RSV), influenza, adenovirus, and parainfluenza are increasingly recognized as pathogens causing pneumonia, particularly during community outbreaks of infection.[167] To reduce potential exposure of HCT recipients to these pathogens, visitors and staff members with signs and symptoms of a viral respiratory illness may not be allowed direct contact with patients.

A potential advantage of reduced-intensity or nonmyeloablative preparative regimens is reduced toxicity of the preparative regimen compared to myeloablative HCT. Reduced-intensity or nonmyeloablative preparative regimens frequently do not result in true neutropenia,[5] and the incidence of mucositis during the early period is reduced.[168] In a matched controlled study, the incidence of bacteremia during the first 30 days post-HCT in the nonmyeloablative recipients was significantly reduced compared to myeloablative recipients.[168] Moreover, nonmyeloablative HCT recipients experienced significantly fewer infections attributable to mucositis during the early period.

The second or middle (Fig. 101-2) period of infectious risk includes the time from engraftment to post-transplant day +100. Pathogens such as CMV, adenovirus, and Aspergillus are common. Adenovirus, CMV, Aspergillus, and P. jiroveci frequently cause interstitial pneumonitis. Patients undergoing reduced-intensity or nonmyeloablative preparative regimens that experience acute GVHD and are treated with corticosteroids have a similar risk of infection during this time period as those undergoing myeloablative HCT.[168]

During the late period (after day +100), the predominant pathogens are the encapsulated bacteria (e.g., S. pneumoniae, H. influenzae, Neisseria meningitidis), fungi/mold, and varicella-zoster virus (VZV). The encapsulated bacteria commonly cause sinopulmonary infections. The risk of infection during this late period is increased in patients with cGVHD as a result of prolonged immunosuppression.

Because of the morbidity associated with opportunistic infection in HCT recipients, optimal pharmacotherapy for prevention and treatment is critical. In 2009, the US Centers for Disease Control and Prevention (CDC) published guidelines for prevention of opportunistic infection in HCT recipients.[4,169] These guidelines were constructed from available data by an expert panel from the CDC, the Infectious Disease Society of America, and the American Society for Blood and Marrow Transplantation. The following discussion incorporates recommendations from the CDC guidelines and also provides information on the pharmacotherapy of opportunistic infections in all types of HCT.

Prevention and Treatment of Bacterial and Fungal Infections

CASE 101-6

QUESTION 1: S.D. is a 26-year-old woman with Ph^+ acute lymphocytic leukemia in first complete remission who is admitted for allogeneic myeloablative HCT. The following orders are written: Admit to a room with a positive-pressure HEPA filter. Flush double-lumen Hickman catheter per protocol. Immunosuppressed patient diet as tolerated. Begin fluconazole 400 mg PO every 24 hours and levofloxacin 500 mg PO every 24 hours on admission. Begin ceftazidime 2 g IV every 8 hours with first fever when ANC is less than 500 cells/μL. Transfuse 2 units of packed RBCs for hematocrit less than 25% and 1 unit of single-donor platelets for platelet count less than 20,000/μL. What is the rationale for these supportive measures?

As a result of disease-related immunosuppression, intensive preparative regimens, and post-transplant immunosuppressive therapy, patients undergoing allogeneic HCT require careful monitoring for regimen-related toxicities and intensive supportive care directed at maintaining adequate blood counts, preventing or treating infection, and providing optimum nutrition.

Placement of a double-lumen or triple-lumen central venous catheter is mandatory in all patients. The need for administration of chemotherapy, blood products, antibiotics, parenteral nutrition, and adjunctive medications over a prolonged period of time precludes the use of peripheral access sites. The use of a central venous catheter allows delivery of maximum concentrations of all medications into a high-flow blood vessel. Administration time is reduced and daily fluid infusion is minimized.

After administration of the preparative regimen and before successful engraftment, allogeneic myeloablative HCT patients undergo a period of pancytopenia lasting from 2 to 6 weeks. During this time, patients may require multiple RBC and platelet transfusions. Packed RBCs and platelets are usually given for a hematocrit less than 25% and a platelet count less than 10,000/μL or 20,000/μL. Transfusions with multiple blood products put patients at risk for blood product-derived infection (e.g., CMV, hepatitis). In addition, sensitization to foreign leukocyte HLA antigens (alloimmunization) may cause immune-mediated thrombocytopenia. Thus, blood product support in the myeloablative allogeneic HCT patient must incorporate strategies that reduce the risk of viral infection and alloimmunization. Effective methods include minimizing the number of pretransplant infusions, using single-donor rather than pooled-donor blood products, irradiating blood products, and filtering blood products with leukocyte reduction filters.

Patients receiving reduced-intensity or nonmyeloablative preparative regimens may or may not experience neutropenia and generally have reduced requirements for blood products. In fact, many centers perform reduced-intensity or nonmyeloablative HCT in the outpatient setting and admit patients to the hospital only for complications requiring more aggressive management.

Several measures are recommended to minimize the risk of infection in autologous and allogeneic myeloablative HCT patients. Private reverse isolation rooms equipped with positive-pressure HEPA filters and adherence to strict handwashing techniques reduce the incidence of bacterial and fungal infections.[4] To reduce exposure to exogenous sources of bacteria in immunosuppressed patients, low microbial diets (Table 101-10) may be instituted on hospital admission, and visitors are prohibited from bringing plants or flowers into the patient's room. Patients are encouraged to maintain good oral hygiene because the mouth can be a source of bacterial or fungal infection. Frequent (4–6 times daily) mouth rinses with sterile water, normal saline, or sodium bicarbonate are effective.[4] Brushing or flossing teeth is avoided during periods of thrombocytopenia and neutropenia.

Table 101-10

Foods Posing Infection Risk in Neutropenic Patients

High-Risk Foods to Avoid When Neutropenic	Infection Risk
Salad	Gram-negative bacillus including Pseudomonas aeruginosa and Campylobacter
Tomatoes, radishes, celery, and carrots	Pseudomonas aeruginosa
Raw eggs	Campylobacter jejuni, Salmonella
Unpasteurized cheeses	Listeria monocytogenes Enterococci
Cold, loose meats	Listeria, Clostridium perfringens, Campylobacter jejuni
Undercooked meat	Salmonella, Listeria, Escherichia coli
Uncooked nuts	Aspergillus niger, Aspergillus flavus
Black pepper/uncooked herbs and spices	Aspergillus spp.

Raw shellfish/sushi	Vibrio vulnificus, Norwalk virus
Bottled water	Pseudomonas, Cytophaga, Campylobacter
Prepared foods that are cooked and then eaten chilled	Listeria
Ice machines	P. aeruginosa, Stenotrophomonas maltophilia

Aggressive use of antibacterial, antifungal, and antiviral therapy, both prophylactically and for documented infection, is an important aspect of patient management. Antibiotics with a broad gram-negative spectrum may be instituted prophylactically once the patient becomes neutropenic (ANC <1,000 cells/μL), or empirically after the patient is neutropenic and experiences fever (oral temperature >38°C). Some transplant centers administer a prophylactic fluoroquinolone such as levofloxacin on admission especially if the neutropenic period is expected to extend beyond 7 days.[170–174]

Fluoroquinolone prophylaxis during periods of neutropenia significantly reduces the incidence of gram-negative bacteremia but generally does not affect mortality.[4] Concerns regarding prophylactic fluoroquinolone use include the emergence of resistant organisms and an increased risk of streptococcal infection.[4,175] In fact, the incidence of Viridians group of streptococci has been increasing.[4,176] Prophylactic antibiotics (e.g., penicillin, vancomycin) are not recommended due to their lack of proven efficacy in preventing streptococcal infections and the concern about antibiotic-resistant bacteria.[4] Regardless of prophylactic strategies, patients who become febrile during neutropenia should immediately receive broad-spectrum IV antibiotic(s) (e.g., ceftazidime, cefepime, imipenem, or meropenem) and prophylaxis should be discontinued.[4,177]

Antifungal prophylactic agents are commonly used in HCT recipients. S.D. is prescribed fluconazole 400 mg/day on admission because prophylactic use until day +75 post-transplant decreases the incidence of systemic fungal infection and fungal death in patients undergoing HCT.[178,179] The use of prophylactic fluconazole has been linked to reports of breakthrough infections with resistant fungi such as C. glabrata and Aspergillus.[180,181]

When broader yeast and mold prophylaxis is required, either posaconazole or voriconazole may be used; however, data are limited in the transplant setting. If S.D. were to require mold prophylaxis, voriconazole 200 mg twice daily would be a reasonable choice. Voriconazole 200 mg twice daily was compared to fluconazole 400 mg once daily in a randomized double-blind trial for prevention of invasive fungal infections in standard risk HCT. No significant differences were seen in fungus-free survival, relapse-free status, and overall survival at 6 months. Toxicities were similar, and there was a trend toward reduced aspergillus infections and less empiric antifungal therapy in the voriconazole arm.[182] Posaconazole has also been used for mold prophylaxis in HCT based on its efficacy as prophylaxis in neutropenic patients.[183] However, data in HCT are very limited. Both azoles affect the CYP3A4 isoenzyme, and their use with calcineurin inhibitors requires judicious monitoring. The use of broader spectrum azoles has also resulted in the development of breakthrough zygomycosis infections, particularly with the use of voriconazole.[184]

The echinocandins have also been used for broader yeast and mold prophylaxis in HCT. Micafungin (50 mg IV every 24 hours) and fluconazole (400 mg IV every 24 hours) were compared in a randomized, double-blind study of patients undergoing HCT. Overall success was defined as the absence of suspected, proven, or probable systemic fungal infection through the end of therapy and as the absence of proven or probable systemic fungal infection through the end of the 4-week post-treatment period. The overall efficacy was greater in the patients who received micafungin (80.0% vs. 73.5% $p = 0.03$). Fewer episodes of aspergillosis occurred in patients treated with micafungin.[185]

Prevention of Herpes Simplex Virus and Varicella-Zoster Virus

CASE 101-6, QUESTION 2: On routine screening before transplantation, S.D. is found to be HSV-seropositive (≥1.11 index value) and VZV-seropositive (≥1 index value). How will this affect her management?

Up to 70% of HSV-seropositive patients undergoing myeloablative allogeneic HCT will experience reactivation of HSV.[186] Prophylactic acyclovir is commonly used in HSV-seropositive patients undergoing allogeneic or autologous HCT to prevent viral reactivation.[4,187] Dosing regimens for prophylactic acyclovir vary widely; the dose of IV acyclovir is typically 250 mg/m^2 IV every 8 hours, whereas oral doses of acyclovir range from 600 to 1,600 mg/day.[4] The recommended duration of acyclovir prophylaxis for HSV varies from day +30 to day +365 post-transplant or longer, depending on the specific type of HCT and other risk factors. Valacyclovir, a prodrug of acyclovir with improved bioavailability, provides sufficient blood concentrations to prevent HSV in patients with mucositis or GI aGVHD.[188] Prophylactic valacyclovir is commonly used at a dose of 500 mg PO every 12 hours.[189,190]

Varicella-zoster virus (VZV)-seropositive patients are at risk for developing herpes zoster, particularly after day +100 post-transplant.[191] Prophylactic acyclovir reduces the risk of VZV reactivation.[192] As with prophylaxis for HSV reactivation, the optimum duration of VZV prophylaxis is controversial, often extending to day +365 post-transplant or longer.

Patients who are HSV-seronegative or VZV-seronegative rarely exhibit primary HSV or VZV infection and are therefore not administered prophylactic acyclovir. If HSV does occur, lesions usually appear on the oral mucosa, nasolabial mucous membranes, or genital mucocutaneous area and can be managed with acyclovir at standard treatment doses.

Because S.D. is HSV- and VZV-seropositive, she is at risk for viral reactivation and should receive prophylactic acyclovir 400 mg PO twice daily, beginning 4 days prior to transplant and continuing until her ANC is greater than 2,500 cells/µL for at least 2 days.

Prevention of Cytomegalovirus Disease

CASE 101-6, QUESTION 3: S.D. is also CMV-seropositive. What is the significance of this finding and what measures can be taken to prevent reactivation of CMV?

Cytomegalovirus has the ability to establish lifelong latent infection after primary exposure. In immunocompromised patients, the virus may reactivate, resulting in asymptomatic shedding or the development of CMV disease. The incidence of CMV infection (defined as isolation of the virus or detection of viral proteins or nucleic acid in any body fluid without clinical symptoms) and CMV disease (signs and symptoms consistent with CMV invasion into a tissue) in HCT recipients is 15% to 60% and 20% to 35%, respectively. The most common manifestations of CMV disease after allogeneic HCT are pneumonitis, fever, and GI infection.[193]

In the CMV-seronegative HCT recipient, primary CMV infection or disease can be prevented by selecting a CMV-seronegative donor and using only blood products from CMV-seronegative donors. No anti-CMV prophylaxis is required in these recipients. In patients who are CMV-seropositive or who have received a CMV-seropositive graft, antiviral drugs are essential to minimize

morbidity associated with CMV reactivation or secondary infection. Two general strategies are possible. Universal prophylaxis involves the administration of ganciclovir from the time of engraftment until approximately day +100 post-transplant. This strategy significantly decreases the incidence of CMV infection and disease compared with placebo.[194] However, prophylactic ganciclovir therapy is associated with neutropenia in 30% of patients, which contributes to an increased risk of invasive bacterial and fungal infections.[194,195] Neutropenia secondary to ganciclovir may lead to interruptions in antiviral therapy or necessitate administration of filgrastim daily or several times per week to maintain adequate neutrophil counts. The other strategy involves preemptive therapy, or risk-adjusted therapy.[188,196] Using this strategy, patients begin therapy only if they have early reactivation of CMV detected through the assay of blood for CMV antigens (e.g., pp65), or viral nucleic acid using polymerase chain reaction (PCR) testing. Using preemptive therapy selectively administers ganciclovir to only those HCT patients at greatest risk for development of CMV disease.[197–199] Antigenemia-based preemptive therapy is as effective as universal ganciclovir prophylaxis for prevention of CMV disease and is associated with reduced CMV mortality.[195,200–203] The induction dose of ganciclovir is typically 5 mg/kg IV every 12 hours for 7 to 14 days, followed by a maintenance dose of 5 mg/kg IV daily until 2 to 3 weeks after the last occurrence of antigenemia or until day +100 post-transplantation.[4] Preemptive therapy limits patient exposure to the potential toxicity of ganciclovir and thus reduces overall cost.[191] Recent data suggest that oral valganciclovir is a safe and effective alternative to ganciclovir for preemptive therapy.[204,205] Foscarnet may also be administered in lieu of ganciclovir, but its use is complicated by nephrotoxicity and electrolyte wasting.[203,206] Monitoring and correction of electrolyte and fluid imbalances are essential when foscarnet is initiated.

Cidofovir is used to treat CMV in HCT patients but is reserved for use when ganciclovir or foscarnet has failed.[207] Dose-related renal dysfunction, which can be seen after even 1 or 2 doses, limits the number of patients able to receive cidofovir.[207] An advantage of cidofovir is its infrequent dosing making it conducive to clinic administration. Monitoring renal function, electrolytes, WBC, and intraocular pressure are essential monitoring parameters.

Autologous HCT recipients who are CMV-seropositive pretransplant should receive antiviral treatment preemptively as described previously.[4,208] Nonmyeloablative or reduced-intensity HCT recipients should also receive preemptive antiviral treatment. Because host T cells may persist in the peripheral blood for up to 6 months after reduced-intensity or nonmyeloablative preparative regimens, their presence may provide some protection against early CMV disease. A matched controlled study comparing the incidence and outcome of CMV infection in myeloablative and nonmyeloablative HCT demonstrated that although the time to onset of CMV antigenemia was similar in the two groups, fewer nonmyeloablative HCT recipients experienced CMV disease in the early period.[209] The overall 1-year incidence of CMV disease was also similar, suggesting that nonmyeloablative HCT recipients are at increased risk for exhibiting late CMV disease (>100 days after transplantation) compared to their myeloablative counterparts.[209] It is therefore recommended that nonmyeloablative HCT patients receive preemptive antiviral therapy and be monitored for development of CMV antigenemia for 1 year after HCT.[209,210]

S.D.'s ANC recovers to greater than 1,000 cells/ μL on day +20, and on day +32, her weekly surveillance blood sample is positive for CMV by PCR. Preemptive ganciclovir induction is initiated at 5 mg/kg IV every 12 hours for 2 weeks followed by maintenance dosing of 5 mg/kg daily. After 3 weeks of therapy, S.D.'s surveillance samples are negative and ganciclovir is discontinued. Weekly surveillance sampling continues until day +100. If surveillance samples again become positive for CMV, ganciclovir therapy should be reinstituted.

Diagnosis and Treatment of Aspergillus Infection

RISK FACTORS

CASE 101-7

QUESTION 1: A.W., a 60-kg, 165-cm, 15-year-old boy, is day +79 after a matched, unrelated, nonmyeloablative PBPC transplant for acute lymphocytic leukemia in third complete remission. He presents to the clinic for evaluation of a temperature of 102.3°F and a 3-day history of nonproductive cough. Significant medical history includes skin and GI GVHD (stable on his current regimen of cyclosporine, mycophenolate mofetil, and prednisone) and congestive heart failure believed to be secondary to anthracycline exposure. A.W. has chronic low-grade nausea and hypomagnesemia necessitating daily IV hydration with magnesium supplementation. Relevant laboratory values are as follows:

Na, 138 mEq/L
K, 4.2 mEq/L
Cl, 100 mEq/L
CO_2, 23 mEq/L
Blood urea nitrogen, 18 mg/dL
SCr, 0.8 mg/dL
Total bilirubin, 0.6 mg/dL
Mg, 1.5 mg/dL
WBC count, 3,500 cells/μL
Platelets, 78,000/μL
ANC, 1,810 cells/μL
Hemoglobin, 10.8 g/dL

He was CMV-seropositive and HSV-seropositive before HCT. Oral medications include cyclosporine 275 mg every 12 hours, mycophenolate mofetil 900 mg every 12 hours, prednisone 60 mg every morning and 12.5 mg every evening (tapering), trimethoprim–sulfamethoxazole (TMP/SMX) 160 mg/800 mg twice daily on Monday and Tuesday, fluconazole 400 mg every morning, valacyclovir 500 mg BID, digoxin 0.125 mg every 12 hours, enalapril 10 mg every 12 hours, and a multivitamin every morning.

On physical examination, A.W. is a chronically ill-appearing child with “moon” face, dry skin with thickened areas, a pleural friction rub, and thinning hair. Blood cultures, urinalysis, and chest X-ray are obtained. Chest X-ray reveals several small cavitary lesions worrisome for fungal disease. A.W. is admitted for further workup and management of presumed Aspergillus infection. What risk factors does A.W. have for developing an infection with Aspergillus?

Invasive molds (most commonly Aspergillus spp., but also Fusarium spp., Scedosporium, and Zygomycetes) are an increasing cause of morbidity and mortality after allogeneic and autologous HCT. Factors contributing to this trend include (a) more effective prevention of bacterial and viral infection which promote mold overgrowth, as described previously; and (b) the use of fluconazole prophylaxis, which has reduced the incidence of candidemia and Candida-related mortality.[178–180,211,212] Aspergillus infection is reported in up to 26% of HCT recipients, and the mortality rate of invasive aspergillosis (IA) is 74% to 92%.[185]

Several risk factors for development of invasive fungal infection have been identified.[211,212] Given that neutrophils are critical for host defense, prolonged neutropenia is considered the single most important predictor of infection at any point after HCT.[181,211] GVHD (acute and chronic) and treatment with corticosteroids are also important risk factors, particularly for aspergillosis, presumably as a result of neutrophil dysfunction.[185,211–213] In addition, the widespread use of fluconazole prophylaxis (400 mg/day) for prevention of invasive candidiasis in transplant patients since the early 1990s has led to a substantial increase in the incidence of invasive aspergillosis and also fluconazole-resistant Candida species such as Candida krusei and Candida glabrata.[211,213,214]

A.W. is receiving corticosteroid treatment for GVHD and fluconazole prophylaxis. These therapies increase his risk for exhibiting invasive aspergillosis.

TREATMENT

CASE 101-7, QUESTION 2: A.W. undergoes bronchoalveolar lavage to identify the organism responsible for his pulmonary infection. Pathologic examination of the fluid obtained reveals septate, branching hyphae, and culture results confirm the diagnosis of Aspergillus fumigatus infection. Imaging scans are negative for extrapulmonary involvement. How is aspergillosis usually diagnosed, and what are the acceptable alternatives for treating this infection?

Early diagnosis and treatment of invasive aspergillosis, which rely on tissue or fluid obtained from the infected site followed by aggressive antifungal therapy, may improve patient survival.[215] Although the lower respiratory tract is frequently the primary focus of infection, Aspergillus may invade blood vessels and spread hematogenously to other organs, including the brain, liver, kidneys, spleen, and skin.[191] Head, chest, abdomen, and pelvic computed tomography scans assist in assessing the extent of disease, treatment options, and overall prognosis. Cultures of respiratory tract secretions lack sensitivity for detecting Aspergillus, and the medical condition of the patient may preclude invasive diagnostic procedures altogether. Many clinicians have adopted the European Organization for Research and Treatment of Cancer criteria for diagnosis of proven, probable, and possible invasive aspergillosis.[216]

Newer diagnostic tests based on the detection of fungal antigens or metabolites, such as galactomannan, 1,3-β-D-glucan, and fungal DNA detection by PCR, are being developed. Galactomannan is a polysaccharide component of the Aspergillus cell wall that is released during fungal cell growth. Galactomannan detection by enzyme-linked immunoassay (GM-EIA) has proved to be a sensitive and specific tool for early detection of Aspergillus infection. The test is useful not only for serum samples but also for bronchoalveolar lavage and cerebrospinal fluid. Concomitant antifungal therapy may cause false-negative results, whereas antibiotics of fungal origin (e.g., piperacillin/tazobactam) have been associated with false positives.[185,217]

ANTIFUNGALS

Outcomes for patients with invasive aspergillosis after HCT are often poor, with approximately 20% of patients alive after 1 year.[211] Treatment success depends not only on the use of intensive antifungal agents but also on recovery of the host immune system and/or reduction of immunosuppression.[215,218] Conventional amphotericin B had traditionally been the gold standard antifungal therapy for invasive aspergillosis with response rates in the range of 28% to 51%, depending on the severity of the underlying immunosuppression; however, 65% of responders eventually died of their infection.[215] Fortunately, broad-spectrum triazoles and echinocandins are available as alternatives. The treatment of invasive aspergillosis has moved away from the use of amphotericin to the use of broad-spectrum azoles for its treatment.

Three broad-spectrum triazole agents (itraconazole, voriconazole, posaconazole) are available for patients. In an early compassionate use trial of invasive aspergillosis unresponsive to amphotericin B, 27% of patients had a complete response to itraconazole, and another 35% experienced improvement in their infection.[219] Patients who had undergone HCT had response rates similar to patients who were less immunocompromised. Unfortunately, oral itraconazole capsules exhibit erratic absorption and the IV form is complicated by the risk of drug precipitation in the IV line.[218] In addition, itraconazole is a potent inhibitor of common CYP isoforms and also has negative inotropic properties.[220,221]

Voriconazole is one of the newer broad-spectrum azoles whose advantage is its excellent (96%) oral bioavailability. Voriconazole has been compared to conventional amphotericin B in a randomized, unblinded trial as primary therapy for established invasive aspergillosis in an immunocompromised host.[222] The primary objective was to demonstrate the noninferiority of voriconazole compared with conventional amphotericin B after 12 weeks of therapy in patients with definite or probable invasive aspergillosis. Patients received voriconazole 6 mg/kg IV every 12 hours for two doses followed by 4 mg/kg IV every 12 hours for at least 7 days, followed by oral voriconazole 200 mg every 12 hours or amphotericin B at a dose of 1 to 1.5 mg/kg/day. Patients refractory to or intolerant of initial therapy could receive other antifungal drugs. Of 144 evaluable patients who received voriconazole, 76 (52.8%) had a partial or complete response compared to 42 of 133 (31.6%) patients treated with amphotericin B. The median duration of therapy for patients treated with voriconazole was 77 days, and 52 of 144 patients switched to an alternative agent. In contrast, the median duration of therapy for patients receiving amphotericin B was 10 days, and 107 of 133 patients switched to another agent (most commonly, a lipid formulation of amphotericin B). The survival rate at 12 weeks in the voriconazole group was 70.8% compared to 57.9% ($p = 0.02$). These results of initial therapy with voriconazole indicate superior response and improved survival in immunocompromised patients, such as allogeneic HCT recipients, with invasive aspergillosis. Voriconazole-treated patients also experienced fewer drug-related adverse effects; however, drug interactions due to P450 3A4 inhibition should be closely monitored.

Posaconazole, a newer broad-spectrum triazole, is available as an oral suspension, oral tablets and an intravenous formulation. The oral suspension has a more variable absorption as compared to the tablet formulation. In general, posaconazole has the lowest minimum inhibitory concentration of any available triazole against Aspergillus spp., including Aspergillus terreus. It is the only triazole with activity against the Zygomycetes. Published clinical experience with posaconazole is limited; however, in an open-label externally controlled trial in patients with invasive aspergillosis refractory to or intolerant of other therapies, the overall success rate was 42% in posaconazole-treated patients compared to 26% for controls ($p = 0.006$).[223]

Echinocandin antifungal agents (caspofungin, micafungin) inhibit the synthesis of β-(1,3)-glucan, an important component of the fungal cell wall. No prospective randomized trials have documented the efficacy of any echinocandin for primary therapy of invasive aspergillosis, and only caspofungin is approved for salvage therapy. An open-label, noncomparative trial evaluated the efficacy of caspofungin in 69 patients who had failed or were intolerant of at least 7 days of standard antifungal therapy.[224] Patients received 70 mg IV of caspofungin on day 1 followed by 50 mg IV daily. Of the 63 evaluable patients, 26 (43%) responded favorably to treatment. Twenty-six of 52 patients (50%) who had received at least 7 days of therapy had a favorable response. In another open-label, noncomparative trial, Denning et al. evaluated the safety and efficacy of micafungin (alone or in combination) in patients with proven or probable aspergillosis. Eighty of 225 patients (35.6%) had a favorable response. Most patients received combination therapy; the 34 patients treated with monotherapy had a similar response rate.[225] Amphotericin B is no longer first-line therapy for the treatment of invasive aspergillosis. It is typically reserved for patients who develop mold infections, such as cryptococcus, that are resistant to the azoles.

In summary, the number of agents available to manage invasive aspergillosis has expanded greatly in the past decade. Although some experts believe that voriconazole is the drug of first choice, considerable controversy still exists regarding acquiring resistance, selecting out other species of molds, and side effect tolerance due to the lack of definitive studies. Therapy should be tailored to the individual patient based on response, tolerability, and cost.

ANTIFUNGAL TOXICITIES AND LENGTH OF ANTIFUNGAL THERAPY AND COMBINATION ANTIFUNGAL THERAPY

CASE 101-7, QUESTION 3: A.W. is started on voriconazole 6 mg/kg IV every 12 hours for two doses, followed by 4 mg/kg IV every 12 hours, plus caspofungin 70 mg IV on day 1 and 50 mg IV daily thereafter. What toxicities can be expected with azole treatment? What is the rationale for combination therapy and how should the patient be monitored? How long should A.W. receive antifungal therapy?

Common toxicities reported with voriconazole include reversible visual disturbances (blurred vision, altered color perception, photophobia, visual hallucinations), skin reactions (rash, pruritus, photosensitivity), elevations in hepatic transaminase enzymes and alkaline phosphatase, nausea, and headache.[222,226,227] Caspofungin has fewer adverse effects. Vein irritation and headache are most common; dermatologic reactions related to histamine release (flushing, erythema, wheals) have also been reported. Increased hepatic transaminase enzymes occur in approximately 6% of patients treated with caspofungin.[224] A.W. should be monitored for changes in liver function and counseled regarding the potential visual side effects of voriconazole. The azoles are also known inhibitors of the CYP3A4 isoenzyme; therefore, drug interaction monitoring is imperative. The major interaction seen in patients undergoing allogeneic HCT is an increase in calcineurin inhibitor levels. Careful monitoring is warranted.

Data supporting improved outcomes with two-drug combinations of triazoles, echinocandins, and polyenes in patients with aspergillosis are sparse. However, in vitro and animal data suggest that an echinocandin plus voriconazole or a polyene may be synergistic.[228–231] Given the overall poor prognosis of invasive aspergillosis in severely immunocompromised patients, many practitioners choose to treat patients with two-drug combination therapy. Voriconazole in combination with caspofungin is thus a reasonable alternative for A.W.

The optimum duration of antifungal therapy for treatment of invasive aspergillosis has not been established.[218] Important considerations include the status of the patient's immune system and the extent of response to treatment. Many clinicians continue aggressive antifungal therapy until the infection has stabilized radiographically and then proceed with less aggressive "maintenance" therapy (e.g., single-agent oral voriconazole) until restoration of the immune system has taken place. It is not uncommon for a patient to require several months of antifungal therapy for effective management of invasive aspergillosis.

Prevention of Pneumocystis jiroveci Pneumonia

CASE 101-7, QUESTION 5: A.W. is receiving TMP/SMX, one double-strength tablet PO BID on Monday and Thursday. What is the rationale for its use?

Pneumocystis jiroveci is a common pathogen that causes Pneumocystis pneumonia (PCP) in patients who have undergone allogeneic HCT. PCP is a potentially lethal infection, and prophylaxis is routinely administered. The optimum prophylactic regimen has not been established, but most centers administer TMP/SMX for PCP prophylaxis.[4] Dapsone and aerosolized pentamidine are alternatives for patients who are allergic to sulfonamides or do not tolerate TMP/SMX for other reasons such as hematologic toxicities. PCP prophylaxis is usually begun after neutrophil recovery because (a) PCP most commonly occurs after engraftment and (b) TMP/SMX is potentially myelosuppressive. Patients should be closely monitored for unexplained neutropenia or thrombocytopenia.

ISSUES OF SURVIVORSHIP AFTER HEMATOPOIETIC CELL TRANSPLANTATION

CASE 101-8

QUESTION 1: H.O. is a 32-year-old woman who received a BU/CY preparative regimen and an HLA-matched sibling HCT for treatment of chronic phase CML at age 21 years. H.O. received her HCT more than 10 years ago, is disease-free, and has not had chronic GVHD for 9 years. Her only medication is one multivitamin tablet daily. What issues of cancer survivorship are of concern to H.O.?

A greater proportion of HCT recipients are surviving their cancer diagnosis without evidence of their primary malignancy, but they are at risk for long-term physical and emotional sequelae of their cancer treatments.[2] Many long-term HCT survivors are no longer under the care of an HCT center and their healthcare providers may be unfamiliar with the complications of HCT. To facilitate the clinical care of long-term HCT recipients, recommendations for screening and preventive practices have been created for adult and pediatric HCT survivors.[232,233] These guidelines should facilitate the provision of health care to HCT recipients. The following paragraphs describe various concerns associated with the morbidity of long-term HCT survivors.[232–234] Long-term HCT survivors should be regularly screened for the development of secondary malignancies, complications of GVHD that affect the oral mucosa, liver, respiratory, endocrine, ocular, skeletal, nervous system, kidney, and vascular systems. The psychosocial health of HCT survivors should also be evaluated.

Immune function can take more than 2 years to recover, even after discontinuation of immunosuppressants.[235] Treatment of GVHD exacerbates immune system defects, necessitating prophylaxis and vigilant monitoring for infectious complications. Fevers should be rapidly assessed and treated to prevent fatal infections. Recipients of HCT also lose protective antibodies to vaccine-preventable diseases; therefore, HCT survivors need to be revaccinated for selected infectious diseases with due consideration for the risk of vaccination.

Hematopoietic cell transplant survivors have a greater risk of secondary malignant neoplasms.[2] An increased incidence of cancer of the skin, oral mucosa, brain, thyroid, and bone is observed after allogeneic HCT, and an increased incidence of myelodysplasia and acute leukemia can occur after autologous HCT for NHL.[2] Survivors should avoid carcinogens (e.g., tobacco) and be screened for secondary malignant neoplasms indefinitely.[2] Long-term impairment of end-organ function may be due to the preparative regimen, infectious complications (either autologous

or allogeneic grafts), and post-transplant immunosuppression (allogeneic grafts only).[232,234] Endocrine dysfunction, specifically of the thyroid, gonads, and growth velocity, is common.[232,233] Adrenal insufficiency can result from long-term corticosteroid therapy used to treat GVHD. Infertility is commonly observed after myeloablative HCT secondary to the high doses of alkylating agents and radiation administered. Frequently, men become azoospermic, and chemically induced menopause develops in women.[2] However, pregnancies have occurred after HCT.[2] Up to 60% of HCT recipients have osteopenia, most likely resulting from gonadal dysfunction and corticosteroid administration; avascular necrosis due to corticosteroids can also occur.[236] A significant portion (15%–40%) of HCT survivors exhibit pulmonary dysfunction with variable symptoms (e.g., restrictive, chronic obstructive lung disease) from multiple causes.[236] Hepatic infections can occur in HCT recipients through blood transfusions or, more commonly, because recipients or donors have a latent hepatitis viral infection. The prevalence of chronic hepatitis C ranges from 5% to 70% in long-term HCT survivors.[237] Because of this, cirrhosis and its complications may become an important late complication of HCT.[237] Hepatic dysfunction can also result from iron overload, which may occur secondary to multiple red blood cell transfusions administered during aplasia after myeloablative preparative regimens and before HCT. Alopecia is a common late effect with BU/CY, as are cataracts with CY/TBI.[75]

H.O. should be routinely monitored for signs of relapse and chronic GVHD. To lower the risk of infectious complications, she should be counseled to obtain prompt medical care for fevers or signs of an infection, and she should be revaccinated if she has not done so since receiving her myeloablative HCT. Thorough evaluation of end-organ function, including renal, hepatic, thyroid, and ovarian function, should be assessed at regular intervals. In addition, her bone mineral density should be determined, and H.O. should be counseled on preventive measures for osteopenia (e.g., calcium supplementation). In addition to standard cancer screening tests, H.O. should be closely monitored for secondary malignant neoplasms.[2]

Pediatric Pharmacotherapy

Marcia L. Buck

CORE PRINCIPLES

	CHAPTER CASES
GROWTH AND DEVELOPMENT	
1 Children undergo considerable physiologic changes between birth and adulthood. Although most follow the same general pattern of growth, the timing of maturation varies from child to child.	**Case 102-1 (Question 1), Table 102-1**
PHARMACOKINETIC DIFFERENCES	
1 All aspects of pharmacokinetics are affected by growth and development. Drug absorption is altered by a variety of mechanisms, with the most significant differences noted during the first months of life.	**Case 102-2 (Question 1), Case 102-3 (Questions 1–4)**
2 Drug distribution is affected by changes in relative organ size, body water content, fat stores, plasma protein concentrations, acid–base balance, cardiac output, and tissue perfusion. The greatest degree of change occurs during the first year of life.	**Case 102-3 (Questions 5, 6), Table 102-2**
3 Metabolic function is highly dependent on patient age. This has been demonstrated in a number of recent studies, which have identified significant differences in half-life during infancy, childhood, and adolescence.	**Case 102-4 (Questions 1–4)**
4 Elimination is reduced during infancy, resulting in slower rates of clearance for many commonly used drugs. Glomerular filtration rate increases throughout childhood. Use of creatinine clearance as an estimate of glomerular filtration rate requires different equations than those used in adults.	**Case 102-5 (Questions 1, 2), Case 102-6 (Question 1)**
5 Adolescence is not simply a link between childhood and adulthood; it is a distinct period of significant physiologic change. The effects of puberty can alter the efficacy or toxicity of many drugs administered during this period.	**Case 102-7 (Question 1)**
PHARMACODYNAMIC DIFFERENCES	
1 Although less well understood than pharmacokinetic differences between children and adults, there are significant age-related effects on	**Case 102-8 (Question 1), Case 102-9 (Questions 1, 2)**

	pharmacodynamics as well. Children may exhibit differences in both therapeutic response and adverse effect profiles.	

MEDICATION DOSING IN CHILDREN

1	The differences in pharmacokinetics and pharmacodynamics observed in children influence the choice of drug dose and dosing interval. For most dose calculations, weight is used to account for growth and development.	**Case 102-10 (Question 1)**
2	All pediatric prescriptions and medication orders must be checked for the appropriateness of the dose, route, and frequency with a pediatric dosing reference.	**Case 102-10 (Question 1)**

PREVENTING MEDICATION ERRORS IN CHILDREN

1	Children are at a greater risk for medication errors than adults, as a result of the need to calculate drug doses and alter dosage formulations.	**Case 102-10 (Question 2)**
2	Electronic prescribing, standardization of drug doses and concentrations, and the introduction of smart-pump technology have been shown to reduce errors in many children's hospitals. One of the most effective methods to avoid errors is the inclusion of pediatric pharmacists in the medication ordering and review process.	**Case 102-10 (Question 3), Table 102-3**

INCREASING PEDIATRIC MEDICATION INFORMATION

1	A number of governmental programs are increasing the availability of pediatric medication information and improving the ability of pediatric healthcare professionals to provide safe and effective drug therapy for children.	**Case 102-10 (Question 4)**

Providing care for children can be one of the most challenging, but rewarding, aspects of pharmacy practice. Although a relatively small number of healthcare providers pursue specialty training in pediatrics and work exclusively with children, most clinicians will provide care for children every day in the community or hospital setting. According to recent population estimates, approximately one-quarter of the US population is younger than 20 years of age, with 6% younger than 5 years of age.[1] Although most children are healthy, this segment of the population still uses a significant amount of healthcare resources. In a recent telephone survey, one in five parents reported giving their child one or more prescription medications within the previous week.[2] A survey conducted in pediatricians' offices found that 53% of children left their visit with a prescription.[3]

Pediatrics, as a specialty, encompasses a very diverse patient population. Patients range in age from premature neonates to adolescents and can vary in weight by 100-fold, from a 0.5-kg premature neonate to a 50-kg 16-year-old. Further complicating the care of children is the relative lack of information on drug dosing and monitoring. Because of the small numbers of children requiring medical treatment and the difficulty in conducting research in these patients, fewer than half of the drugs currently available in the United States are approved by the Food and Drug Administration (FDA) for pediatric use.[4,5] As a result, as many as 60% of all prescriptions written by pediatricians are for "off-label" uses.[6] Dosing and monitoring information for off-label uses is often based on case series and clinical trials published in the medical literature and may not be readily available in general drug references.

Healthcare providers caring for children must be capable of assessing the appropriateness of drug doses for this diverse population and providing recommendations for dosage adjustments and patient monitoring with limited resources. This requires knowledge of the pharmacokinetic and pharmacodynamic differences between children and adults and how these differences impact both therapeutic and adverse drug effects.

Table 102-1

Commonly Used Age Definitions

Premature neonate	**Born at <36 weeks' gestational age**
Term neonate	Born at ≥36 weeks' gestational age
Neonate	Birth–1 month of age
Infant	>1 month–1 year of age
Child	>1–11 years of age
Adolescent	12–16 years of age

GROWTH AND DEVELOPMENT DURING CHILDHOOD

CASE 102-1

QUESTION 1: C.J. is a 4-month-old, 6.5 kg baby boy who has recently started teething. His parents ask for advice on a medication to alleviate C.J.'s pain. What factors will influence your decision about the choice of medication and dosing regimen for C.J.? What medication and dose will you recommend to his parents?

Children undergo considerable physiologic changes between birth and adulthood. Although many changes are easily observed, such as the ability to walk or the development of language, others are less evident. C.J.'s analgesic dose will be based on his age and weight, as estimates of the numerous pharmacokinetic and pharmacodynamic differences between children and adults. To discuss the changes that occur with growth and development, pediatric patients are typically grouped by age (Table 102-1). These definitions are helpful to provide a consistent framework for dosing recommendations, but it should be kept in mind that they are arbitrary and can oversimplify the differences among individual patients. Although children tend to grow and develop in a relatively similar manner, the timing of maturation varies from child to child. Children do not grow in a predictable, linear fashion, but rather in periodic bursts, with additional variation caused by differences in genetic predisposition, nutritional intake, and environment.[7,8] Research on the impact of growth and development on pharmacokinetics and pharmacodynamics, often referred to as developmental pharmacology, has grown considerably during the past several decades, improving our ability to optimize the efficacy of drug therapy in children while minimizing adverse effects.

The most appropriate analgesic for C.J. would be acetaminophen. Aspirin is no longer used as an analgesic in children because of its association with Reye syndrome, a rare condition causing mitochondrial damage and resulting in hepatic failure. Nonsteroidal anti-inflammatory drugs, such as ibuprofen, are not recommended for use in infants younger than 6 months of age because of an increased risk for renal impairment. C.J. should receive an acetaminophen dose of 10 to 15 mg/kg given every 4 to 6 hours as needed, with no more than five doses or 75 mg/kg given in a 24-hour period. Based on his age and weight, an appropriate recommendation for C.J. would be to give 65 mg (2 mL) of the acetaminophen 160 mg/5 mL oral suspension by mouth every 6 hours as needed. If C.J. continues to need medication for more than 24 hours, his parents should contact C.J.'s primary healthcare provider.

PEDIATRIC PHARMACOKINETIC DIFFERENCES

All aspects of pharmacokinetics are affected by growth and physical maturation, beginning during gestation (pregnancy) and ending in adulthood. These changes are complex, and their timing can vary widely from patient to patient.

Drug Absorption

ORAL DRUG ABSORPTION

CASE 102-2

QUESTION 1: A.H., a 1.5-kg, 4-week-old infant girl born at 29 weeks' gestational age, is being treated with phenobarbital for seizures associated with a period of asphyxia at birth. She is currently receiving a maintenance dose of 7.5 mg (5 mg/kg) given intravenously (IV) once daily. The team wishes to transition her to oral therapy now that she is receiving full enteral feeds. A trough serum phenobarbital concentration obtained during IV therapy was 17.5 mcg/mL, within the desired range of 15 to 40 mcg/mL. Switching the patient to phenobarbital elixir 7.5 mg given orally once daily results in a serum concentration of only 8.9 mcg/mL after 1 week of therapy. What factors might explain the lower concentration, and how should A.H. be managed?

Enteral absorption of drugs is altered at birth and does not approximate adult patterns for several months.[7,8] Gastric fluid volume is greatly reduced at birth. Gastric acid production is decreased, giving the neonate a higher, nearly neutral pH in the stomach. This results in a greater absorption of acid-labile drugs such as penicillin G and erythromycin, but reduced absorption of weakly acidic drugs such as phenobarbital and phenytoin. Gastric acid output increases during the first 1 to 2 weeks of life, but only reaches adult values at 2 to 3 years of age. Transport of bile acids into the gastrointestinal lumen and pancreatic enzyme production are also reduced, further altering the absorption of pH-sensitive drugs and reducing enterohepatic recirculation. Amylase activity is minimal at birth and remains low until the third month of life.[9] Pancreatic lipase activity is detectable by 32 weeks' gestational age, but remains low at birth and throughout the next 2 to 3 months. In contrast, gastric lipase is present at birth and accounts for a greater percentage of fat absorption during early life. In addition to these differences, neonates are also born with relatively sterile gastrointestinal tracts. Normal bacterial colonization typically occurs within days for term infants, but may be delayed in premature infants who reside in the more sterile environment of an intensive care unit. The effectiveness of drugs that rely on gastrointestinal flora for activation or degradation may be significantly altered during this period.

Gastric emptying time is delayed and intestinal transit time is prolonged at birth, but both quickly increase within the first few days of life because contractions in the stomach become more coordinated and intestinal contractions become more frequent, stronger, and sustained. Premature infants have delayed development of normal gastric emptying and intestinal transit, as shown in a study of acetaminophen dosing in which premature infants at 28 weeks' gestational age had a 2-hour delay in absorption compared with older infants.[10] Adult values for gastric emptying and intestinal transit time are generally reached by 4 to 8 months of age.

For drugs absorbed through passive diffusion, reduced splanchnic blood flow during the first weeks of life can reduce the rate and extent of absorption by altering concentration gradients across the intestinal villi.[7] Reduction in blood flow may also place neonates at risk for damage to the gut lining from hyperosmolar drug formulations. As a result, many institutions delay use of the enteral route for drug administration until the patient is receiving at least one-quarter to half of their nutritional needs through enteral feedings. This allows dilution of drug doses and may reduce the risk for mucosal damage. Lower levels of metabolic enzyme activity in the intestine may reduce first-pass metabolism of drugs given enterally.[11,12] Boucher et al.[12] found that the bioavailability of zidovudine decreased from 89% in neonates during the first 2 weeks of life to 61% in older infants, reflecting increased first-pass metabolism in the older patients. Intestinal enzymatic activity does not approach adult values until 2 to 3 years of age.

The lower phenobarbital serum concentration after A.H. was placed on enteral therapy is most likely the result of reduced drug absorption in the gastrointestinal tract, resulting from the higher gastric pH and reduced splanchnic blood flow. The maintenance phenobarbital dose for A.H. should be increased to achieve a trough serum concentration within the desired range. An increase of the oral dose to 10 mg would be appropriate, with a plan to obtain a trough concentration within 3 to 5 days. Although this value will not yet reflect the steady state concentration, due to the long half-life of the drug, it will be useful to guide additional dosing changes.

INTRAMUSCULAR DRUG ABSORPTION

CASE 102-3

QUESTION 1: C.B. is a 3.6-kg newborn boy, born at 39 weeks' gestational age, who was transferred to the newborn nursery after delivery. Routine care for neonates during the first hours of life generally includes administration of erythromycin eye ointment for prevention of neonatal ophthalmia and 1 mg of phytonadione (vitamin K_1) given intramuscularly (IM) to prevent vitamin K-deficiency bleeding of the newborn. C.B.'s parents question the need to give their baby a shot so soon after birth. How would you explain the rationale for giving phytonadione IM rather than orally?

In the United States, phytonadione is typically given by IM injection after birth. Drug administration by IM injection typically results in a delay in time to reach peak serum concentrations in neonates. This delay is related to reduced muscle size, weaker muscle contractions, and an immature vasculature resulting in more erratic blood flow to and from the muscle.[7,8] Although considered a disadvantage when rapid absorption is needed, such as with antibiotic administration, the delay in systemic absorption after IM injection is used as an advantage for the administration of phytonadione after birth. The delayed absorption from muscle results in a depot-like effect, providing a slow release of the drug into the systemic circulation until the infant's dietary intake is adequate to maintain necessary vitamin K serum concentrations.[13] A similar delay in drug absorption may occur with subcutaneous injection because of the lower percentage of body fat in neonates. The delay in absorption seen with IM and subcutaneous administration becomes negligible after the first months of life. When counseling C.B.'s parents, it will be important to stress the benefit of the slower absorption of vitamin K with IM administration compared with the rapid absorption and clearance of a single oral dose. A single IM injection of vitamin K will protect their son from bleeding until he is approximately a month old, when he should be taking in enough breast milk or infant formula to maintain adequate vitamin K concentrations.

TRANSDERMAL DRUG ABSORPTION

CASE 102-3, QUESTION 2: C.B. is scheduled for a circumcision before discharge. The surgical site will be prepped with a 10% povidone–iodine solution. What factors influence the absorption of medications via this route in the neonatal patient? Based on these factors, how should the povidone–iodine be applied to minimize toxicity?

In contrast to enteral, IM, and subcutaneous administration, transdermal or percutaneous administration results in greater drug absorption in neonates than it does in older children and adults. Enhanced absorption results from a greater skin to body surface area ratio, approximately 3 times that of adults, as well as a thinner stratum corneum, better epidermis hydration, and greater perfusion.[7,8] The greater degree of percutaneous absorption in infants has resulted in significant toxicity. Hexachlorophene, when used routinely to bathe infants, has resulted in seizures and is now considered contraindicated in this age range. Application of povidone–iodine as a topical disinfectant before surgery has been linked to neonatal thyroid dysfunction and, as a result, is now used only in limited quantities for brief periods to limit percutaneous iodine absorption. In spite of the knowledge of this adverse effect, cases continue to be reported in the medical literature.[14] Even relatively common topical products can produce systemic toxicity. Frequent use of diaper rash products containing hydrocortisone can produce suppression of the hypothalamus–pituitary–adrenal axis in as little as 2 weeks.

Cleaning and disinfecting the skin before surgery in a neonate requires special attention to the selection of agent, surface area affected, and the length of skin contact. For C.B., a 10% povidone–iodine solution should be gently applied to the penis and surrounding skin immediately before surgery and removed as soon as the 5- to 10-minute circumcision has been completed to minimize the risk for systemic toxicity resulting from enhanced percutaneous iodine absorption.

CASE 102-3, QUESTION 3: Are transdermal anesthetics an appropriate option for use before C.B.’s procedure?

Both 4% lidocaine and eutectic mixture of local anesthetics (EMLA) cream, which contain lidocaine and prilocaine, are widely used as topical anesthetics for infants and children before venipuncture, IV catheter placement, or circumcision. Both have been shown in clinical trials to be safe and effective.[15] The low concentration of the active ingredients and the limited duration of contact, 30 to 60 minutes, prevent excessive systemic absorption when applied to intact skin. Either analgesic cream would be appropriate for C.B. EMLA should be applied an hour before the start of the circumcision, whereas 4% lidocaine cream should be applied 30 minutes before the procedure. A thin layer of cream should be applied, without an occlusive dressing, and the baby diapered until the start of the procedure. The cream should be completely removed before the application of the 10% povidone–iodine solution.

Other transdermal medications should be avoided or used with caution for only limited periods in infants. After the first year of life, transdermal application becomes a more useful route of administration for several medications. Methylphenidate and clonidine patches are used in the treatment of attention deficit hyperactivity disorder (ADHD) in school-aged children, and both lidocaine and fentanyl patches are used for the treatment of older children and adolescents with severe pain.

RECTAL DRUG ABSORPTION

CASE 102-3, QUESTION 4: A week after C.B.'s discharge from the hospital, he is brought into the emergency department after becoming lethargic and febrile at home. His parents have tried giving him oral acetaminophen, but he is vomiting and unable to take liquids. Is rectal administration of acetaminophen an acceptable option for C.B. in the hospital after he has been stabilized?

Rectal administration is a useful route of drug delivery for many pediatric patients. Most drugs are well absorbed by this route, but the strong rectal contractions in infants can result in an inability to retain suppositories for the length of time needed to achieve optimal absorption.[7,8] Gels and liquid dosage preparations that do not require an extended time for dissolution are better options. Rectal diazepam gel is often used by parents of children with seizure disorders to provide rapid control of worsening seizures while awaiting emergency medical personnel. In an observational trial of 358 children, the median time from administration of rectal diazepam by a parent to cessation of seizures was 4.3 minutes.[16]

Rectal acetaminophen would be a viable option for C.B. It is rapidly absorbed through this route. Many drug dosing references recommend a slightly higher rectal acetaminophen dose (10–20 mg/kg) to account for a potentially lower bioavailability.

Drug Distribution

Growth and development also affect drug distribution. Organ size, body water content, fat stores, plasma protein concentrations, acid–base balance, cardiac output, and tissue perfusion all change throughout childhood, altering the pattern of distribution and extent of drug penetration.[7] The greatest degree of change occurs during the first year of life.

CASE 102-3, QUESTION 5: In the emergency department, C.B. is refusing to breast-feed and is having difficulty breathing. Neonatal sepsis with possible meningitis is suspected. Laboratory values and vital signs include the following:

Temperature, 39.4°C
Heart rate, 202 beats/minute (normal 107–182 beats/minute)
Blood pressure, 85/62 mm Hg (normal systolic 70–75 mm Hg, diastolic 50–55 mm Hg)

He currently weighs 3.4 kg and appears slightly dehydrated. His parents report that C.B. has had fewer wet diapers than usual during the last 24 hours. What physiologic differences in the neonatal period would affect your choice of empiric antibiotics for the treatment of neonatal central nervous system infections? What drugs would you select and what doses would you recommend?

Empiric antibiotic therapy for sepsis and meningitis for C.B. typically consists of ampicillin and aminoglycoside. Although not commonly used in adults because of the relatively low degree of penetration across the blood–brain barrier, this combination is very effective in the neonatal period when drug distribution into the central nervous system is higher. Constituting only 2% of total body weight in an adult, the brain makes up 10% to 12% of the weight of an infant. As a result, the brain serves as a much larger potential compartment for drug distribution. In addition, the percentage of systemic blood flow that reaches the cerebral vasculature is greater. These factors, along with a potential for greater passive diffusion of drugs across the functionally immature blood–brain barrier, can result in higher drug concentrations within the central nervous system of infants compared with older children and adults.[7,8] This can produce both benefit and risk to the infant. Drugs given to treat meningitis or seizures are more likely to achieve therapeutic concentrations within the central nervous system, but there is also a greater potential risk for drug-induced neurotoxicity.

BODY WATER

One of the most significant differences in drug distribution during childhood is the decrease in total body water content with increasing age. Approximately 85% of a premature newborn's weight and 70% to 80% of a term newborn's weight are body water, compared with only 60% to 65% in a 1-year-old.[7,8] After a year of age, the percentage declines from 50% to 60% and remains relatively constant. Extracellular water decreases in a similar manner, from 40%–45% in the newborn to 20%–25% by the end of the first year of life. Intracellular water content, however, remains relatively stable. These changes result in a much greater distribution of highly water-soluble drugs, such as the aminoglycosides or linezolid, and a reduced accumulation of highly lipid-soluble drugs, such as amphotericin, amiodarone, benzodiazepines, or digoxin.

The pharmacokinetic profile of gentamicin has been well described in infants and children as a result of its role in empiric antibiotic therapy for neonatal sepsis and meningitis. The volume of distribution of gentamicin in premature neonates ranges from 0.5 to 0.7 L/kg, reflecting the higher extracellular water content at this age. This value falls to 0.4 L/kg by the end of the first year of life and further declines from 0.2 to 0.3 L/kg by adulthood.[17] As a result of their higher volume of distribution, the weight-based dose for an infant is often much higher than a comparable dose in an adult. Based on C.B.'s age and weight, the Pediatric Dosage Handbook,[17] one of the most widely used pediatric drug references, recommends an ampicillin dose of 170 mg (50 mg/kg) given IV every 6 hours and a gentamicin dose of 8.5 mg (2.5 mg/kg) given IV every 8 hours, or if using extended-interval dosing, 13.6 mg (4 mg/kg) every 24 hours. Using these same weight-based doses in a 70-kg adult would result in doses much higher than the typical recommended adult dose.

BODY FAT

Whereas the effects of growth and development on changes in body water content are well defined and typically require adjustments in drug dosing only during infancy, the effects of changes in body fat are not yet well understood. Body fat increases throughout gestation and infancy. A premature neonate may have as little as 1% to 2% body fat, whereas a term infant will have closer to 10%–15% body fat. A 1-year-old will have a body fat of 20% to 25%, similar to that of an adult. Children following normal growth patterns have relatively little change in their body fat percentage between the second year of life and the onset of puberty. However, the increasing rate of childhood obesity has generated concern about the efficacy and safety of current weight-based dosing strategies.[18] In a 2010 retrospective study of 699 children between 5 and 12 years of age admitted to a children's hospital during a 6-month period, overweight children (defined as having a body mass index greater than the 85th percentile for age) accounted for 33% of the admissions.[19] Evaluation of their medication orders revealed that 8.5% of the doses ordered were for less than the recommended dose, whereas 2.8% were for an excessive dose. The need to make dosage adjustments in these children remains controversial; only limited research is available documenting the effects of childhood obesity on the pharmacokinetics and pharmacodynamics of commonly used pediatric medications.

PROTEIN BINDING

CASE 102-3, QUESTION 6: On the third day of admission, the microbiology laboratory reports the culture and sensitivity results for C.B. Although the cerebrospinal fluid and urine cultures were negative, the peripheral blood culture grew Escherichia coli. The organism appears to be sensitive to a wide range of antibiotics, including penicillins, cephalosporins, gentamicin, and sulfamethoxazole-trimethoprim. What would your recommendation be for C.B.'s continuing treatment?

Many of the drugs that would treat C.B.'s infection are highly protein bound. Plasma protein binding is reduced in neonates as a result of decreased circulating levels of both albumin and α_1-acid glycoprotein, as well as decreased binding affinity.[7,8,11] With the known susceptibilities and their long history of efficacy and safety, continuing C.B.'s current ampicillin and gentamicin regimen for 7 to 10 days would be an appropriate choice. Although ampicillin is known to be present in higher unbound concentrations in infants compared with adults (Table 102-2), use of standard dosing recommendations for C.B. based on age should be adequate to prevent toxicity. Sulfamethoxazole-trimethoprim would not be appropriate. Administration of drugs with a high binding affinity for albumin, such as the sulfonamides, during the neonatal period can result in competition with bilirubin for binding sites. The resulting increase in unbound bilirubin can lead to kernicterus, neurologic damage caused by deposition of bilirubin in the brain, primarily in the basal ganglia.[20] For this reason, sulfonamides are not recommended for neonates and are not approved by the FDA for use in infants younger than 2 months of age. Ceftriaxone, another possible option for C.B., also is known to be highly protein bound. Although approved for use in neonates, it is contraindicated in those with hyperbilirubinemia. As a precaution, many hospitals restrict its use in the neonatal population to only those patients who have infections resistant to other antibiotics.

The clinical impact of changes in protein binding can be difficult to predict. Separation and measurement of the unbound (free) fraction can be used to guide therapy for drugs such as valproic acid or phenytoin, but this process is more labor-intensive and expensive and, as a result, may not be available at all hospitals. Larger blood sample volumes may also be required, which can lead to excessive blood loss in premature infants. An estimation of the unbound concentration can be made from total serum drug concentrations, but may not be accurate in infants. Methods to estimate unbound serum valproic acid concentrations from total concentrations that were developed for adults have been found to be ineffective in predicting free levels in neonates and infants.[21]

Table 102-2

Examples of Drugs Present in Greater Unbound Concentrations in Neonates than in Adults

Alfentanil	Penicillin G
Ampicillin	Phenobarbital
Ceftriaxone	Phenytoin
Cefuroxime	Propranolol
Diazepam	Salicylates
Digoxin	Sulfonamides
Lidocaine	Theophylline
Ketamine	Valproic acid
Morphine	
Nafcillin	

Metabolism

Much of the research currently being conducted in developmental pharmacology is focused on changes in metabolic function.[7,8,11,22–49] Our understanding of the ontogeny of metabolic enzymes is improving rapidly, because in vitro data gathered from studies quantifying hepatic microsomal proteins and determining levels of enzymatic activity are combined with information obtained through pharmacokinetic and pharmacogenomic research. It is clear that the onset of function varies among enzymes; whereas some exhibit metabolic activity in utero, others demonstrate activity only after several months of life. The development of metabolic enzyme function continues during the first years of life and does not appear to be complete until after puberty. There appears to be considerable interpatient variability. Enzyme development can be affected by the underlying health of the child, nutritional status, and exposure to substrate. Metabolic activity also reflects genetic polymorphisms, just as in adults.

PHASE I DRUG METABOLISM

CASE 102-4

QUESTION 1: N.M. is a 1.38-kg, 3-week-old girl who was born at 28 weeks' gestational age. She has recently been started on nasogastric feedings, but has had repeated episodes of emesis and is not producing regular stools. Erythromycin is recommended to increase her gastric motility. What can you tell your team about the ability of N.M. to metabolize this drug? What dose of erythromycin would you recommend for N.M.?

Phase I reactions, which include oxidation, reduction, hydroxylation, and hydrolysis, develop at varying rates during childhood, resulting in the wide range of half-lives reported for many drugs. The cytochrome P-450 (CYP) 3A enzymes, which play a major role in drug metabolism, including that of erythromycin, develop early in life.[7,8,11,22–27] The earliest isozyme in this group to show activity is CYP3A7, the primary metabolic enzyme present in utero. It has been found on the endoplasmic reticulum of fetal hepatocytes by the end of the first trimester and serves a role in the transformation of fetal dehydroepiandrosterone and the detoxification of retinoic acid derivatives transferred from maternal serum across the placenta.[22,23,25–27] Enzymatic activity of CYP3A7 declines rapidly after birth, with a 50% reduction during the first month of life. Levels continue to decline at a slower rate through the next 6 months and are typically undetectable after 1 year of age. As levels of CYP3A7 decline, CYP3A4 and CYP3A5 levels rise. Although present during fetal development, the level of CYP3A4 activity is nearly 100-fold less than that of CYP3A7 until after birth.[22,27] Increases in CYP3A4 occur over the first months of life, often reaching levels of enzymatic activity higher than that seen in adults during early childhood. Development of CYP3A5 function is highly variable among infants and children and does not appear to be related to patient age.

It can be anticipated that N.M. will have a slower rate of erythromycin metabolism as a result of lower levels of CYP3A4 activity, so a more conservative approach to dosing is often used. An oral erythromycin dose of 7 mg (5 mg/kg) given every 8 hours would be an appropriate starting dose for N.M. In addition to increasing the risk for adverse effects, higher serum erythromycin concentrations can lead to greater inhibition of CYP3A4. This may place N.M. at risk for toxicity from accumulation of other drugs metabolized via CYP3A4, such as fentanyl and midazolam.

Upregulation of CYP2D6 appears to begin in the last stage of gestation as a part of the complex transition of the baby to extrauterine life.[22–24,28] In fetal liver tissue samples obtained early in gestation, CYP2D6 activity has been reported to be only 1% to 5% of adult values.[22] Earlier studies suggested that levels of enzymatic activity remained low during infancy, but more recent research has demonstrated that CYP2D6 activity increases rapidly during the third trimester, and by the second week of life, values are similar to values in adults.[23] CYP2D6 levels remain relatively constant throughout childhood. The impact of genetic polymorphisms of CYP2D6 on elimination half-life in children is comparable to that demonstrated in adults and appears to play a greater role in determining metabolic function than ontogeny.[23,24,28] A study of atomoxetine response in children and adolescents with ADHD found that CYP2D6 poor metabolizers had greater increases in heart rate and blood pressure and impaired weight gain compared with extensive metabolizers taking comparable doses, reflecting higher serum concentrations with the poor metabolizer phenotype.[29]

The enzymatic activity of CYP2C9 and CYP2C19 develops throughout childhood.[22,23,30] Studies of fetal hepatocytes demonstrated CYP2C9 activity at only 1% of adult values from 8 to 24 weeks' gestation, with an increase from 10% to 20% between 25 and 40 weeks. Enzyme activity continues to increase after birth, reaching 25% of adult values by approximately 5 months of age. Unlike other enzymes, CYP2C9 activity remains at only 50% of adult values until after puberty. The development of CYP2C9 activity is illustrated by the change in the rate of metabolism of phenytoin with advancing age. The apparent (calculated Michaelis–Menten) half-life of phenytoin in premature infants is approximately 75 hours, compared with 20 hours in a term neonate and 8 hours in a 2-week-old.[31]

Development of CYP2C19 function also occurs in utero, with enzyme activity 10% to 20% that of adults at birth.[23] Enzymatic activity increases gradually during the first 3 months of life to near full adult values. As with CYP2D6, genetic polymorphisms for CYP2C9 and CYP2C19 play an important role in determining individual patient response. Population modeling of pantoprazole pharmacokinetics in term neonates and premature infants revealed a longer elimination half-life than that reported in adults, supporting the lower levels of CYP2C19 activity in this age group.[32] The study also demonstrated significantly greater drug concentrations in the patients who had the poor metabolizer genotype.

The ontogeny of CYP2E1 has been studied in conjunction with the ability of infants to metabolize acetaminophen. Fetal hepatic CYP2E1 concentrations are typically undetectable during the first trimester, but begin to increase during the second trimester.[33] Levels are approximately 10% to 20% of adult values at birth. Enzyme concentrations continue to increase at a more gradual pace, until by 3 months of age, CYP2E1 expression becomes similar to that in adults. The increase in CYP2E1 metabolic capacity, along with maturation of glucuronidation, is responsible for the changing patterns of acetaminophen metabolite formation during infancy.

CASE 102-4, QUESTION 2: N.M. is now tolerating her enteral feedings and was recently extubated. However, she has had increasing episodes of apnea, a pause in breathing of 20 seconds or greater frequently present in premature newborns, during the past 2 days. Based on current dosing guidelines, you have recommended a caffeine citrate loading dose of 20 mg/kg given IV to be followed by a maintenance dose of 5 mg/kg given once daily to treat her apnea.[34] While reviewing the dosing information, you note that the elimination half-life for caffeine in neonates is approximately 70 to 100 hours, whereas the half-life for older infants, children, and adults is only 5 hours. What would explain that dramatic difference in half-life?

The changing elimination half-life of caffeine reflects the onset and maturation of CYP1A2 activity. The metabolism of caffeine during infancy has been extensively studied because

---

many neonates are exposed in utero as a result of maternal intake and premature infants often receive caffeine for the treatment for apnea.[22–23,34,35] Studies have shown that CYP1A2 activity is negligible in fetal liver tissue and in newborns who were not exposed to it in utero.[35] The lower levels of enzymatic activity result in a longer caffeine half-life and allow once-daily dosing.[36] In contrast, newborns exposed to caffeine during gestation have higher levels of CYP1A2 activity at birth. Enzymatic activity rises progressively during the first months of life. By 6 months of age, it may exceed adult values, giving the infant a caffeine half-life of only 4 to 5 hours and necessitating more frequent dosing.

CASE 102-4, QUESTION 3: While N.M. was receiving mechanical ventilation during her first weeks of life, she was sedated with an infusion of midazolam. Many IV products, including some brands of midazolam, contain benzyl alcohol as a preservative and are labeled “Not for Use in Infants.” What is the rationale for restricting the use of benzyl alcohol in the neonatal population?

Alcohol dehydrogenase, another Phase I enzyme, is present in utero, but in concentrations less than 5% of adult values.[23] Enzymatic activity does not approach functional maturity until approximately 5 years of age. The lack of alcohol dehydrogenase activity has a profound impact on the ability of newborns to metabolize benzyl alcohol, a common preservative in injectable drug products. In 1982, five neonates died after developing gasping respirations that progressed to respiratory failure, severe metabolic acidosis, renal and hepatic failure, thrombocytopenia, and cardiovascular collapse.[37] All of the infants had been repeatedly exposed to benzyl alcohol as a preservative in IV flush solutions. This toxicity, termed gasping syndrome, resulted from accumulation of the parent compound, as well as the benzoic acid metabolite. Another series of ten patient deaths was reported from a second institution.[38] From these case series, the threshold for toxicity was estimated to be a total daily exposure of 99 mg/kg/day. Within months of these reports, the FDA issued a safety alert calling attention to this reaction and recommending use of preservative-free products or preparations with alternative preservatives in newborns.[39] This change in practice led to the virtual elimination of gasping syndrome and brought to light the significance of differences in neonatal metabolism on drug toxicity. Pediatric clinicians continue to be vigilant for benzyl alcohol exposure, because several drugs routinely used in premature and critically ill neonates are not available in preservative-free preparations.[40]

PHASE II DRUG METABOLISM

Phase II reactions, including glucuronidation, sulfation, and acetylation, also undergo change throughout childhood. Present in low levels in fetal hepatic and renal tissues, the uridine 5'-diphosphate glucuronosyltransferase (UGT) enzymes responsible for the glucuronidation of both drugs and endogenous substances have minimal metabolic activity. A gradual increase in UGT expression occurs in the first 6 months of life, but still remains lower than that of adults for the first 2 to 3 years of life. Genetic polymorphisms produce additional variation in UGT expression.[11,22,23,41–44] The reduced ability of infants to perform glucuronidation has been known for many years as a result of the chloramphenicol "gray baby syndrome." Chloramphenicol was a widely used antibiotic during the 1950s. Within several years of its introduction, case reports began to appear in the medical literature describing emesis, abdominal distension, and cyanosis followed by cardiovascular collapse in infants given the drug.[46] The mechanism for this toxic effect was later found to be reduced activity of UGT2B7, the primary enzyme responsible for chloramphenicol metabolism, that allowed accumulation of the parent compound.[23,41]

CASE 102-4, QUESTION 4: N.M. also received morphine as an infusion during mechanical ventilation. Careful attention is needed when administering opioids to neonates to avoid drug accumulation. What differences in metabolism might affect the dosing requirements of morphine in the premature neonate such as N.M.?

Glucuronidation of morphine to morphine-6-glucuronide and morphine-3-glucuronide via UGT2B7 can be demonstrated in premature neonates born as early as 24 weeks' gestational age, but at a much slower rate than that of term neonates.[23,43,47,48] Studies of fetal liver microsomes have confirmed the presence of UGT2B7, with a rate of enzymatic activity only 10% to 20% of adult values.[22] Morphine metabolism increases rapidly during the last trimester of intrauterine life and the first weeks after birth. Clearance has been estimated to increase fourfold between 24 and 40 weeks' postconceptional age, but remains substantially slower than that of adults until approximately 3 years of age.[47,48]

Sulfation is a more important pathway in the metabolism of morphine during early infancy than later in life. Unlike UGT enzymes, sulfotransferases (SULTs) develop extensively in utero, reaching levels of enzyme activity similar to that of adults at birth.[22,23,49] Intrauterine expression of SULT1A1, which is responsible for fetal metabolism of thyroid hormones, SULT2A1, the enzyme that metabolizes steroid hormones, and SULT1A3, which metabolizes catecholamines, occurs early in gestation and remains relatively constant thereafter. Not all SULT enzyme development takes place in the liver. Expression of SULT2A1 occurs primarily in the fetal adrenal gland.

The reliance on sulfation during infancy is found with several drugs besides morphine, including catecholamines, thyroid hormones, theophylline, and acetaminophen. Glucuronidation of acetaminophen via UGT1A6 and UGT1A9 is decreased in infants, and as a result, the primary route of acetaminophen metabolism is formation of sulfate conjugates for the first year of life.[23,45] Glucuronide pathways begin to predominate later in infancy and eventually surpass sulfation as the predominate route for acetaminophen metabolism.

Because of the slower rate of morphine clearance in neonates, particularly those born prematurely, morphine should be initiated at lower doses than those recommended for older infants and children. An appropriate starting dose for N.M.'s morphine infusion would be 0.005 to 0.01 mg/kg/hour. N.M. should be closely monitored for adverse effects, including hypotension, respiratory depression after extubation, and constipation.

Elimination

CASE 102-5

QUESTION 1: E.C. is a 1.85-kg infant girl born at 30 weeks' gestation. As with the other neonates described earlier, she is started on empiric antibiotic therapy with ampicillin and gentamicin shortly after birth. E.C. is given ampicillin 92.5 mg (50 mg/kg) IV every 12 hours and gentamicin 4.6 mg (2.5 mg/kg) IV every 24 hours. In the next bed, N.M., now 2 months old and 2.6 kg, is on the same regimen for a fever and elevated white blood cell count during the past 24 hours. N.M. is given ampicillin 130 mg (50 mg/kg) IV every 6 hours and gentamicin 6.5 mg (2.5 mg/kg) IV every 8 hours. What is the rationale for the differences in these patients' dosing intervals?

GLOMERULAR FILTRATION

Like the liver, the kidneys are not fully developed at birth. The ability to filter, excrete, and reabsorb substances is not maximized until 1 year of age.[7,8,50,51] At birth, full-term neonates have an

---

average glomerular filtration rate (GFR) of only 2 to 4 mL/minute/1.73 m^2; in premature infants, the value may be even lower (0.6–0.8 mL/minute/1.73 m^2). There is a rapid rise in GFR during the first 2 weeks of life, with values increasing from 20 to 40 mL/minute/1.73 m^2 as a result of increased renal blood flow, increased function of the existing nephrons, and the appearance of additional nephrons, all of which may be timed to coincide with birth.[51] GFR increases from 80 to 110 mL/minute/1.73 m^2 by 6 months of age and continues to increase in a linear manner until it approaches adult values of 100 to 120 mL/minute/1.73 m^2 by 1 year of age. The impact of this increase in GFR can be seen in the neonatal dosing recommendations for many renally eliminated drugs, including the aminoglycosides and vancomycin. To account for reduced renal function, most pediatric references use a combination of patient weight and age (postnatal, postconceptional, or postmenstrual) to determine gentamicin dosing in neonates.[17] As a premature newborn, E.C. is likely to have significantly reduced glomerular filtration. E.C.'s gentamicin regimen will consist of the standard neonatal dose (2.5 mg/kg) given at a less frequent interval than that of 2-month-old N.M. to compensate for her renal insufficiency.

TUBULAR SECRETION

The elimination of ampicillin is also affected by changes in the rate of tubular secretion.[7,8,50] Like GFR, tubular secretion is reduced immediately after birth, but gradually increases during the first year of life. In addition to the penicillins, a reduction in tubular secretion also results in a prolonged elimination half-life for cephalosporins, furosemide, and digoxin. Digoxin has been used for many years in the management of supraventricular tachycardia in neonates. The half-life of digoxin decreases from approximately 30–40 hours in a term neonate to 20–25 hours in a 1-year-old as renal function matures. Selection of a digoxin dose must take into account the difference in elimination. The recommended oral digoxin maintenance dose for a neonate is 5 mcg/kg/day, whereas a 2-year-old would need to receive twice that amount to achieve target serum digoxin concentrations.[52] Ampicillin doses are typically adjusted by lengthening the dosing interval to compensate for reduced tubular secretion. E.C. (a newborn delivered at 30 weeks' gestation) would be dosed every 12 hours, whereas an older child such as N.M. would be expected to clear ampicillin more rapidly and would be dosed every 6 hours.

CASE 102-5, QUESTION 2: How should renal function be assessed in E.C. and N.M.?

As with adults, renal function should be closely monitored in children and drug doses adjusted accordingly. Unlike adults, blood urea nitrogen and serum creatinine values are not always useful as indicators of renal function. In the first days after birth, serum creatinine values reflect maternal creatinine transferred through the placenta and may appear falsely elevated. After the first week, serum creatinine values are typically low as a result of less muscle mass, especially in premature neonates, and may not accurately represent renal function.[8] Urine output is often used as an additional measure of renal function in this population. Diaper weights can be used to estimate output in E.C. and N.M., with values greater than 1 mL/kg/hour considered adequate renal function. At the time of initiation of therapy, if both babies are maintaining urine output values greater than 1 mL/kg/hour, the dosing regimens recommended in the Pediatric Dosage Handbook[17] can be used without further alteration. If urine output falls, the dosing intervals of both antibiotics may require adjustment. A trough serum gentamicin concentration should be obtained to further guide dosing.

CASE 102-6

QUESTION 1: H.G. is a 10-year-old boy admitted with osteomyelitis in his left ankle. The team plans to treat H.G. with vancomycin for 6 weeks. He is 140 cm (55 inches) tall and weighs 32 kg (70 pounds). His serum creatinine is 0.5 mg/dL (normal for age 0.5–1.5 mg/dL). Determine H.G.'s creatinine clearance.

After infancy, serum creatinine may be used to estimate clearance. The equations used in adults, such as Cockroft–Gault, Jellife, or the Modification of Diet in Renal Disease (MDRD), are not appropriate for patients younger than 18 years of age.[8,53,54] There are several equations designed for pediatric use; the National Kidney Disease Education Program (NKDEP) and the National Kidney Foundation recommend the bedside isotope dilution mass spectroscopy (IDMS) Schwartz equation[53,54]:

$$CL_{Cr} = (0.14 \times Ht)/S_{Cr} \qquad \text{(Eq. 102-1)}$$

where CL_{Cr} is creatinine clearance (mL/minute/1.73 m^2), Ht is height (cm), and S_{Cr} is serum creatinine (mg/dL).

Using this method, H.G. has a calculated creatinine clearance of 116 mL/minute/1.73 m^2, indicating normal renal function. As with patients of any age, this equation should be used only as an estimate of renal function. It should be interpreted with caution in patients with little muscle mass or those who are dehydrated.

Pharmacokinetic Changes During Puberty

CASE 102-7

QUESTION 1: A.M. is a 16-year-old, 67-kg boy with osteosarcoma. He has received morphine for pain throughout his numerous hospitalizations for surgery and chemotherapy during the past 2 years, requiring an infusion rate as high as 0.5 mg/kg/hour. During this period, he has also progressed through puberty and is now a mature adult male. During his last admission, it was noted that his pain was well controlled on an adult morphine infusion rate of 10 mg/hour, equivalent to 0.15 mg/kg/hour. It was noted by the medical team that A.M.'s morphine infusion requirements were actually lower than in earlier admissions, although his pain scores have been unchanged. What might explain the change in A.M.'s response to morphine?

Although developmental pharmacology has traditionally focused on the differences in neonatal pharmacokinetics, there is growing interest in the influence of puberty on drug disposition.[55–57] Adolescence is not simply a link between childhood and adulthood, but is a distinct period of significant physiologic change. Hormonal fluctuations and sexual maturation can alter the efficacy or toxicity of many drugs administered during this period. Drug distribution can be altered as a result of an increase in body fat. Rapid increases in serum protein concentrations that occur during puberty alter drug binding characteristics.[56] Renal function, as measured by GFR, may exceed average adult values, resulting in rapid clearance of renally eliminated drugs such as aminoglycosides and vancomycin. Metabolic activity changes as well.[57] A study conducted in adolescents receiving morphine during a sickle cell crisis revealed a reduction in drug clearance with advancing sexual maturation.[58] Postpubertal adolescents, such as A.M., had weight-normalized clearance values 30% lower than younger patients during early puberty, suggesting a possible reduction in UGT2B7 activity. The titration of A.M.'s morphine must encompass not only the changes in drug clearance resulting from growth and development but also the progression of his

---

disease and his need for pain control. Assessment of pain, using frequent self-report or a standardized pain scale, as well as heart rate, blood pressure, and respiratory rate, is essential for appropriate adjustment of A.M.'s morphine infusion.

A second example comes from a recent study of lopinavir pharmacokinetics in children who exhibited identified age- and sex-related differences in drug clearance.[59] When normalized for weight, there was no significant difference in clearance between prepubertal boys and girls. After the age of 12, boys had a mean rate of lopinavir clearance 39% greater than girls. The area under the concentration–time curve in boys was only half that of the girls. The authors suggest that this difference may reflect a reduction in CYP3A4 in girls that becomes apparent only with sexual maturation. Similar sex-related results have been reported in lopinavir studies conducted in adults. Caffeine metabolism via CYP1A2 has also been found to differ by sex in adolescents.[60] The rate of N-demethylation slows in both sexes after puberty, but appears to decrease earlier in puberty for girls than for boys. Other investigators have identified pharmacokinetic changes during adolescence with acetaminophen, alprazolam, carbamazepine, digoxin, isoniazid, lamotrigine, lorazepam, and theophylline.[56]

PEDIATRIC PHARMACODYNAMIC DIFFERENCES

Although not as well studied as pharmacokinetics, developmental changes in pharmacodynamics during growth may have equally significant effects on response to drug therapy in children.

CASE 102-8

QUESTION 1: S.L. is a 0.725-kg infant boy with an estimated gestational age of 24 weeks. He was brought to the neonatal intensive care unit immediately after birth with severe hypotension. A dopamine infusion was started at a rate of 10 mcg/kg/minute and quickly titrated to 20 mcg/kg/minute without significant benefit. What might explain S.L.'s lack of response, and how should his hypotension be managed?

Maturational changes in receptor conformation, density, and affinity, as well as signal transduction, can result in clinically significant differences in response to common therapies.[61] Although a dopamine infusion of 20 mcg/kg/minute will produce an adequate increase in myocardial contractility and elevate systemic vascular resistance in most children and adults, infants may not have a significant change in cardiovascular response. Infants have long been suspected to be relatively resistant to the effects of β-adrenergic agonists, including dopamine, dobutamine, and epinephrine. Recent research suggests the lack of response is related to a relative reduction in adrenergic receptor density or a downregulation of receptors within the myocardium of premature and critically ill neonates.[62] A higher dopamine infusion rate, up to 40 mcg/kg/minute, may be necessary to achieve an adequate blood pressure for S.L. If the dopamine is increased, S.L.'s extremities must be closely monitored for any signs of excessive peripheral vasoconstriction. Supplemental therapy with hydrocortisone, at a dose of 0.7 mg (1 mg/kg) IV every 8 hours, may also be used to manage his hypotension.

CASE 102-9

QUESTION 1: You will be counseling the parents of E.S., a 7-year-old girl with refractory seizures as a result of Lennox-Gastaut syndrome, on the use of lamotrigine. While preparing for your discussion, you notice in the manufacturer's prescribing information a black box warning regarding the risk for serious skin rashes. The incidence is listed as 0.8% in children 2 to 16 years of age, but only 0.3% in adults.[63] What might explain the difference in the incidence of an adverse effect by age?

Differences in pharmacodynamics resulting from growth and development can alter more than just therapeutic response. A drug's adverse effect profile may be distinctly different during childhood. A classic example of this phenomenon is the higher incidence of serious dermatologic reactions, including toxic epidermal necrolysis, in children taking lamotrigine compared with that of adults.[64–66] This was first suspected during initial pediatric clinical trials and appeared to be associated with rapid dose titration during the first several months of treatment, which had been based on previous studies in adults.[65] The slower dose escalation, now recommended for pediatric patients, is starting E.S.'s lamotrigine dose at 0.15 mg/kg/day and increasing by 0.15- to 0.3-mg/kg/day increments every 2 weeks, and may reduce the likelihood for these reactions.

CASE 102-9, QUESTION 2: What is the possible mechanism(s) for the increased risk for toxicity with lamotrigine in children such as E.S.?

Research has led to several theories for the greater incidence of serious dermatologic reactions in children. Some investigators have suggested that this is a dose-related toxicity more evident in children who have a limited capacity to metabolize lamotrigine through glucuronidation to its inactive metabolites.[65] This theory, however, does not explain why other patient groups known to have higher serum lamotrigine concentrations during treatment, such as the elderly, are not at increased risk. Others have speculated that this represents an immune-mediated hypersensitivity response, because many of the affected patients reported have had previous reactions with other antiepileptic drugs.[66] Children with refractory seizures, such as those with Lennox-Gastaut syndrome, who are often treated with multiple agents beginning in the first years of life may be more likely to develop hypersensitivity. Although the mechanism underlying the age-related difference in the incidence of lamotrigine-associated rashes is not yet well understood, the importance of patient counseling is clear. The caregivers of all children receiving lamotrigine should be made aware of the risk and the need to seek medical care as soon as any signs of rash or erythema are noted.

MEDICATION DOSING IN CHILDREN

CASE 102-10

QUESTION 1: A.K. is a 7-year-old, 20-kg boy recently diagnosed with ADHD. After developing insomnia when treated with methylphenidate, he was switched to clonidine by his pediatrician. The recommended starting dose for clonidine in children is 5 mcg/kg/day divided and given in two to four doses.[67] His prescription is for clonidine 0.05 mg by mouth twice daily. Because A.K. does not yet swallow tablets easily, he will need a solution made from the tablets. It will be prepared from a published extemporaneous formulation with a final concentration of 0.1 mg/mL. What steps are necessary to ensure the accuracy of this prescription?

The differences in pharmacokinetics and pharmacodynamics observed in children influence the choice of dose and dosing interval.[68] Because incorporating all of these variables would result in dosing calculations too difficult for practical use, weight has traditionally been chosen as the single best estimate of growth. Pediatric drug references provide most doses in units per weight, such as mg/kg/day or mcg/kg/dose. Among the exceptions to this are chemotherapeutic agents, which are dosed by body surface area, incorporating height as an additional variable. Because of the difficulty in accurately determining height (or length) in young children, it is not commonly used for other drugs.

Age can be an important variable, especially for premature infants, in whom it can be used to account for differences in volume of distribution and elimination half-life. For example, neonatal gentamicin dosing is often based on a rubric of gestational or postconceptional age, postnatal age, and weight.[17] A recent study of clonidine clearance in the early postnatal period suggests that both age and weight should be used to optimize clonidine doses in newborns being treated for neonatal abstinence syndrome.[69] In the future, pediatric dosing recommendations for many drugs may be based on more than just weight to incorporate new pharmacokinetic data.[70]

Medication orders or prescriptions with doses outside of the dosing range listed in a pediatric drug reference should always be questioned for appropriateness. Older children and adolescents should transition to adult dosing whenever the calculated weight-based dose exceeds the usual adult dose. When evaluating a pediatric prescription or medication order, determining whether the dose is appropriate for the patient's weight is not the only step undertaken by the pharmacist. As with all patients, allergies, underlying diseases, and concomitant therapy must be taken into account as well.

A.K.'s clonidine dose of 0.05 mg twice daily is equivalent to 5 mcg/kg/day, the appropriate starting dose for a child. Using a 0.1-mg/mL extemporaneous solution, his dose will be 0.5 mL twice daily. The label on A.K.'s clonidine bottle should include the concentration of the formulation, as well as the dose in both mg and mL. Before the start of treatment, A.K.'s parents should be counseled about the drug, the dose, and potential adverse effects. They should be given or have access to an oral dosing syringe or spoon to accurately measure the dose.

PREVENTING MEDICATION ERRORS IN CHILDREN

CASE 102-10, QUESTION 2: After 2 days of therapy, A.K. returns to his pediatrician's office with his parents. He is lethargic and feels dizzy when getting out of bed. His blood pressure is 90/54 mm Hg (normal for age and weight is 99/59 mm Hg), suggesting a possible clonidine overdose. As you begin to investigate the potential cause of A.K.'s symptoms, what factors may have led to an error in A.K.'s case?

Medication errors pose a significant risk for infants and children.[71–75] Whereas the rate of medication errors reported in studies of adults is approximately 5%, rates in many pediatric studies have ranged from 10% to 15%.[71–73] The need to calculate weight-based doses can lead to mathematic errors. In A.K.'s case, the dose must be multiplied by the patient's weight, divided into individual doses, and converted from micrograms to milligrams. Unit conversions and decimal point errors are particularly dangerous in pediatrics, because a 10-fold overdose of a drug with a narrow dosing range such as clonidine, digoxin, morphine, or fentanyl can be fatal.[76] In addition to prescribing errors, dosage formulation manipulation, such as the preparation of an extemporaneous liquid in this case, increases the risk for drug preparation errors. Oral liquid medications also present a risk for administration errors. Healthcare providers and caregivers in the home must be aware of the potential for errors and the need for precise dose measurement. A.K.'s medical history must include information on how the clonidine had been prepared by the pharmacy as well as how his parents were preparing and administering his doses.

CASE 102-10, QUESTION 3: What steps could have been taken to prevent the medication error that occurred with A.K.?

There are a number of methods to reduce the potential for medication errors, including recommendations from the Joint Commission, the American Academy of Pediatrics, and a recent Cochrane review (Table 102-3).[74,75,77–82] Use of standard concentrations for IV products and oral liquids, smart-pump technology, bar coding, and electronic prescribing with clinical decision support tools have been found to significantly reduce errors in pediatric hospitals. In the outpatient setting, medication errors can be reduced by the inclusion of patient-specific information on prescriptions, including diagnosis and patient weight.[83] The product label, whether it is a prescription or over-the-counter medication, should include all the information needed to correctly prepare and administer the dose. Caregivers should have access to the appropriate tools for measuring liquid medications, such as oral dosing spoons or syringes, and the opportunity to practice preparing a dose under the supervision of a healthcare provider to ensure that they are able to prepare the dose correctly.[84]

Table 102-3

Methods for Reducing Pediatric Medication Errors

Improve Ordering and Preparation
Perform careful medication histories, including assessment of oral liquid concentrations Provide access to current pediatric medication information
Include patient weight (in kg) on all medication orders and prescriptions
Include dosage calculations on orders and prescriptions
Limit the number of concentrations available for high-risk medications
Use accurate measuring devices, in both the hospital and home settings
Implement Appropriate Technology
Adopt weight-based electronic prescribing or dose-checking software Employ barcode technology to reduce patient identification and medication administration errors
Use smart-pump technology (programmable IV pumps with weight-based dosing limits)
Use Staff Expertise
Provide pediatric-specific continuing education for all staff on a routine basis Develop pediatric-specific medication orders and protocols to guide care
Assign staff with pediatric expertise to all committees involved in medication management

Involve Families and Other Caregivers
Encourage all caregivers to ask questions about their child’s medications
Recommend that all caregivers know the names and doses of their children’s medications or carry information about their medications
Remind caregivers to include nutritional supplements, herbal or complementary therapies, and over-the-counter medications when giving a medication history
Ensure that caregivers can accurately prepare the medication dose

IV, intravenous.

One of the most effective methods to prevent medication errors has been to include pharmacists in the medication ordering and review process.[83,85] The value of pharmacists in reducing pediatric medication errors was demonstrated by Folli et al.[85] In this landmark study, clinical pharmacists performed prospective evaluations of medication orders at two children’s hospitals for a 6-month period. The overall rate of medication errors detected by the pharmacists averaged 4.7 per 1,000 medication orders. Of these, 5.6% were considered potentially lethal. The majority of the errors (64.3%) occurred in children younger than 2 years of age. The most common type of error identified by the pharmacists was incorrect dosage. The authors concluded that pharmacy intervention had a significant effect on medication error prevention, a finding that resulted in the expansion of pediatric clinical pharmacy services in many institutions. Pharmacists in the community provide the same benefit when reviewing pediatric prescriptions and play a significant role in caregiver medication education.

INCREASING AVAILABILITY OF PEDIATRIC MEDICATION INFORMATION

CASE 102-10, QUESTION 4: Although the dose of clonidine for the treatment of ADHD is available in most pediatric dosing references, it is not found in the manufacturer’s prescribing information (package insert) for the drug because the treatment of ADHD is not currently an FDA-approved indication. What is being done to increase the availability of pediatric drug information?

Although the availability of pediatric drug information has been limited in the past, several recent initiatives from the FDA are increasing the number of clinical trials being conducted in infants and children. The Pediatric Exclusivity Program, part of the FDA Modernization Act of 1997, was developed to address the lack of pediatric study data, including medication prescribing information.[8,86–88] The Exclusivity Program provides pharmaceutical manufacturers with incentives to study their products in children, including a 6-month extension at the end of a drug's patent life if a pediatric study is conducted. The 1998 Pediatric Rule and the Research Equity Act of 2003 authorized the FDA to require that manufacturers conduct clinical trials of drugs that would be used in a significant number of patients. The Best Pharmaceuticals for Children Act supplements the previous incentives by the creation of a mechanism for funding studies of older, off-patent medications that are often used in children.

These programs have been successful in adding pediatric dosing and adverse effect information to the prescribing information of many drugs routinely used in children. As of June 2017, the FDA had issued 430 written requests for pediatric studies, and 241 drugs had been granted a patent extension under the Exclusivity Program.[86] An assessment of the first 7 years of the program found that 50% of the studies conducted resulted in the new information supporting the use of the drug in children.[87] In spite of this success, much work remains to be done. Modifications in clinical trial design to incorporate pharmacogenomic studies and the use of combined pharmacokinetic–pharmacodynamic analyses have been recommended to further refine our knowledge of drug disposition in children.[87,88] The emphasis on the needs of pediatric patients has not been limited to just the United States; similar programs are in place in the European Union and throughout Asia. With the growing interest in developmental pharmacology and pharmacogenomics, as well as the increased funding and support for pediatric clinical trials worldwide, our understanding of the unique differences in how children respond to drug therapy continues to improve.

Pediatric Fluid, Electrolytes, and Nutrition

Michael F. Chicella and Jennifer W. Chow

	CORE PRINCIPLES	CHAPTER CASES
①	Fluid requirements and calories normalized to body weight are much greater in very small children than in older children and adults. It is important to understand how to calculate the normal fluid and caloric needs of children, and how fluid and caloric needs change with changes in clinical status.	**Case 103-1 (Question 1), Case 103-2 (Questions 1–3), Case 103-3 (Questions 1–3), Tables 103-1–103-6**
②	Human milk is the ideal food for a human infant. In addition to meeting the infant's nutritional requirements, human milk provides the infant with protection against a wide variety of infectious diseases and noninfectious disorders. Solid foods are generally introduced at 4 to 6 months of age, and pure cow's milk is generally introduced after 1 year.	**Case 103-4 (Questions 1, 2, 4, 5)**
③	Infant formula is available in three different formulations: cow's milk based, soy based, and protein hydrolysate (elemental). Cow's milk-based formulas are the standard for most infants. Soy-based and protein hydrolysate formulas are primarily intended for infants who are intolerant of cow's milk-based formulas. Other therapeutic formulas are available or can be made for infants with disease states that preclude the use of one of these three main types of formula.	**Case 103-4 (Question 3), Case 103-5 (Question 1), Case 103-6 (Questions 2, 3), Table 103-5**
④	Growth assessment is an important focus of pediatric health care, especially during the first year of life. With the exception of the intrauterine period, the most rapid growth occurs during the first year.	**Case 103-6 (Question 1)**
⑤	Parenteral nutrition in infants and children is usually initiated below estimated caloric needs and advanced as tolerated over the course of 3 or more days until goal caloric needs are met.	**Case 103-6 (Question 4)**
⑥	Parenteral nutrition can be used to supply sufficient nutrients to promote healing and a normal rate of growth in sick infants and children. However, parenteral nutrition is associated with clinically significant risks and complications.	**Case 103-7 (Questions 1–5, 7–9), Table 103-6**
⑦	Specialized pediatric amino acid solutions are available for infants younger than 1 year of age. These products were designed to produce plasma amino acid patterns closely matching those of human milk-fed infants.	**Case 103-7 (Question 6)**
⑧	Irreversible liver damage can occur with long-term parenteral nutrition. Parenteral nutrition-associated liver disease usually presents as an	**Case 103-7 (Questions 10, 11)**

elevated direct (conjugated) hyperbilirubinemia and can occur as early as 2 weeks after beginning parenteral nutrition.	
⑨ A number of modifications can be made to the patient's parenteral nutrition regimen to alleviate or slow the progression of cholestasis. The initiation of enteral feeding, even if limited to low-volume trophic feeding, appears to be the most effective method for preventing cholestasis.	**Case 103-7 (Question 11)**

Adequate nutrition is an essential component of the health maintenance of children and, in part, has been responsible for the dramatic reduction of infant mortality seen in the United States during the 20th century. Clinical experience has confirmed the value of optimal nutrition in resisting the effects of disease and trauma and in improving the response to medical and surgical therapy. The metabolic demands of rapid growth and maturation, in addition to the low nutritional reserves present during infancy, make the potential benefit of good nutrition to critically ill pediatric patients even greater.

Breast-feeding is the ideal method of feeding an infant and should be continued for at least the first year of life whenever possible. When this is not feasible, various infant formulas are available that provide appropriate nutrients for infants using the oral route. A pediatric patient who has a functioning intestinal tract, but is unable to achieve adequate oral intake, can be fed enterally using a tube inserted into the stomach or small intestine. Indications for providing specialized enteral nutrition include malnutrition, malabsorption, hypermetabolism, failure to thrive, prematurity, and disorders of absorption, digestion, excretion, or utilization of nutrients.

Despite the many formulas and feeding techniques available, several medical and gastrointestinal (GI) dilemmas that limit the use of the GI tract for nutritional support can occur in infants and children. Premature infants with severe respiratory disease, congenital abnormalities of the GI tract, or necrotizing enterocolitis are typical candidates for support with parenteral nutrition (PN). Older children with short bowel syndrome, severe malnutrition, intractable diarrhea, or inflammatory bowel disease have been treated successfully with PN therapy. Pediatric patients receiving chemotherapy for the treatment of malignancies or bone marrow transplant and children with severe cardiac failure also have been successfully rehabilitated with PN.

Many disorders that adversely affect nutrient intake or absorption also have an adverse impact on fluid and electrolyte status. Consequently, fluid, electrolyte, and nutrient management should be approached in an integrated manner. This chapter reviews selected aspects of fluid and electrolyte management and nutrition therapy for the pediatric population.

FLUID AND ELECTROLYTE MAINTENANCE

Management of fluid and electrolyte disturbances involves providing normal daily maintenance requirements and replacing deficits and ongoing losses. To design rational fluid therapy, it is necessary to know the normal composition of body water and to understand the routes through which water and solutes are lost from the body and the effects of disease and medications on water and electrolytes. Sodium-containing fluids are often referred to as fractions of normal saline (NS) (0.9% NaCl). Normal saline contains 154 mEq/L of sodium chloride.

Calculation of Maintenance Fluid and Electrolyte Requirements

CASE 103-1

QUESTION 1: P.J., a 2-day-old, 3.5-kg term female infant has developed abdominal distension, and her oral feedings have been stopped. Calculate a maintenance fluid and electrolyte prescription for her. Her serum electrolytes include the following:

Sodium, 137 mEq/L
Potassium, 4.2 mEq/L
Chloride, 105 mEq/L
CO_2, 23 mEq/L

While P.J. receives nothing by mouth (NPO), her fluid and electrolyte needs must be met intravenously. Estimate her requirements.

General recommendations for calculating maintenance fluid have not changed significantly since first outlined by Holliday and Segar in 1957.[1] Similarly, electrolyte and nutrient replacement is still based on guidelines published in 1988 by Greene et al.[2] Fluid, electrolyte, and nutrient requirements on the basis of weight are provided in Table 103-1. Although a commercially available intravenous (IV) solution will be used, each component of the solution can be calculated separately. Using the guidelines in Table 103-1, P.J.'s maintenance requirements can be estimated as follows:

Fluid $100\text{ mL/kg/day} \times 3.5\text{ kg} = 350\text{ mL/day}$ or 15 mL/hour (Eq. 103-1)

Sodium $2\text{–}4\text{ mEq/kg/day} \times 3.5\text{ kg} = 7\text{–}14\text{ mEq/day}$ (Eq. 103-2)

Potassium $2\text{–}3\text{ mEq/kg/day} \times 3.5\text{ kg} = 7\text{–}10.5\text{ mEq/day}$ (Eq. 103-3)

Fluid and electrolyte requirements can be met by infusing a solution of 5% dextrose with one-quarter NS (38 mEq/L) and 20 mEq/L of KCl at 15 mL/hour. This provides 12 mEq (3.4 mEq/kg/day) of NaCl and 7 mEq (2 mEq/kg/day) of KCl in 360 mL (103 mL/kg/day) of fluid per day.

Additionally, fluid and electrolyte requirements can also be altered when fluid and electrolyte losses are increase or when excretion is impaired. When abnormal fluid losses are present, they must be given back to the patient daily. Replacement fluid is generally 1 mL for every 1 mL lost, but can be more or less based on the patient's clinical status. In general, NS can be initially used for most replacement fluids.

The requirements for fluid and calories normalized to body weight are much greater in very small children than in older children and adults as can be seen in Table 103-1. This is because infants have a much larger body surface area relative to weight, lose more fluid through evaporation, and dissipate more heat per kilogram than their older counterparts. Furthermore, very low-birth-weight (VLBW) infants cannot concentrate urine and are at increased risk for dehydration if inadequate fluids are provided.

Dehydration

CASE 103-2

QUESTION 1: H.S. is a 2-year-old lethargic girl with a 2-day history of vomiting and minimal oral intake. Yesterday, she required only three diaper changes instead of her usual eight and has needed only one change today. Her vital signs are as follows:

Temperature, 39°C
Pulse, 140 beats/minute (normal, 80–130 beats/minute)
Respiratory rate, 30 breaths/minute (normal, 30–35 breaths/minute)
Blood pressure (BP), 80/45 mm Hg (normal, 80–115 mm Hg systolic and 50–80 mm Hg diastolic)

On physical examination, her eyes appear sunken, her mucous membranes are dry, and her skin is dry and cool to touch. Although she is crying, there are no tears, and the skin over her sternum tents when pinched. Her weight today is 11.4 kg; 3 weeks ago, it was 12.9 kg. What do these findings represent? What immediate treatment should be provided?

Table 103-1

Daily Parenteral Nutrient Requirements in Children

Nutrient	Weight/Age	Requirement
Fluid	<1.5 kg	150 mL/kg
	1.5–2.5 kg	120 mL/kg
	2.5–10 kg	100 mL/kg

	10–20 kg	1,000 mL + 50 mL/kg for each kg >10 kg
	>20 kg	1,500 mL + 20 mL/kg for each kg >20 kg
Calories	Up to 10 kg	100 kcal/kg
	20 kg	1,000 kcal + 50 kcal/kg for each kg >10 kg
	>20 kg	1,500 kcal + 20 kcal/kg for each kg >20 kg
Protein[a]	Infants	2–3 g/kg
	Older children	1.5–2.0 g/kg
	Adolescents and older	1.0–1.5 g/kg
Fat[b]	Infants and children	Initially 0.5–1 g/kg and then increase by 0.5–1 g/kg (maximum of 3 g/kg in preterm neonates, 4 g/kg older infants and children) (≥4% of calories as linoleic acid)
	>50 kg	One 500-mL bottle (100 g fat)
Electrolytes and Minerals[c]		
Sodium	Infants and children	2–4 mEq/kg
Potassium	Infants and children	2–3 mEq/kg
Chloride	Infants and children	2–4 mEq/kg
Magnesium	Preterm and term infants	0.25–0.5 mEq/kg
	Children >1 year (or >12 kg)	4–12 mEq
Calcium	Preterm and term infants	2–3 mEq/kg
	Children >1 year (or >12 kg)	10–20 mEq
Phosphorus	Preterm and term infants	1.0–1.5 mmol/kg
	Children >1 year (or >12 kg)	10–20 mmol
Trace Elements		
Zinc	Preterm infants	400 mcg/kg
	Term infants	
	<3 mos	250 mcg/kg
	>3 mos	100 mcg/kg
	Children	50 mcg/kg (up to 5 mg)
Copper	Infants and children	20 mcg/kg (up to 300 mcg)
Manganese	Infants and children	1 mcg/kg (up to 50 mcg)
Chromium	Infants and children	0.2 mcg/kg (up to 5 mcg)
Selenium	Infants and children	2 mcg/kg (up to 80 mcg)

[a] "Infant" amino acids contain histidine, taurine, tyrosine, and cysteine, which are essential in infants but not older patients.

[b] Because linoleic acid represents 54% of the fatty acid in soy bean oil and 77% in safflower oil, 7% to 10% of calories must be provided as fat emulsion. This can be given daily over the course of 24 hours (preferred in patients predisposed to sepsis and preterm infants) or 2 to 3 times weekly.

[c] These doses are guidelines and all patients should be evaluated individually for appropriateness of dosing. For example, patients with short bowel syndrome may require large doses of magnesium, and patients with renal insufficiency may require none to low amounts of potassium, calcium, phosphorous, and magnesium.

Guidelines for the use of vitamins, trace elements, calcium, magnesium, and phosphorus in infants and children receiving total parenteral nutrition: report of the Subcommittee on Pediatric Parenteral Nutrient Requirements from the Committee on Clinical Practice Issues of the American Society for Clinical Nutrition [published corrections appear in Am J Clin Nutr. 1989;49(6):1332; Am J Clin Nutr. 1989;50(3):560]. Am J Clin Nutr. 1988;48(5):1324–1342.

H.S.'s lethargy, decreased urine output, tearless crying, dry mucous membranes, dry skin with fever, sunken eyes, mild tachycardia with low normal blood pressure, and poor skin turgor are all signs of dehydration. This is consistent with her 2-day history of vomiting and poor intake. Her weight loss of 1.5 kg gives a further clue to the extent of dehydration. Dehydration or fluid loss is determined most accurately by weight loss. Because 1 g of body weight is approximately equal to 1 mL, her fluid deficit is estimated to be 1,500 mL. The percentage dehydration is estimated using the following formula:

Table 103-2

Clinical Signs of Dehydration

Severity	Dehydration (%)	Psyche	Thirst	Mucous Membranes	Tears	Anterior Fontanel	Skin	Urine Specific Gravity
Mild	<5	Normal	Slight	Normal to dry	Present	Flat	Normal	Slight change
Moderate	6–10	Irritable	Moderate	Dry	±	±	±	Increased
Severe	10–15	Hyperirritable to lethargic	Intense	Parched	Absent	Sunken	Tenting	Greatly increased

$$\% \text{ Dehydration} = \text{Normal body weight} - \text{Actual body weight} / \text{Normal body weight} \times 100 \qquad \text{(Eq. 103-4)}$$

If recent weights are unavailable, the extent of dehydration can be approximated from physical findings as described in Table 103-2. Tachycardia and marginal blood pressure dictate the need for immediate IV rehydration. Normal serum sodium concentration ranges from 135 to 145 mEq/L of sodium; thus, normal saline approximates the sodium concentration of plasma and is often used as a volume expander. In this patient, 10 to 20 mL/kg of normal saline (12.9 kg × 10–20 mL/kg = 129–258 mL) should be infused as rapidly as possible to establish normal blood pressure. For symptomatic patients, including those with seizures, the serum sodium concentration should be increased acutely only to the degree necessary to abate symptoms.

CASE 103-2, QUESTION 2: Calculate H.S.'s fluid and electrolyte needs and provide recommendations for her fluid orders to the team. Her serum electrolyte results were as follows:

Sodium, 128 mEq/L (normal, 135–145 mEq/L)
Potassium, 3.1 mEq/L (normal, 3.5–5 mEq/L)
Chloride, 88 mEq/L (normal, 102–109 mEq/L)
HCO_3^-, 30 mEq/L (normal, 22–29 mEq/L)

In addition to normal maintenance fluids, H.S. must be provided with fluids and electrolytes to replace her deficit secondary to dehydration and compensate for increased insensible water loss because of fever. Each component of the fluid can be calculated separately, using Equations 103-5 to 103-7.

$$\text{Fluid deficit} = \text{Weight loss (kg)} \times 1{,}000\ \text{mL/kg} \quad \text{(Eq. 103-5)}$$

$$\text{Fever adjustment} = 10\% \times \text{Maintenance for each } ^\circ\text{C} \geq 37^\circ\text{C} \quad \text{(Eq. 103-6)}$$

$$(\text{CD} - \text{CO}) \times F_d \times \text{Weight} = \text{mEq required} \quad \text{(Eq. 103-7)}$$

where CD is the concentration of sodium desired (mEq/L), CO is the concentration observed (mEq/L), F_d is the apparent distribution factor as a fraction of body weight (Table 103-3), and weight is the baseline weight before illness (kg). In consideration of both maintenance needs and current deficits, fluid and electrolyte requirements for H.S. would be estimated as follows.

FLUID

$$\begin{array}{lr} \text{Maintenance} & 1{,}000\ \text{mL} + (50 \times 2.9) = 1{,}145\ \text{mL} \\ \text{Fever} & 2^\circ\text{C} \times 0.1\,(1{,}145) = 229\ \text{mL} \\ \text{Deficit} & 1.5\ \text{kg} \times 1{,}000\ \text{mL/kg} = \underline{1{,}500\ \text{mL}} \\ & \text{Total fluid} = 2{,}874\ \text{mL} \end{array} \quad \text{(Eq. 103-8)}$$

Table 103-3

Electrolytes and Apparent Distribution

Electrolyte	**F_d (L/kg)**
Sodium	0.6–0.7
Bicarbonate	0.4–0.5
Chloride	0.2–0.3

SODIUM

$$\text{Maintenance } 3\ \text{mEq/kg} \times 12.9\ \text{kg} = 38.7$$

$$\text{Deficit } (135 - 128\ \text{mEq/L}) \times 0.6\ \text{L/kg} \times 12.9\ \text{kg} = 54.2$$

$$\text{Total sodium} \sim 93\ \text{mEq} \qquad \text{(Eq. 103-9)}$$

CHLORIDE

H.S. has a mild metabolic alkalosis as evidenced by her serum chloride of 88 mEq/L and her serum bicarbonate of 30 mEq/L. This is most likely because of the loss of hydrogen and chloride in her vomitus. Thus, both the sodium and potassium replacements should be administered as chloride salts.

POTASSIUM

Potassium is primarily an intracellular ion. It moves in and out of cells in exchange for hydrogen ions to maintain a normal blood pH. Therefore, in metabolic alkalosis, the intracellular shift of potassium will decrease the serum potassium concentration. When the pH normalizes, as will occur with rehydration, the hydrogen ions will move intracellularly and the potassium will move extracellularly, thus causing the serum potassium concentration to increase. Additionally, potassium is also excreted by the kidney in exchange for hydrogen ion conservation. These factors make the serum potassium concentration difficult to interpret. Intravascular volume depletion causes hypoperfusion of the kidney and can result in acute renal failure; therefore, the prudent approach is to give no potassium until urine output is clearly established. Then, only maintenance doses of potassium should be administered until a normal acid–base and fluid status are established and the serum potassium can be assessed more accurately. Hence, H.S. should receive approximately 26 to 39 mEq of potassium (2–3 mEq/kg × 12.9 kg) once urine flow is established.

Administration of Fluid Requirements

CASE 103-2, QUESTION 3: J.H.'s nurse asks for details of how the fluid therapy should be administered. How should these calculated needs be given?

Requirements for the first 24 hours of parenteral fluid therapy should provide approximately 2,875 mL of fluid to account for maintenance fluid needs, fever replacement, and deficit replacement. In addition to fluid, at least 93 mEq of sodium (maintenance needs plus deficit replacement) should be provided in the first 24 hours. It is important to provide sufficient amounts of sodium and water.

Rehydration fluids are usually dispensed in volumes less than the 24-hour requirement. This is to prevent wasting IV fluids caused by changes in electrolyte needs during replacement therapy. Because this patient requires approximately 3 L of fluid, only 1 L would be prepared initially, and this would likely consist of dextrose 5% and 0.2% NS (or greater). Approximately 15 mEq/L of potassium would be added to the next liter of IV solution if the patient had a reasonable urine output.

The infusion rate should be calculated to provide one-third of the daily maintenance fluid plus one-half of the deficit replacement during the first 8 hours. The remainder of the maintenance fluid (adjusted for fever) and deficit replacement should be administered during the next 16 hours. Usually, serum electrolytes are monitored every 6 to 8 hours during rehydration therapy to ensure that appropriate electrolytes are being provided. Usually, the concentration of serum electrolytes is monitored frequently during fluid replacement therapy of deficits. In general, the serum sodium concentration should not be increased by more than 10 to 12 mEq/L/day. After the initial fluid deficits are replaced, the infusion rate of the IV fluid would be decreased to 48 mL/hour (1,152 mL or approximately maintenance fluid rate).

Dehydration Associated with Diarrhea

CASE 103-3

QUESTION 1: S.B. is a 4-month-old, 5.9-kg boy presenting with a 4-day history of diarrhea (five to eight large, liquid stools each day). On a well-child visit 4 weeks ago, his weight was 6 kg. Since the onset of diarrhea, he has only been receiving oral rehydration fluids. Physical examination reveals the following:

Temperature, 38.8°C
Pulse, 110 beats/minute (normal, 80–160 beats/minute)
Respirations, 45 breaths/minute (normal, 20–40 breaths/minute)
BP, 100/58 mm Hg (normal, 75–105 mm Hg systolic and 40–65 mm Hg diastolic)
His skin is pale, warm, and dry. He is very irritable, and his mucous membranes are dry. S.B.'s laboratory values are as follows:
Sodium, 159 mEq/L
Potassium, 3.3 mEq/L
Chloride, 114 mEq/L
CO_2, 12 mEq/L
Blood urea nitrogen (BUN), 22 mg/dL
Creatinine, 0.9 mg/dL
Correlate S.B.'s history and physical findings with the reported laboratory values.

Diarrheal fluid losses commonly contain high concentrations of bicarbonate, accounting for S.B.'s metabolic acidosis. This, in turn, has resulted in a rapid respiratory rate as the body attempts to compensate for the acidosis by eliminating carbon dioxide. The increased insensible water losses of fever and tachypnea have resulted in the loss of water in excess of sodium, producing hypernatremia.

CASE 103-3, QUESTION 2: How should S.B.'s dehydration be managed?

S.B. has relatively normal vital signs and will not require rapid fluid replacement to correct hypotension. Hypernatremia in S.B. indicates fluid losses in excess of sodium and this should be corrected. With hypernatremia, the central nervous system (CNS) increases intracellular osmolarity load to prevent intracellular dehydration of cells in the CNS. Rapid correction of hypernatremia can cause excessive movement of water into the cells of the CNS and has been associated with seizures. Therefore, S.B.'s fluid and electrolyte deficits should be corrected over the course of 2 to 3 days at a consistent rate, rather than rapidly. In general, serum sodium should not be decreased more than 2 mEq/hour (maximum, 15 mEq/L/day).

S.B.'s requirements are estimated using the same methods described previously. First, the approximate extent of dehydration must be estimated. S.B.'s weight of 6 kg at the time of his well-child visit at 3 months of age was at the 50th percentile. If his growth has continued at this rate, his current pre-illness weight should be approximately 6.5 kg.[3] This weight should be used to calculate his maintenance requirements. Thus, his water deficit is approximately 0.6 L, or 9%. Using this approximation, his fluid and electrolyte requirements can be estimated as follows.

FLUID

Maintenance	$6.5 \times 100\ \text{mL/kg} = 650\ \text{mL/24 hours}$
Fever	$1.8^\circ\text{C} \times 0.1\ (650\ \text{mL}) = 117\ \text{mL/24 hours}$
	$600\ \text{mL/3 days} = 200\ \text{mL/24 hours}$
Deficit	Total daily needs $= 967\ \text{mL}$ or $40\ \text{mL/hour}$
	(Eq. 103-10)

SODIUM

Maintenance	$3\ \text{mEq/kg} \times 6.5\ \text{kg} = 19.5\ \text{mEq/24 hours}$
Deficit	This is calculated as total body deficit (normal–actual)
Normal	$145\ \text{mEq/L} \times 0.6\ \text{L/kg} \times 6.5\ \text{kg} = 566\ \text{mEq}$
Actual	$159\ \text{mEq/L} \times 0.6\ \text{L/kg} \times 5.9\ \text{kg} = 563\ \text{mEq}$
Deficit	$= 3\ \text{mEq}$ or $1\ \text{mEq/day}$ (Eq. 103-11)

POTASSIUM

As discussed in Case 103-2, Question 2, the serum potassium value of 3.3 mEq/L may not be indicative of S.B.'s total body potassium status. A metabolic acidosis in S.B. should have facilitated the movement of hydrogen ions into the cells and the movement of potassium from the intracellular to the extracellular space. Thus, the serum potassium of 3.3 mEq/L probably indicates a total body deficit. Therefore, a maintenance potassium dosage of 13 to 20 mEq/day (approximately 2 to 3 mEq/kg) of potassium should be added to the intravenous fluid. Serum electrolytes should be measured every 8 to 12 hours, and the intake of all electrolytes should be readjusted based on the results.

BICARBONATE

With metabolic acidosis, bicarbonate should be administered as well. No maintenance amount is customarily given, but deficit replacement is calculated in a manner similar to that used for sodium (Table 103-3). The volume of distribution of bicarbonate is 0.5 L/kg. For S.B., the bicarbonate deficit is as follows:

$$\begin{aligned}\text{Calculated Deficit Requirement} &= (\text{Normal} - \text{Actual}) \times V_d \times W_t \\ &= (23\text{–}12)\ \text{mEq/L} \times 0.5\ \text{L/kg} \times 6.5\ \text{kg} \\ &= 36\ \text{mEq} \qquad \text{(Eq. 103-12)}\end{aligned}$$

Initially, about half this amount should be added to the intravenous fluid and replaced during the first 8 to 12 hours. His serum electrolytes then should be reassessed, and the dosages adjusted accordingly. The entire bicarbonate deficit need not be replaced at once because other compensatory mechanisms will contribute to endogenous bicarbonate sparing.

CASE 103-3, QUESTION 3: Recommend an appropriate replacement fluid for S.B.'s therapy.

S.B.'s fluid and electrolyte maintenance requirements and deficits should be corrected with dextrose 5% and approximately 0.2% NS with half as the chloride salt and half as $NaHCO_3$. An infusion of this solution at 43 mL/hour should correct approximately one-half the calculated fluid and bicarbonate deficits within 24 hours in addition to his normal daily doses. After he urinates, 15 mEq/L KCl can be added to the next liter of solution to provide approximately 2.6 mEq/kg/day to this patient. The concentration of serum electrolytes should be measured often, and the concentration of electrolytes in the replacement fluid should be adjusted every 8 to 12 hours based on laboratory results. The amount of fluid replacement should be modified based on whether this patient's diarrhea has resolved and fever has subsided.

Rehydration of the dehydrated patient may be achieved by either the oral or intravenous route. In some patients, vomiting may preclude effective oral rehydration. If the losses are diarrheal and no problem with vomiting exists, the oral route may be a cost-effective alternative to the parenteral route. Various solutions have been used to rehydrate children orally. In an asymptomatic dehydrated child, the sodium concentration of an oral rehydration fluid should contain at least 70 mEq/L of sodium.[4]

The composition of several products is shown in Table 103-4. A glucose concentration of 2% optimizes water and electrolyte absorption from the GI tract[4]; more concentrated glucose solutions can worsen rather than ameliorate diarrhea. Use of the oral route and the more concentrated sodium solutions may allow safe rehydration of hypernatremic dehydration in a shorter time frame than the 2 to 3 days previously noted.[4]

INFANT ENTERAL NUTRITION

Caloric requirements of infants can be estimated using the formula provided in Table 103-1. The American Heart Association has suggested that infant feeding be divided into three stages.[5] In the nursing period, only liquids are provided. During the transitional period, solid foods are introduced, but human milk, or commercially prepared infant formula, still provides the major source of the infant's caloric and nutrient supply. In the modified adult period, most nutrition is derived from the solid foods consumed by other household members.

At birth, the human GI tract is adapted for the consumption of a human milk-based diet. Intestinal lactase is present from 36 weeks' gestation and exhibits its maximal activity during infancy. Pancreatic amylase secretion is low, and the bile salt pool is decreased relative to that of older persons, resulting in decreased fat absorption.[6] Human milk provides nutrients in their most usable form for the developing GI tract.

Human Milk Feeding

CASE 103-4

QUESTION 1: M.E. is a 1-day-old full-term infant. M.E.'s mother will breast-feed her infant. What are the nutritional implications of this decision for M.E.?

Human milk is the ideal food for a human infant and should be encouraged to be continued for the first year of life as long as mutually desired by both mother and child.[7] There are three phases to human milk production. During the first 5 days of lactation, a viscous, yellow liquid known as colostrum is produced. Colostrum is rich in protein, minerals, and other substances (e.g., immunoglobulins). During the next 5 days, transitional milk is produced; in the last phase, mature human milk is produced. The exact nutritional content of human milk varies from mother to mother; however, mature human milk provides sufficient protein, minerals, and calories regardless of the mother's nutritional status. Mature human milk generally provides 70 kcal/100 mL, and fat accounts for more than 50% of the caloric content.[8] The fat in human milk is highly digestible and absorbable.[8] An additional 40% of calories is provided as carbohydrates, primarily in the form of lactose, and the remaining 10% is provided as protein. Whey and casein are the two primary proteins in mature human milk, with whey being the major protein component (whey-to-casein ratio of 60:40).[9] Human milk is of such biologic quality and bioavailability that adequate growth can be attained with a lower overall intake of protein than is provided by commercially prepared infant formulas, which contain lower whey-to-casein ratios.[9]

The iron content of human milk is inadequate for term infants; however, supplementation generally is unnecessary in the breast-fed infant.[10] Regardless of maternal status, the vitamin D content of human milk is inadequate. Thus, M.E. will require 400 international units of vitamin D while she is exclusively breast-fed.[11]

Additionally, human milk provides the infant with protection against a wide variety of infectious diseases, including otitis media, diarrhea, pneumonia, and bronchiolitis. Evidence further suggests that human milk provides protection against noninfectious disorders, such as allergies, inflammatory bowel disease, insulin-dependent diabetes mellitus, and sudden infant death syndrome.[7,8] Human milk contains immunologically active cellular components and antibodies. These include secretory IgA, both T and B lymphocytes, macrophages, and neutrophils.[7,8] The lipases and amylase present in human milk may facilitate digestion of fat and carbohydrates in the still developing GI tract. Proteins present in human milk serve as carriers for trace minerals and facilitate their absorption.[9] Oligosaccharides and glycopeptides may promote the colonization of the GI tract by Lactobacilli and decrease colonization by Bacteroides, Clostridia, enterococci, and gram-negative rods, all of which may be pathogenic.[8]

Table 103-4

Composition of Oral Rehydration Products[4]

Product	Na+ (mEq/L)	K+ (mEq/L)	Cl− (mEq/L)	Bicarbonate Source (mEq/L)	Carbohydrate (%)
Enfalyte	50	25	45	34 citrate	3
Rehydralyte	75	20	65	30 citrate	2.5
Pedialyte	45	20	35	30 citrate	2.5
Gatorade	23.5	<1	17	—	4.6
WHO salts	75	20	65	10 bicarbonate	2

WHO, World Health Organization.

CASE 103-4, QUESTION 2: What potential complications are associated with breast-feeding? What instructions should be given to M.E.'s mother?

Complications associated with breast-feeding are few; however, there are some potential problems. "Breast milk jaundice" associated with an indirect (unconjugated) hyperbilirubinemia can occur in the breast-fed infant during the first week of life and generally resolves by the fourth week of life. Although the infant's skin, sclera, and palate become yellow, this is generally not a dangerous condition. Nevertheless, if the bilirubin level becomes too high, the infant could develop an encephalopathy known as kernicterus. However, it is generally not necessary for the mother to stop breast-feeding while the infant has jaundice. The American Academy of Pediatrics (AAP) recommends that infants nurse at least 8 to 12 times daily while jaundiced.[12] Some maternal infections have the potential to be transmitted to the infant during breast-feeding. Human immunodeficiency virus (HIV) and human T-lymphotropic virus 1 (HTLV-1) can be transmitted via breast milk, and therefore, maternal infections with these viruses are contraindications to breast-feeding.[7,8] Other viruses, such as herpes simplex virus, can be transmitted if contact with active lesions occurs during breast-feeding. Similarly, some medications taken by the mother are detectable in her breast milk. Only a few agents (e.g., antineoplastics, radiopharmaceuticals, ergot alkaloids, iodides, atropine, lithium, cyclosporine, chloramphenicol, bromocriptine), however, are absolute contraindications to breast-feeding.[7,8]

CASE 103-4, QUESTION 3: M.E.'s mother suffers from migraine headaches, which have increased in frequency since M.E.'s birth. M.E.'s mother takes an ergot alkaloid for the acute management of her headaches and therefore has decided not to breast-feed M.E. She will be using infant formula instead. How are these products prepared and how do they differ from human milk?

Because of the excretion of ergot alkaloids into breast milk and the risk for toxicity to the infant, it is advisable to either select an alternative medication or discontinue breast-feeding and use an infant formula. Examples of infant formulas are provided in Table 103-5. According to AAP guidelines for commercially prepared infant formula composition, formula should provide 20 kcal/ounce, osmolality should be between 300 and 400 mOsm/L, protein quantity should be a minimum of 1.8 g/100 kcal and should not exceed 4.5 g/100 kcal, and fat quantity should be between 3.3 and 6 g/100 kcal, supplying between 30% and 54% of calories. Infant formulas generally begin with a cow's milk base; however, intolerance to pure cow's milk has resulted in several modifications. The predominant protein in cow's milk is casein, which is more difficult for infants to digest than the human milk protein, whey. Consequently, infant formulas generally have less casein than cow's milk, although not to the level of human milk. The casein present in cow's milk formulas also may be heat-denatured to improve its digestibility. In addition, the fat source in cow's milk is replaced by one of several vegetable oils, allowing for easier digestion. Last, the carbohydrate source in cow's milk-based formula is supplemented with lactose or sucrose because the lactose content of cow's milk is only 50% to 70% of that in human milk. Soy-based and protein hydrolysate formulas are available for infants who are intolerant of cow's milk-based formulas.

Soy-based formulas use soybean as the protein source.[13] The soy is heat-treated to enhance protein digestibility and improve the bioavailability of some nutrients. Although nutrients, such as methionine, zinc, and carnitine, are still present, their concentrations are relatively low. Therefore, the manufacturer routinely adds methionine to all soy-based formulas. Zinc and carnitine may not be added, and exogenous supplementation may be necessary. Soy-based formulas substitute sucrose, corn syrup, or a combination of the two for lactose as the carbohydrate source. Additionally, soy protein formulas are more expensive than cow's milk-based formulas. The AAP recommends that the use of soy-based formula be limited to patients with primary lactase deficiency (galactosemia), patients with secondary lactose intolerance from enteric infections or other causes, vegetarian families in which animal protein formulas are not desired, and infants who are potentially cow's milk protein allergic, but who have not demonstrated clinical manifestations of allergy. Long-term use of soy-based formulas in premature and low-birth-weight infants should not be recommended. Soy-based formulas have aluminum contamination and have been associated with the development of rickets. Soy-based formulas are also not recommended for infants with documented allergic reactions to cow's milk protein because of the potential for cross-antigenicity between the two proteins. Additionally, soy protein formulas are not recommended for the routine management of colic.

Elemental formulas, made with hydrolysate formulas, are another option for infants who are intolerant of cow's milk-based formulas. The milk proteins (i.e., casein and whey) are heat-treated and enzymatically hydrolyzed to enhance digestibility of protein hydrolysate formulas, which are fortified with additional amino acids that are lost during processing. As with soy protein formulas, protein hydrolysates substitute sucrose, tapioca, or corn syrup for lactose as the carbohydrate source. Protein hydrolysate formulas often include significant amounts of medium-chain triglycerides because they are easily absorbed. Because the proteins are extensively hydrolyzed, these formulas probably are the least allergenic of the infant formulas and, therefore, may be appropriate for infants with true allergy to cow's milk protein. Nevertheless, prospective studies on the safety of such a substitution in human infants have not been undertaken because it would be unethical to intentionally expose infants with documented allergies to a potential allergen. Protein hydrolysate formulas are the least palatable of the available pediatric formulas and are more costly than other formulas.[14]

Table 103-5

Infant Formulas

Cow's Milk-Based Formulas	Soy-Based, Lactose-free Formulas	Protein Hydrolysate, Elemental, Premature Infant Formulas

Enfamil with iron	Isomil	Alimentum
Similac with iron	Nursoy	Nutramigen
Gerber Good Start	ProSobee	Pregestimil
	Alsoy	NeoCate
	Gerber Soy Plus	Neosure Advance
	Similac Sensitive	Enfamil Premature
		Similac Special Care

Infant formula is available from the manufacturers in three forms: ready-to-feed formula, powder for reconstitution, and concentrated liquid. The ready-to-feed form is the most convenient but also the most expensive. The powder and the concentrated liquid are less expensive; however, both require that predetermined amounts of boiled water be added before use. To save money, some parents will dilute infant formula to a greater extent than is recommended to make the formula last longer. This practice should be discouraged because excessive free water intake by infants younger than 1 year of age may result in hyponatremia and, ultimately, seizures. Similarly, supplementing an infant's diet with free water, for whatever reason, may also result in hyponatremia and seizures and should be discouraged. Periodically, manufacturing problems can occur, resulting in the recall of a product from the market.[15] Therefore, it is important for the patient's healthcare providers to stay abreast of manufacturers' recalls.

Introduction of Pure Cow's Milk

CASE 103-4, QUESTION 4: At 2 months of age, M.E. is found to have a hematocrit (Hct) of 33% (normal, 35%–45%). After questioning her mother, you learn that M.E. was taken off infant formula 1 month ago and changed to whole cow's milk to decrease food costs. How are these two findings related, and how should M.E. be managed?

Pure cow's milk, straight from the dairy counter in the grocery store, is not recommended for infants younger than 1 year of age. Unlike human milk, the iron in cow's milk is present in inadequate concentrations and absorbed poorly from the human GI tract. For this reason, most infant formulas are fortified with iron. Cow's milk has been associated with GI blood loss in infants younger than 140 days of age.[16] When the milk is heated to a higher temperature than the usual pasteurization temperature, as it is in formula preparation, the association of cow's milk with GI bleeding is no longer present; therefore, the component responsible for the blood loss appears to be a heat-labile protein. Furthermore, cow's milk contains excessive amounts of solute that cannot be eliminated by the immature kidney. Also, cow's milk does not contain taurine, an amino acid that is important in retinal development.

To treat M.E.'s anemia, iron should be added to her diet. This can be done by changing back to an iron-fortified infant formula, feeding her an iron-fortified cereal, or giving a therapeutic ferrous sulfate liquid medication. The appropriate iron replacement dose for severe anemia is 4 to 6 mg/kg/day of elemental iron in divided doses with follow-up of the infant's hemoglobin and hematocrit.

Introduction of Solid Foods

CASE 103-4, QUESTION 5: At 4 months of age, M.E.'s mother asks about the introduction of "baby foods" into M.E.'s diet. How should the clinician respond?

Human milk or commercially prepared infant formula provides adequate nutrition for an infant for the first 12 months of life. Introduction of solid foods before the age of 4 months, although common in the past, is discouraged because the younger infant is unprepared to swallow foods other than liquids. Solids (first cereals, then fruits, and vegetables) should be introduced when the child has good control of the head and neck movements (i.e., usually at the age of 4–6 months).[5] Preferably, one new food should be introduced at a time, at 1-week intervals, to allow assessment of food allergy.

Therapeutic Formulas

CASE 103-5

QUESTION 1: L.B. is a 2-week-old infant whose newborn screen is positive for phenylketonuria (PKU). Discuss the concepts behind the production of therapeutic formulas and the dietary management of patients with inborn errors of metabolism. How should L.B.'s diet be modified?

Inborn errors of metabolism are disorders in which an enzyme or its cofactor is absent or insufficient to meet metabolic demands.[17] As a result, one or more precursor compounds in a metabolic pathway can accumulate before the defective step. Correspondingly, one or more metabolic products that normally would have been generated after the defective step in the metabolic pathway are not sufficiently available.

The dietary management of metabolic errors is based on the following strategies:

- Reduce the intake of a precursor compound that cannot be metabolized.
- Supplement the deficient compounds that would have been produced if the normal metabolic pathway had not been blocked.
- Add a substrate that provides an alternative pathway for elimination of an accumulated toxin.

Therapeutic formulas are designed to reduce the intake of precursor compounds or to provide the deficient metabolic end product.

When hydroxylation of phenylalanine to tyrosine does not take place, phenylalanine accumulates in the blood and results in mental retardation. Because PKU has been diagnosed in L.B., his diet should be modified using a formula containing little or no phenylalanine. The tyrosine deficiency of PKU also can be managed by the addition of tyrosine to the phenylalanine-free therapeutic formulas that are available for patients with PKU. When L.B. progresses to solid foods, it will be important to limit or avoid foods that contain high levels of protein such as eggs and soybeans.

Other metabolic errors present in infancy include galactosemia (galactose cannot be metabolized to glucose), homocystinuria (methionine is not converted to cysteine), urea cycle disorders (ammonia detoxification is impaired), and maple syrup urine disease (metabolism of the branched-chain amino acids leucine, isoleucine, and valine is blocked).

These metabolic errors are managed by manipulating the diet.[17] In galactosemia, the carbohydrate source should not contain galactose

---

or lactose. In homocystinuria, methionine should be present only in quantities sufficient to meet basic requirements, and cysteine should be supplemented. In the urea cycle disorders, protein often is provided only as essential amino acids, and a high-energy diet is provided to maximize the formation of nonessential amino acids from nitrogen and to minimize ammonia production. In maple syrup urine disease, natural protein is fed in small quantities to provide the minimal requirement of branched-chain amino acids, and a branched-chain amino acid-free supplement is added to provide adequate protein intake.

Route of Administration

Nutritional support using the GI tract is the preferred approach when possible. Enteral nutrition provides several advantages. First, interposition of the GI mucosa between the nutrient supply and the circulation allows absorptive function to provide a homeostatic control. Second, the flow of nutrients from the GI tract to the liver via the portal circulation before reaching the systemic circulation also assists homeostatic control. Third, the lack of enteral nutrition allows normal GI tract flora to overgrow and translocate into the blood, ultimately resulting in bacteremia. Finally, the intestinal mucosa depends on intraluminal absorption for much of its energy supply. Hence, provision of at least a small amount of enteral feeding, referred to as trophic feeds, helps to ensure a healthy GI tract and may facilitate advancement to full enteral feedings at the appropriate time.[18]

Normal oral feeding is the most basic method for patients who are willing and able to eat or drink. Patients whose GI motility, structure, and function are normal but whose oral feeding is prevented by an altered state of consciousness, uncoordinated sucking and swallowing, or other conditions that prevent adequate oral ingestion can be fed by a GI tube in intermittent boluses or by continuous infusion.

Bolus tube feedings more closely mimic the normal state. They periodically distend the stomach, which aids in gastric secretion and emptying. When bolus tube feeding is undertaken, the volume of formula or expressed breast milk required to provide sufficient calories for a 24-hour period is administered through the tube in equal aliquots every 2, 3, 4, or 6 hours. The frequency of administration depends on the patient's age, gastric capacity, and the infant's ability to maintain a normal serum glucose concentration between feedings. In general, younger and more premature infants require more frequent feedings. Intolerance to bolus tube feedings can be manifested as diarrhea, gastroesophageal reflux with emesis, or poor motility. Poor motility usually is apparent when large volumes of feeding, referred to as residuals, remain in the stomach when the next feeding is due.

Continuous tube feedings can be given at a constant rate of infusion by pump into the stomach or duodenum when bolus feedings have failed. This approach may be better tolerated by premature infants and children with diarrhea.

Patients with intrinsic GI disease (Table 103-6) or malabsorption may require total or supplemental PN. Concurrent administration of low-volume, trophic enteral feedings may provide important nutrients to the gut mucosa even when the parenteral route supplies all of the necessary systemic nutrients.[18] Administration of PN into a peripheral vein is limited to those patients expected to require parenteral feeding only for a short time (i.e., 2 weeks) because the amount of nutrients that can be safely infused peripherally is limited. In patients who require long-term PN, the IV solution is more concentrated and must be administered into a central vein.

Nutritional Assessment

CASE 103-6

QUESTION 1: T.C. is a 4-month-old, lethargic boy. On examination, he has a moderately distended abdomen and dry mucous membranes. No other remarkable abnormalities are noted. His weight is 6.5 kg (50th–75th percentile for age). Previously, when he was 2 months old, T.C. weighed 5.6 kg (75th percentile for age), and his length was 57 cm (50th percentile for age). His mother reports that for the past 5 to 7 days, he has had five to eight large, liquid stools per day. His infant formula has not changed. He is to be hospitalized for evaluation of his diarrhea and weight loss and for fluid and nutritional management.

After correction of his initial fluid and electrolyte deficits, an assessment of his nutritional status shows the following:

Weight, 6.5 kg (50th–75th percentile)
Length, 62 cm (50th percentile)
Albumin, 3.8 g/dL (normal, 4–5.3 g/dL)
Prealbumin, 7 mg/dL (normal, 20–50 mg/dL)

How would you assess T.C.'s nutritional status?

Growth assessment is an important focus of pediatric health care, especially during the first year of life. With the exception of the intrauterine period, the most rapid growth occurs during the first year. On average, a normally growing infant gains approximately 30 g/day. Typically, healthy infants weigh approximately 3 times their birth weight by their first birthday.

The patient's nutritional status should be assessed before beginning a nutritional support regimen and reassessed at regular intervals during the course of treatment. If the patient previously was well nourished, the goal is to maintain that status until a normal diet can be resumed. In a child who was previously malnourished, an effort should be made to promote "catch-up" growth and to normalize the biochemical nutritional measures. One in five children admitted to the hospital experience acute or chronic malnutrition.[19] Malnutrition in children is a risk factor for decreased social skills and impaired intellectual development.[20]

Factors used to determine nutritional status in children include dietary history, weight, height, and visceral protein measurements (e.g., albumin, prealbumin). Other measurements used in adults, such as 24-hour creatinine excretion, 24-hour nitrogen excretion, and nitrogen balance, are reserved for older children because complete collections of urine are difficult to obtain and because the percentage of non-urea nitrogen present in urine is variable in infants.

Anthropometric measurements can also be used to assess T.C.'s nutritional status. Height, weight, and head circumference are used to determine nutritional status in infants and children. Standards for these measurements have been derived from pediatric patients in the United States and compiled into graphs referred to as growth curves (**http://www.cdc.gov/growthcharts**).[3] An individual patient's measurements are compared with the graph of normal values for that specific age group. As prematurely born infants age, a standard growth curve adjusted for prematurity can be used. Using these measurements, comparisons with standards are possible: weight for age, height for age, and weight for height.[3] A weight that is below the fifth percentile for the patient's height is considered an indication of acute malnutrition. Similarly, a height and weight that are below the fifth percentile for the patient's age indicate chronic malnutrition. It is important to consider the height and weight of the child's parents because genetics are important determinants of the height and weight that a child may ultimately achieve. Additionally, the revised growth charts include the body mass index (BMI) for age for children older than 2 years. The BMI helps identify children at risk for obesity and type 2 diabetes, two problems that have recently become concerns in children.[3]

Table 103-6

Common Indications for Parenteral Nutrition Support[a]

Extreme prematurity
Respiratory distress
Congenital GI anomalies
Duodenal atresia
Jejunal atresia
Esophageal atresia
Tracheoesophageal fistula
Pyloric stenosis
Congenital webs
Hirschsprung disease
Malrotation
Volvulus
Abdominal wall defects
Omphalocele (herniation of viscera into the umbilical cord base)
Gastroschisis (defect of abdominal wall, any location except umbilical cord)
Congenital diaphragmatic hernia
Necrotizing enterocolitis
Chronic diarrhea
Inflammatory bowel disease
Chylothorax
Pseudoobstruction
Megacystis microcolon
Abdominal trauma involving viscera
Adverse effects of treating neoplastic disease
Radiation enteritis
Nausea and vomiting
Stomatitis, glossitis, and esophagitis
Anorexia nervosa
Cystic fibrosis
Chronic renal failure
Hepatic failure
Metabolic errors

[a] Other indications for parenteral nutrition may exist.

GI, gastrointestinal.

Numerous biochemical indices are also used in the assessment of nutritional status. Of these, the most readily available and widely used is the serum albumin concentration. Although a low serum albumin can be a specific indicator of protein-calorie malnutrition, its long half-life (20 days)[19] makes it an insensitive indicator for developing and resolving malnutrition.

Prealbumin can also function as a biochemical marker of nutritional status.[19] Because of its shorter half-life, prealbumin has the advantage of being more sensitive than albumin to acute nutritional changes, and it is still useful when exogenous albumin infusions are given.[19]

CASE 103-6, QUESTION 2: After initial IV rehydration and receiving nothing by mouth (NPO) for 48 hours, T.C.'s stool output has decreased dramatically. Is this characteristic of infants with chronic diarrhea? How should T.C.'s enteral diet be initiated?

A prompt decrease in stool output when enteral intake is stopped is typical of infants with chronic diarrhea. Nonetheless, evaluation of bowel function and adaptation has shown that enteral nutrition is superior to PN with regard to histologic recovery, improvement of D-xylose absorption, protein absorption, and disaccharidase activity.[21] In fact, improvement in histology or absorptive function might not occur until enteral nutrients are given.[18] Thus, for T.C., every effort should be made to provide some nutrition enterally.

The enteral regimen should be initiated with a lactose-free formula, such as an elemental formula or a soy-based formula. Although any soy-based formula would be appropriate, Isomil DF is a soy-based formula with added fiber that is indicated for infants with diarrhea. Infants with chronic diarrhea can have small bowel mucosal damage and decreased disaccharidase activity.[4] Carbohydrate absorption depends on digestion of disaccharides and polysaccharides to monosaccharides through disaccharidase activity in the intestinal lumen. Substitution of free glucose orally may overcome the problem of carbohydrate digestion and absorption. Administration of large amounts of oral glucose should be limited, however, because of its osmotic effect and potential to worsen diarrhea. Furthermore, incompletely absorbed carbohydrate is available to colonic bacteria for fermentation, the end products of which can produce diarrhea through colonic irritation.

Unlike carbohydrate, protein rarely causes diarrhea, but the mucosal damage present in patients with chronic diarrhea, such as T.C., can reduce the absorptive surface area so that protein malabsorption may occur. This can be minimized through the administration of a formula containing protein in the form of dipeptides and tripeptides, which are absorbed more efficiently than free amino acids.

Dilution of hypertonic formulas to half strength may improve formula tolerance. The concentration is increased in a stepwise fashion to full strength if there is no carbohydrate malabsorption and if stool output is not excessive. Tolerance may be improved by continuous infusion of the enteral product. If enteral refeeding results in the return of diarrhea, fluid and electrolytes must be replaced with an equal volume of an IV solution of similar electrolyte composition to the stool loss.

CASE 103-6, QUESTION 3: How can T.C.'s tolerance to the formula and his recovery of intestinal function be assessed?

Malabsorption or formula intolerance can be assessed by stool studies, which would include assessing for the presence of reducing substances and stool pH. Lactose is a reducing sugar and its presence in stool is an assessment of carbohydrate absorption. The bacterial fermentation products of malabsorbed carbohydrates can result in a decreased stool pH, which suggests malabsorption. To further evaluate carbohydrate absorption, D-xylose may be given orally; a blood sample is drawn 4 to 5 hours later to determine the amount absorbed. This test may be of initial prognostic value in predicting which patients will require prolonged courses of treatment.[21] More than 5% of ingested fat in a stool collection (typically obtained for 3 days) is indicative of fat malabsorption. All these tests can be evaluated during outpatient visits to guide the refeeding process.

Once the diarrhea has resolved, standard infant formula feedings should be established using an enteral elemental or soy-based formula. Regardless of the time chosen, a gradual stepwise conversion is suggested. A small volume of standard formula is substituted for an equal volume of elemental or soy-based formula, and the substitution volume is increased daily until the elemental or soy-based formula is eliminated completely from the regimen. If a specific nutrient intolerance has been identified, a standard formula that does not contain that nutrient must be selected. For example, a patient with cow's milk protein intolerance may require a soy protein formula or an elemental formula.

Pediatric Parenteral Nutrition

The basic requirements for a parenteral nutrient regimen are listed in Table 103-1. These guidelines for the initiation of a nutrient regimen should be individualized to specific patient needs. The correct regimen for any specific patient is that which supplies sufficient nutrients to promote a normal rate of growth without toxicity. In particular, patients with ongoing, abnormal nutrient losses may require much larger doses of certain nutrients. Individualization of the nutrient prescription cannot be overemphasized. Many of the requirements listed in Table 103-1 apply to nutrients administered by the enteral route as well. In some instances, the absorption of a particular nutrient from the GI mucosa is incomplete, and enteral requirements are substantially higher. This is particularly true of the major minerals (calcium, magnesium, and iron) and trace elements.

Indications

Parenteral nutrition is indicated for any infant or child unable to take in sufficient nourishment to maintain normal growth. Some specific indications are listed in Table 103-6.

VERY LOW-BIRTH-WEIGHT INFANTS

Extremely premature or VLBW infants require specialized nutritional support for two distinct reasons. First, the third trimester in utero is a time of rapid growth and accumulation of protein, glycogen, fat, and minerals.[22] The infant born in the very early stages of the third trimester does not accumulate these stores and, therefore, must receive nutrients earlier than a more mature infant. Second, extreme prematurity is associated with poor coordination of the suck and swallow reflex, poor GI motility, and incomplete absorption. Therefore, enteral nutrients may need to be administered via an orogastric or nasogastric tube, and PN supplementation probably will be needed. PN, especially of amino acids, should be initiated soon after birth to duplicate intrauterine growth and prevent a catabolic state in the first few days of life. The fetus has a continuous supply of amino acids that is immediately stopped after preterm birth.[23] A standardized solution containing amino acids and dextrose can be used for infants weighing less than 1 kg in the first 24 hours of life. There has been some reluctance to administer amino acids this soon after birth because of increased risk of hyperammonemia, uremia, and metabolic acidosis. Several studies, however, have shown early introduction of amino acids is safe, provides a positive nitrogen balance, and promotes better health outcomes.[24,25]

RESPIRATORY DISTRESS

Respiratory distress may preclude the ability to consume sufficient nutrients enterally because high respiratory rates prevent coordinated breathing and swallowing. In infants who are hypoxic, or at high risk for hypoxia, aggressive enteral feedings during the acute phase of their illness can increase the likelihood of bowel ischemia. Often, these situations are resolved in 3 to 5 days, but this can rarely be predicted at the outset. Trophic feedings (1–5 mL/hour) are often implemented to maintain GI tract integrity. Nutritional support in such cases is initiated by giving parenteral fluids, which provide dextrose as a caloric source. This allows the infant to conserve endogenous energy substrates, an important consideration for the VLBW infant whose entire body composition may contain as little as a 3- to 4-day energy supply.[22] PN should be initiated as soon as it becomes clear the enteral feeding will not be possible for at least 3 to 5 days, or when several days have elapsed and no clear time frame can be determined for the establishment of enteral feeding. Although a short course (5 days or less) of PN may be used, the quantity of nutrients supplied during the process of initiation and gradual increase to full requirements is so low that extremely short courses may be difficult to justify. Peripheral PN using fat emulsion as a significant source of calories, however, can provide up to 70 kcal/kg and, with appropriate types and amounts of protein, result in modest weight gain and nitrogen equilibrium.

GASTROINTESTINAL ANOMALIES

Infants with GI anomalies often require PN because the implementation of enteral feedings may be delayed. For example, GI tract atresia or stenosis can obstruct, or partially obstruct, the lumen of the GI tract. This prevents or slows the passage of fluids and nutrients and can result in vomiting, depending on the location of the obstruction. Similarly, infants with necrotizing enterocolitis have zones of ischemic bowel and are at risk for bowel perforation if fed enterally.[26] Infants with these disorders need PN until the viability of the entire GI tract can be assured.

CHRONIC RENAL FAILURE AND HEPATIC DISEASE

Chronic renal or hepatic disease requires modification of a normal diet to account for the impaired elimination of nitrogenous waste or impaired protein metabolism. Careful caloric supplementation with a reduced amount of protein may permit normal growth while minimizing excess urea production in an infant with renal failure.

CASE 103-6, QUESTION 4: Approximately 48 hours after discharge from the hospital, T.C. returns to the emergency department with abdominal distension and bloody diarrhea. He is diagnosed with postgastroenteritis syndrome. T.C. cannot receive nutrients enterally, and PN is to be initiated because he is nutritionally depleted. Describe for the members of the medical team how a regimen of PN should be instituted in T.C. What aspects of his disease may alter specific nutrient needs?

When initiating PN, the protein (amino acids), glucose (dextrose), fat (lipids or fat emulsion), fluid, and electrolyte, mineral, and vitamin components of the regimen are managed as separate entities. In addition, the route of PN delivery is important to consider because the amount of glucose, potassium, and calcium must be limited if the infusion is given peripherally. In general, 12.5% dextrose, 40 mEq/L potassium, and 10 mEq/L calcium are the maximal amounts that should be provided by infusion into a peripheral vein. These nutrients can be increased if a central venous catheter is placed. The fluids, electrolytes, minerals, and vitamins are initiated at full daily maintenance doses after correction of any preexisting abnormalities. Protein should be initiated at full daily doses in term infants and children with normal renal and hepatic function. Glucose and fat are started at lower doses and increased daily until requirements are reached.

Protein should be started in T.C. at full daily requirements of 2 to 3 g/kg/day. Azotemia and acidosis have occurred in infants receiving more than 4 g/kg/day of protein; however, these complications are rare at the recommended dosage. Parenteral glucose administration is initiated at 5 to 8 mg/kg/minute (7.2–11.5 g/kg/day). At normal maintenance fluid rates, 10% dextrose represents a generally well-tolerated starting solution for patients of virtually any age or size, except the VLBW infant.

In T.C.'s case, the dextrose concentration will begin and continue at 10% because of the peripheral catheter limitations. This concentration will provide 7.3 mg/kg/minute. If a central catheter later becomes necessary, the concentration can be increased by 5% each day until the caloric requirement is met. This increase should be accompanied by blood and urine glucose monitoring. If the blood glucose is 150 mg/dL or greater, or if the urine glucose exceeds "trace" amounts, the PN infusion rate should be decreased by at least 25% and a second IV solution should be added to provide needed fluids and electrolytes. Alternatively, the dextrose concentration can be decreased or insulin can be infused concomitantly and titrated to a desired serum glucose concentration of 120 to 140 mg/dL.

Fat emulsion should be initiated at 1 g/kg/day and increased daily by 0.5 to 1 g/kg/day until the maximal dosage of 3 g/kg/day is reached. The daily fat dose should be infused at a constant rate because fats are better tolerated when infused over the course of 24 hours.[27] Serum triglycerides should be monitored every other day while the dose of fat is being increased. Patients with a fasting triglyceride concentration of 150 mg/dL or less may have their fat dose increased. In patients who are receiving inadequate calories, triglycerides may be elevated because endogenous fats are being mobilized. If the triglyceride concentration is greater than 150 mg/dL, the serum sample must be examined visually. A clear sample with a mildly elevated triglyceride concentration probably indicates the use of endogenous fat stores for energy. Conversely, a turbid or lipemic sample indicates the patient's inability to use the amount of intravenous fat administered. In this case, further increases in the fat dose should be delayed until triglyceride concentrations decrease.

Special Considerations and Complications

CASE 103-7

QUESTION 1: J.H., a 4-day-old boy, was born at 31 weeks' gestation. His birth weight was 1,950 g, and he now weighs 2,000 g. On the first day of life, he was given a commercial preterm infant formula by orogastric tube in gradually increasing quantity with supplemental IV fluids. Now, on the fourth day of life, he has a distended abdomen and his stools contain bright red blood. An abdominal radiograph shows pneumatosis intestinalis (gas within the intestinal wall seen on X-ray). All enteral feedings are stopped (NPO). What do these findings represent? What are the implications for J.H.'s nutritional management?

Abdominal distension, bloody stools, and pneumatosis intestinalis are characteristic of necrotizing enterocolitis historically.[28] The causes of this disorder are unclear, but it occurs more often in premature than in term infants; it can occur in clusters of cases, rarely is seen before enteral feeding is instituted, and can be associated with rapid increases in enteral intake.[29] Because J.H. will receive antibiotics for 10 to 14 days and remain NPO, he requires PN. The planned duration of the regimen makes central venous access a necessity.

GOALS OF LONG-TERM SUPPORT

CASE 103-7, QUESTION 2: The following day, intestinal perforation requires the resection of two-thirds of J.H.'s distal jejunum and one-third of his ileum, with creation of a jejunostomy. The ileocecal valve and the entire colon are left intact. During the operation, a central venous catheter is placed. What is the goal of PN for J.H.?

J.H. will be NPO for a prolonged time. Therefore, the goals of his PN must be to promote normal growth as well as healing of his diseased gut and surgical wounds. Because J.H. is a premature infant, it will be difficult to predict how well he will tolerate PN. VLBW infants tolerate normal doses of pediatric amino acids without difficulty; however, some clinicians initiate protein at a lower daily dose (e.g., 1.0 g/kg/day) and advance by 0.5 g/kg/day each day until a goal of 2 to 3 g/kg/day is achieved. Fat should be started at 0.5 to 1 g/kg/day and increased by 0.5 g/kg/day up to 3 g/kg/day. Glucose should be initiated at 5 to 10 g/kg/day and increased by 2 to 3 g/kg until the desired caloric intake is achieved. Appropriate doses of electrolytes and minerals may be started immediately using the guidelines listed in Table 103-1.

FAT EMULSIONS: COMPLICATIONS

CASE 103-7, QUESTION 3: What must be considered in making decisions regarding fat administration in J.H.?

Although J.H. can receive adequate calories using only glucose and crystalline amino acids, he will require fat to provide a more physiologic diet and to prevent essential fatty acid deficiency (EFAD), which develops quickly in low-birth-weight infants who have little fat reserve. J.H. should receive a minimum of 5% of his total caloric requirement as fat emulsion to minimize the risk of EFAD. Ideally, his nutrition regimen will provide approximately 40% of calories from fat, which is similar to what is provided by human milk.

Infusions of fat emulsion have been associated with impaired oxygen transport and pulmonary ventilation–perfusion mismatch. This adverse effect occurs more often when the dose of fat is 4 g/kg or greater and is infused for a relatively short (4 hours) period. Current practice is to increase gradually the doses of fat from 0.5 to 1 g/kg/day up to a maximum of 4 g/kg/day and to infuse the fat emulsion over the course of 24 hours to minimize the likelihood of pulmonary problems and to promote clearance.

It is unclear whether IV fat administration is detrimental to patients with sepsis. Infusion of fat emulsion has resulted in lymphocyte and neutrophil death.[30] On the other hand, the linoleic acid in IV fat is the precursor to arachidonic acid, prostaglandins, thromboxane, interleukins, and immune-mediating cells. Theoretically, this may minimize bacteremia. Necrotizing enterocolitis, intestinal perforation, and surgery predispose J.H. to sepsis. Therefore, he should have his IV fat infused at an appropriate dose over the course of 24 hours. Because fat clearance can be impaired during infection, it is also prudent to monitor his triglyceride concentrations.

Free fatty acids can displace bilirubin from its albumin binding sites, thereby placing the infant at risk for kernicterus.[31] Therefore, before advancing the fat dose, the total bilirubin and direct bilirubin should be measured. Patients with an indirect bilirubin (total bilirubin minus direct bilirubin) of 10 mg/dL or less whose albumin levels are normal are at low risk for kernicterus. Indirect bilirubin usually peaks before 1 week of age. After the risk for indirect hyperbilirubinemia has passed, the fat dose can be increased as recommended in Table 103-1. The infusion of 1 g/kg over the course of 24 hours is associated with minimal risk for decreased bilirubin binding[31]; however, rapid infusion of this same dose can displace bilirubin from albumin binding sites. Given the low level of indirect bilirubin found on routine monitoring and the planned fat infusion rate, J.H. should not be at risk for kernicterus.

Egg phospholipids are used to emulsify fats; therefore, patients with a known allergy to eggs (e.g., fever, chills, urticaria, dyspnea, bronchospasm, chest pain) should not receive fat emulsion.

GLUCOSE INTOLERANCE

CASE 103-7, QUESTION 4: Because J.H. is a premature infant, PN is initiated using 5% glucose, 2.5 g/kg/day of amino acids, and 0.5 g/kg/day of fat emulsion. The volume of PN should be 240 mL based on a maintenance fluid requirement of 120 mL/kg (Table 103-1). On the second day, he receives 10% glucose, 2.5 g/kg/day of amino acids, and 1 g/kg/day of fat. On the third day, glucose is increased to 15%, amino acids remain at 2.5 g/kg/day, and fat emulsion is increased to 1.5 g/kg/day. On the fourth day, glucose is increased to 20%, amino acids remain at 2.5 g/kg/day, and fats are increased to 2 g/kg/day. After this solution has been infused for 8 hours, his urine test yields 1% for glucose (normal, no glucose) and his blood glucose level is 210 mg/dL (normal, 120 mg/dL). Explain this new finding and the problems it may cause. How should hyperglycemia be managed?

Maximal glucose oxidation rates in milligrams per kilograms per minute are inversely related to age and decrease from 15 to 18 mg/kg/minute in neonates and young infants to 4 to 5 mg/kg/minute in adults. In full-term neonates and infants receiving maintenance fluids (100 mL/kg/day), glucose concentrations can be started at 10 g/kg/day (equivalent to dextrose 10%) and advanced by 5 g/kg (equivalent to dextrose 5%) every 24 hours up to approximately 25 g/kg/day (equivalent to dextrose 25%). In preterm neonates, such as J.H., dextrose is started at a lower dose and advanced at smaller increments, usually 2 to 3 g/kg/day. Glucose tolerance varies significantly, so each patient should be considered individually.

At J.H.'s prescribed fluid rate of 10 mL/hour, 20% glucose represents 16.7 mg/kg/minute of glucose. The hyperglycemia and glycosuria probably have occurred because the increases in the infusion rate have exceeded J.H.'s ability to adapt to the glucose dose. Patients who have been euglycemic on their glucose dose and then become glucose intolerant should be evaluated, however, for other causes, such as infection and addition of exogenous corticosteroids. Hyperglycemia and glycosuria can result in serum hyperosmolarity, osmotic diuresis, and dehydration. Regardless of the cause, the hyperglycemia should be treated by reducing the glucose administration rate. The rate of the PN infusion can be decreased further if hyperglycemia continues or increased if the hyperglycemia resolves.

When the PN order is written for the subsequent days, the glucose increases should be made in smaller amounts up to the full daily maintenance calorie requirements. Frequent blood and urine glucose monitoring must be continued. Severe glucose intolerance in patients who require PN can be managed with insulin to normalize serum glucose. Although insulin is compatible with PN solutions, it does adsorb to glass, polyvinyl chloride, and filters, resulting in decreased delivery of insulin.[32] Frequently, pediatric patients have changing insulin requirements that prevent the addition of insulin to PN solutions. A separate continuous infusion of regular insulin (initial dose, 0.05–0.1 units/kg/hour) titrated to control serum glucose concentrations offers a practical solution to minimize waste of the PN solution.[33] It is essential to discontinue the insulin infusion if the PN solution is discontinued to avoid hypoglycemia.

EFFECTS OF BRONCHOPULMONARY DYSPLASIA AND MECHANICAL VENTILATION

CASE 103-7, QUESTION 5: J.H. remains dependent on a ventilator because of his immature lungs. How could J.H.'s respiratory disease influence his nutritional regimen?

After 28 days of age, J.H.'s ventilator dependence defines him as having bronchopulmonary dysplasia (BPD), a chronic lung disease of infancy. Historically, BPD is characterized by an increase in resting energy expenditure, increased work of breathing, and growth failure.[34,35] Therefore, J.H.'s caloric requirement may be higher than expected. Additionally, J.H.'s ventilator may also alter the approach to his caloric supply. Very high carbohydrate loads have been associated with an increase in carbon dioxide production.[36] This, in turn, may make it difficult to wean J.H. from the mechanical ventilator. As discussed, rapid infusions of fat emulsion can also have a detrimental effect on pulmonary function. Fat emulsion should not be omitted from J.H.'s PN regimen; rather, a slower infusion rate, with gradual dose increases, while monitoring pulmonary function is appropriate.

PEDIATRIC AMINO ACID FORMULATIONS

CASE 103-7, QUESTION 6: Why would a specialized pediatric amino acid solution be preferable to a standard adult formulation for J.H.?

Patients 1 year of age or older tolerate standard adult amino acid preparations (e.g., Aminosyn and Travasol) well. For infants, two specifically designed pediatric amino acid formulations (PAAFs)—TrophAmine and Aminosyn PF—are available.

PAAFs were developed in response to the abnormal plasma amino acid patterns noted in infants receiving adult amino acid formulations. The products were designed with the goal of producing plasma amino acid patterns closely matching those of 2-hour postprandial, human milk-fed infants. Theoretically, normal plasma amino acid patterns will promote normal protein synthesis in growing infants.

Pediatric amino acid formulations differ from conventional amino acid formulations in several ways. First, they contain a higher content of branched-chain amino acids (leucine, isoleucine, and valine) and a lower content of glycine, methionine, and phenylalanine. In addition, PAAFs have a higher percentage of essential amino acids with a wider distribution of the nonessential amino acids. Finally, PAAFs are unique in that they contain three essential amino acids for neonates: taurine, tyrosine (as N-acetyl-L-tyrosine), and cysteine (added as L-cysteine HCl). Adult solutions contain little if any of these amino acids. Neonates have immature liver functions. This results in decreased levels of both hepatic cystathionase and phenylalanine hydroxylase enzymes. Without these enzymes, neonates cannot adequately convert methionine to cysteine or phenylalanine to tyrosine or synthesize taurine from cysteine. Deficiencies in these amino acids can have a significant impact on the health of the neonate. For example, taurine has a role in retinal development, protection and stabilization of cell membranes, neurotransmission, regulation of cell volume, and bile acid conjugation. Taurine also may be important in decreasing or preventing cholestasis associated with long-term PN.

Several investigators have studied the clinical, nutritional, and biochemical effects of TrophAmine in term and preterm infants.[37,38] The use of TrophAmine was found to result in nearly normal amino acid patterns. In addition, patients receiving TrophAmine had greater weight gain and significantly better nitrogen utilization than similar groups using the adult formulations. TrophAmine and Aminosyn-PF, given for a 7-day period, produced comparable weight gain and nitrogen retention.[39] In one study, some of the VLBW infants experienced metabolic acidosis.[37] L-Cysteine, an HCl salt, provides an additional 5.7 mEq of chloride/100 mg and may have contributed to the acidosis. Whereas the manufacturer's recommended dose of 40 mg of L-cysteine per gram of amino acid may be too much for the VLBW infant, the most appropriate dose of L-cysteine for the VLBW infant has not been determined.

To date, PAAFs have been effective in producing a positive weight gain and positive nitrogen balance, and normalizing amino acid patterns in preterm neonates. They also allow for the provision of larger doses of calcium and phosphorus because PAAFs lower the pH of the final PN solution. Providing greater amounts of calcium and phosphorus, in appropriate ratios, should minimize metabolic bone disease. Further evaluation of these products is needed to determine the magnitude of the proposed benefits (i.e., improved nitrogen retention, better weight gain, enhanced bone growth, and decreased cholestasis) and the most appropriate L-cysteine dose to use in VLBW infants. In any event, these potential benefits, and clinical experience with these products, have resulted in the use of PAAFs as the standard of care in infants requiring PN.

CARNITINE

CASE 103-7, QUESTION 7: Why would carnitine supplementation be warranted in J.H.?

Carnitine has many functions within the body, but it primarily serves to transport long-chain fatty acids (LCFA) across the mitochondrial membrane where they undergo β-oxidation to produce energy. Deficiency in carnitine lessens LCFA availability for oxidation, resulting in the accumulation of LCFA and a decrease in ketone and adenosine triphosphate (ATP) production. This can adversely affect the CNS and skeletal and cardiac muscles. Carnitine deficiency in premature infants also has been linked to disorders such as GI reflux, apnea, and bradycardia.[40]

Whereas carnitine is a nonessential nutrient in adults and is readily available from a diet that includes meat and dairy products, it appears to be an essential nutrient in neonates and infants. This population has low body stores of carnitine and a decreased ability to synthesize it on their own. The premature infant has even lower stores because carnitine accumulation occurs during the third trimester. Human milk and most cow's milk-based infant formulas contain carnitine. Some soy-based formulas have additional carnitine added during manufacturing. PN, however, is not routinely supplemented with carnitine. Therefore, infants who are exclusively fed by PN are at risk for developing complications associated with carnitine deficiency.[40]

Because J.H. has two risk factors for the development of carnitine deficiency (prematurity and exclusive use of PN), and because carnitine has little or no adverse effects associated with its use, it is appropriate to provide J.H. with a carnitine supplement. Carnitine is available as both an oral and IV formulation. The recommended dose in J.H. is 10 to 20 mg/kg/day. The addition of carnitine directly to PN improves carnitine plasma concentrations and nutritional status.

METABOLIC BONE DISEASE (RICKETS)

CASE 103-7, QUESTION 8: On the chest radiograph taken to evaluate the septic episode just described, the radiologist notes that J.H. has two rib fractures and that the bones appear undermineralized. The most recent laboratory values show a serum calcium (Ca) of 9.3 mg/dL (normal, 8.5–10.5 mg/dL), a serum phosphorus of 3.6 mg/dL (normal, 4.0–8.5 mg/dL), and an alkaline phosphatase of 674 units/L (normal, 350 units/L). What diagnosis is suggested by these findings? How and why has J.H.'s nutrition regimen placed him at risk for this disease?

During the last trimester of pregnancy, bone accretion is accelerated, reaching its peak at about 36 weeks. Premature infants, therefore, require larger calcium and phosphorous doses. Limitations to venous access, however, may preclude the infusion of concentrated calcium solutions peripherally, and the patient's end organs may be resistant to vitamin D. Thus, metabolic bone disease is not unexpected in a premature infant such as J.H.

Aluminum, a contaminant in some parenteral salt products (particularly calcium), also may play a role in impaired bone mineraliziation.[41] Low serum phosphorus with high alkaline phosphatase, undermineralized bones, and fractures resulting from routine handling are consistent with a diagnosis of rickets.

Parenteral nutrition solutions provide calcium and phosphorus in much smaller amounts than the infant would accumulate in utero.[42] Solution pH, temperature, calcium salt, and final calcium and phosphorus concentrations influence their solubility in PN solutions. An acidic PN solution favors the solubility of these salts. The pH of commercially available amino acid preparations ranges from 5.4 in PAAFs to 7 in adult amino acid formulations. The addition of L-cysteine, with a pH of 1.5, also makes the solution more acidic. Because dextrose also is acidic, solutions with higher dextrose concentrations are more acidic. Of note, colder storage temperatures promote calcium and phosphorus solubility. Therefore, refrigerated PN solutions may appear to be free of precipitate on visual inspection. Calcium and phosphate can precipitate, however, when warmed to room temperature, or when infused into patients with fever or in incubators. Calcium salt selection is another important consideration because the chloride salt dissociates rapidly and favors precipitation, whereas the gluconate and gluceptate salts dissociate less quickly.

Serum phosphorus concentrations should be monitored several times per week and phosphorus intake adjusted to prevent symptomatic hypophosphatemia. Serum calcium is not useful as an indicator of disease activity because it will remain normal at the expense of bone mineralization. This is demonstrated by J.H.'s serum calcium at the time of diagnosis.

Parenteral Nutrition-associated Liver Disease

CASE 103-7, QUESTION 9: On the 56th day of life, J.H. is noted to be mildly jaundiced. A review of his laboratory tests reveals the following:

	Age (days)				
Test	22	29	36	43	50
Aspartate aminotransferase (AST) (units/L) (normal, <40)	14	17	15	20	25
Alanine aminotransferase (ALT) (units/L) (normal, <28)	6	7	10	10	11
Alkaline phosphatase (international units/L) (normal, <350)	103	158	345	506	695
Bilirubin					

Indirect (normal, <1 mg/dL)	0.9	0.9	0.8	0.8	0.9
Direct (normal, <0.2 mg/dL)	0.1	0.1	0.8	1.6	3

Could this be related to his PN?

Parenteral nutrition-associated liver disease (PNALD) is severe liver disease due to extended parenteral feeding, which can cause permanent damage and even liver failure. In past decades, hepatic damage has been reported in up to one-half of infants receiving PN,[43] with a higher prevalence (up to 50%) in VLBW infants such as J.H. Although it is still a concern today, PNALD is less prevalent because of a better understanding of how to treat infants requiring long-term PN. The laboratory abnormalities reported in J.H. are typical of this complication. The first change observed is usually an elevated direct (conjugated) bilirubin, which can occur as early as 2 weeks after beginning PN. Increases in the

serum concentrations of the hepatic enzymes, AST and ALT, lag 2 weeks or more behind the rise in direct bilirubin. Alkaline phosphatase also can rise, but it is a nonspecific indicator of liver disease. Alkaline phosphatase is produced by the liver, GI tract, and bones. Although the laboratory results observed in J.H. are consistent with the pattern associated with PNALD, and many components of PN solutions have been associated with the development of cholestasis, other potential causes also exist.[43] PNALD is a diagnosis of exclusion; therefore, other causes, such as viral hepatitis, must be ruled out.

J.H. has several other risk factors for developing cholestasis, and prolonged enteral fasting may be the most significant.[43] Stimulation of bile flow and gallbladder contraction depend on GI hormones, which depend on enteral feeding for their release.[43] Absence of these hormones, therefore, can promote cholestasis.[43] Immature hepatic function secondary to prematurity also places J.H. at risk, as does the duration of PN therapy. As the duration of PN use increases, so does the prevalence of hepatic disease in premature infants; 25% of infants nourished in this manner for 30 days or more show evidence of cholestasis.[43] Surgical patients have a greater likelihood of developing hyperbilirubinemia than medical patients, especially those requiring GI surgery.[43] Many surgical procedures are associated with a higher risk of jaundice.[43] Finally, J.H.'s infection increases his risk for cholestasis.[43]

The use of adult amino acid preparations in infants increases the risk of cholestasis. In one study, the incidence of cholestasis in VLBW infants receiving TrophAmine was reduced to 23% relative to historical controls of 30% to 50%.[44] In another study comparing the two PAAFs mentioned above, 33% of infants receiving Aminosyn PF developed cholestasis as compared with 13% of infants who received TrophAmine.[45] An additional risk factor for cholestasis not present in J.H. is the administration of large amounts of protein or dextrose. Because amino acids are actively transported in hepatocytes, it is important to provide appropriate types and amounts of amino acids to minimize the development of cholestasis. In one study, a high-protein regimen (3.6 g/kg/day) was associated with an earlier onset and greater degree of cholestasis than a low-protein regimen (2.3 g/kg/day).[46] Similarly, dextrose overload is also a known cause of hepatic steatosis. Therefore, overly aggressive feeding of J.H. with PN should be avoided.

In addition to the hepatic damage, gallstones have been reported in infants and children receiving PN.[43] The ileal resection performed during the acute phase of his necrotizing enterocolitis may put J.H. at increased risk for this hepatobiliary complication as well.

CASE 103-7, QUESTION 10: What modifications to J.H.'s PN regimen should be made in the presence of cholestasis?

First, the institution of enteral feeding must be considered. Even low-volume trophic feeding may help alleviate the condition and should be attempted in cholestatic patients. Next, the protein and glucose dose provided by the PN should be evaluated. During cholestasis, calories should be provided using an appropriate mix of protein, carbohydrate, and fat.

Although the effect of cycling a patient off PN has not been evaluated in clinical trials, this should be considered. Cycling PN, in which the infusion rate is gradually decreased to off for a period and then restarted and gradually increased to the desired rate, will decrease the length of time the liver is exposed to PN. VLBW infants, however, may become hypoglycemic even with very gradual decreases in infusion rate, so this option should be used with care. In any event, a short time off PN (e.g., 2 hours) should be attempted.

The trace elements provided by the formulation should be examined. Both copper and manganese are enterohepatically recycled and may accumulate in liver disease. Manganese can also contribute to hepatotoxicity and should be removed from J.H.'s PN solutions. Studies have not established when removal of copper and manganese is warranted. The inappropriate removal of copper could lead to anemia, osteopenia, and neutropenia. Therefore, decreasing the copper dose and monitoring serum concentrations of both copper and manganese should guide therapy.

Current studies have demonstrated that using omega-3 long-chain fatty acids, derived from fish oil, can reverse the liver damage caused by PNALD. Fish oil is high in eicosapentaenoic and docosahexaenoic acids, which do not impair bile flow and may actually diminish fat accumulation in the liver. Omegaven, the parenteral fish oil-based intravenous fat emulsion, is being used under the compassionate use protocol and not currently approved by the FDA.[47] Other research is being done using an oral formulation of fish oil in infants as a supplement to reverse PNALD.[48]

Pharmacologic interventions have had limited success in the management of PNALD. Phenobarbital has not been shown to be effective in reducing or reversing it.[49] Ursodiol 10 to 20 mg/kg/day has been used successfully in the treatment of other cholestatic liver diseases, and preliminary reports indicate that it may also improve PNALD in children.[50] Ursodiol, a naturally occurring nontoxic bile acid, presumably works by displacing and replacing the endogenously produced, potentially toxic bile salts that accumulate with cholestasis.

The antibiotic metronidazole also appears promising in the prevention of PNALD in adults. Metronidazole inhibits the bacterial overgrowth in the GI tract that occurs with intestinal stasis. The bacteria are responsible for increased formation of hepatotoxic bile acids such as lithocholate; 25 mg/kg/day of metronidazole has been shown to be effective.[51]

CASE 103-7, QUESTION 11: Project the course of J.H.'s liver disease if PN is discontinued and enteral feedings are instituted within 2 weeks. What may occur if enteral feedings cannot be instituted?

It is difficult to predict a successful wean from PN. Historically, success has been associated with longer length of intact small intestine. Additionally, studies in children with short bowel syndrome have shown that serum citrulline levels may predict the ability to successfully wean a patient from PN. Citrulline is a free amino acid that is produced by the small bowel enterocytes. Therefore, it may be warranted to measure J.H.'s serum citrulline level before weaning from PN.[52]

If PN can be discontinued soon after the onset of cholestasis, the prospects for J.H. to recover normal hepatic function are good. Jaundice usually resolves within 2 weeks after PN is discontinued, and the biochemical abnormalities normalize soon thereafter.[43] The pathologic changes observed on biopsy resolve even more slowly. Biopsy evidence of cholestasis has been observed for up to 40 weeks after resolution of clinical and serologic evidence of hepatic disease.[43]

If enteral feedings cannot be instituted successfully, the prognosis for J.H.'s liver function is not as good. Studies have demonstrated that infants receiving PN for 90 days or more had biopsy evidence of irreversible liver damage.[43] Thus, it clearly is advantageous to convert J.H.'s nutrition to the enteral route as soon as he tolerates such a change.

104

Common Pediatric Illnesses

Chephra McKee, Brooke Gildon, and Bethany Ibach

CORE PRINCIPLES	CHAPTER CASES
① Medication administration to children can be challenging. For oral administration, dosing syringes or droppers should be used rather than household spoons or cups. The administration of medications by any route may require special techniques in an uncooperative child.	**Case 104-1 (Question 1)**
② Diaper dermatitis presents as a mild red rash that often progresses to increased redness and lesions outside the diaper area. Barrier creams are recommended for initial treatment with the addition of a topical antifungal for dermatitis lasting longer than 3 days and spreading outside the diaper area.	**Case 104-2 (Questions 1, 2)**
③ Fever in children may be the result of a common viral infection, but could also be an indicator of a more serious bacterial infection or lead to complications such as febrile seizures. Proper management depends in large part on accurate assessment.	**Case 104-3 (Questions 1, 2)**
④ The treatment of cough and cold symptoms in children younger than 6 years of age is generally supportive with nasal saline, hydration, and humidification. Over-the-counter agents have little proven effectiveness and have been associated with severe adverse effects owing to inadvertent overdoses during parental administration.	**Case 104-4 (Question 1)**
⑤ Constipation can be defined by a delay or difficulty in stooling for at least 2 weeks duration. Constipation is most commonly functional, and may be managed with behavioral modification or drug therapy.	**Case 104-5 (Question 1)**
⑥ Gastroenteritis, although usually self-limiting, may result in clinically significant dehydration in infants and children. Assessment of the degree of dehydration is important in determining whether oral rehydration is appropriate or hospital admission with intravenous rehydration is required.	**Case 104-6 (Questions 1–3)**
⑦ Gastroesophageal reflux is a common disorder in young infants. Most will require no intervention. Some, however, will require feeding modifications and possibly drug therapy, including acid-suppressing or prokinetic agents.	**Case 104-7 (Questions 1, 2)**
⑧ Otitis media is a middle ear infection associated with effusion, rapid symptom development, and evidence of middle ear inflammation.	**Case 104-8 (Questions 1–3)**

Options for therapy include antibiotic management and watchful waiting, the choice of which depends on the age of the child and severity of disease. Amoxicillin (or amoxicillin/clavulanate) remains the antibiotic of choice despite the high incidence of penicillin nonsusceptible Streptococcus pneumoniae.	
⑨ Acute pharyngitis may be caused by respiratory viruses or bacteria, most commonly Streptococcus pyogenes. Treatment goals for bacterial pharyngitis include resolution of symptoms and prevention of rheumatic heart disease. Amoxicillin is the antibiotic of choice for bacterial pharyngitis.	**Case 104-9 (Questions 1, 2)**

Children represent more than 25% of the population and receive an average of three prescription medications before 5 years of age. According to the Slone Survey, between 1998 and 2007, 56% of children younger than 12 years of age had taken at least one medication in the previous week.[1] Prescription medications accounted for only 20% of cases; thus, the use of over-the-counter (e.g., nonprescription) medications was most prevalent. The most predominant over-the-counter medications used were acetaminophen, pseudoephedrine, ibuprofen, dextromethorphan, antihistamines, and iron. The most prevalent prescription medications were amoxicillin and albuterol. The prevalence of chronic medication use for dyslipidemia, hypertension, type 2 diabetes, and attention deficit hyperactivity disorder has increased in recent years, illustrating that chronic disease management is becoming more important in pediatric medicine.[2,3] Given the prevalence of medication use in children, it is essential that health care providers be prepared to educate families and children on the appropriate use of over-the-counter and prescription medications.

ADMINISTERING MEDICATION TO CHILDREN

CASE 104-1

QUESTION 1: M.B., a 16-month-old girl weighing 9 kg, has been diagnosed with an ear infection. She will be receiving amoxicillin (400 mg/5 mL) 5 mL by mouth every 12 hours. What tips for successfully administering these medications should be recommended?

Oral Medications

The administration of oral medications to a young child or infant often requires two adults: one to gently restrain the child while the other rapidly and accurately administers the medication. If only one adult is available, one can restrain the arms and legs of the child in a swaddling blanket or large towel as depicted in Figure 104-1.

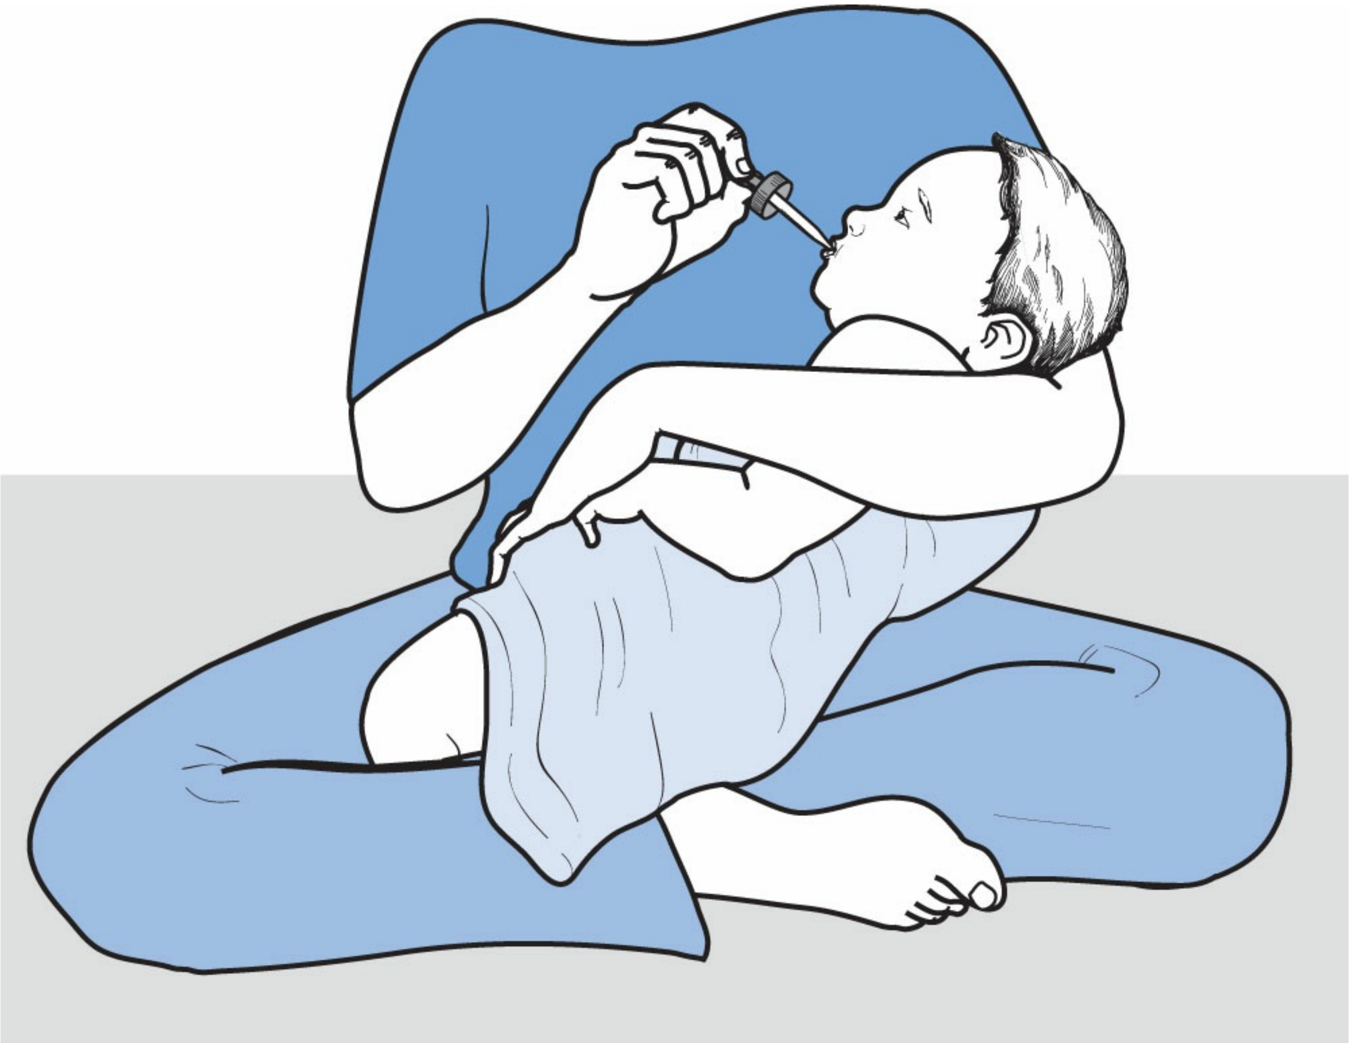

Figure 104-1 Administration of oral liquid medication to a young child. (1) Premeasure the medication and have it within reach. (2) Hold the child in your lap, placing one of the child's arms behind your back and both of the child's legs between your legs. Restrain the child's other arm securely with your nondominant arm. (3) Tilt the child's head back slightly, pressing gently on the child's cheeks to open the mouth. Using your dominant hand, aim the dropper or syringe between the rear gum and cheek. Administer small amounts of medication (1–2 mL) at a time, making sure the baby swallows.

The administration device (syringe, dropper, or dosing spoon) that generally accompanies a liquid medication product provides the most accurate measurement of the desired dose. For infants, liquid medications are most easily administered to the back cheek in 1- to 2-mL amounts with an oral syringe. Household teaspoons should not be used to measure medications because teaspoons are of variable sizes and hold 3 to 8 mL of a liquid. Other considerations involve the unit of measurement. To decrease errors and improve precision of drug delivery, it is recommended to use milliliter-based dosing exclusively while prescribing and administering liquid products.[4] Regarding unique delivery devices, studies have shown that parents have more difficulty accurately delivering doses using dosing cups than other devices.[5]

In some situations, crushed tablets or capsule contents mixed in small amounts (1–2 teaspoons) of food (e.g., chocolate pudding, applesauce, ice cream, jelly, and chocolate syrup) offer an alternative to liquid formulations. The taste of liquid dosage formulations is generally improved by refrigeration and flavoring agents, and "chasers" (i.e., popsicle, chocolate syrup, or a flavored drink after a dose) are also helpful. Although medications can be delivered in small amounts (10–15 mL) of liquid in a bottle (juice, milk, and formula), doses should not be diluted into an entire scheduled feeding or prepared ahead of time in batches in anticipation of future administration. Limiting the volume more likely facilitates delivery of the entire dose, and adding the medication to a feeding bottle immediately before delivery minimizes the potential of drug instability. Drug interactions with foods and dairy products should also be considered before drugs are added to feeding formulas. Most children are able to swallow tablets at 5 to 8 years of age. Duplicate supplies of medication should be provided to the caregiver, when midday doses are required for children who attend school or childcare in the event a dose is dropped. Children of all ages should be encouraged and praised for their cooperation in taking their medicine. Rewards and positive reinforcements can be useful to gain cooperation in an older child.

For M.B.'s amoxicillin, the parents should be given a dosing syringe and shown how to measure 5 mL. If M.B. is uncooperative with medication administration, she may need to be restrained and the medication delivered in 1- to 2-mL increments. The parents should be ready to provide M.B. with something that tastes good immediately after administering the medication.

Ear, Nose, and Eye Drops

Otic, ophthalmic, and nasal medications usually need to be administered to infants and young children in a different manner than adults. Otic medications should be instilled by pulling the auricle down and out in infants and young children, whereas older children should have the auricle of the ear held up and back to straighten the ear canal. During the instillation of nose and eye drops, position infants and toddlers with their head lower than the rest of the body because gravity assists in dispersing the medication. This can be achieved by laying the infant across a bed with the shoulders projecting over the edge of the bed. Restraining the infant often is required during the administration of ophthalmic formulations. When administering the eye medication (Fig. 104-2), the caregiver must be cautious to avoid injury to the eye caused by sudden movements of the infant. The technique of placing the hand, which holds the eye medication on the forehead of the infant during administration, can help to minimize eye injury because the hand holding the eye dropper will move when the infant's head moves.

To minimize fear and improve cooperation during instillation of eye, nose, or ear drops, the procedure should be explained to the child as simply as possible. It is best to warm the medication in your hand for a few minutes before administration because medications can feel cold inside the ears or nose even when stored at room temperature.

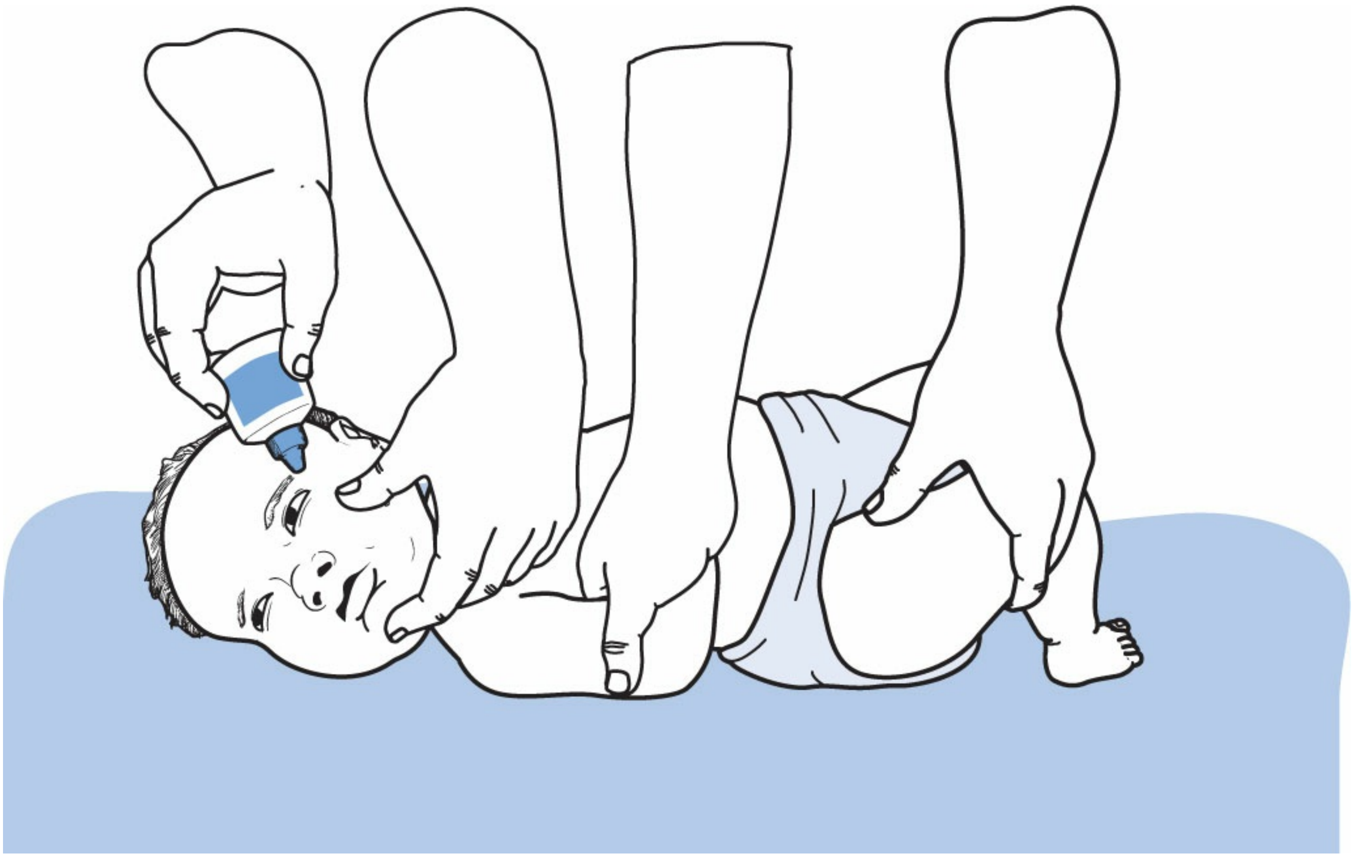

Figure 104-2 Administering eye drops to a young child. (1) Place the child on a flat surface. Enlist the help of a second adult to restrain the child or swaddle the child. (2) Holding the child's head steady, gently pull the eyelids apart. The hand that is holding the medication dropper can rest on the child's head while administering the medication to minimize the potential for injury to the eye if the child's head moves abruptly. Administer the medication as directed.

If ear drops were to be administered to M.B., she should be lying down with the affected ear up. The auricle should be pulled down and out, and the ear drops placed in the ear canal. She should remain in that position for at least 1 minute.

INFANT CARE

Diaper Rash

ETIOLOGY

Diaper dermatitis is commonly encountered in pediatric practice, occurring in up to

35% of infants at any given time. Although the pathogenesis of diaper dermatitis is not well defined, a number of factors (e.g., chemical irritants, friction, and bacteria) have been associated with skin inflammation in the diaper area. In particular, skin wetness and pH have been implicated in diaper dermatitis, and wetness appears to have greater influence than that of pH. Overhydration of the skin increases the permeability of low-molecular-weight compounds and exacerbates the effects of friction.[6] Cloth diapers covered with plastic pants or disposable diapers with plastic outer linings decrease air circulation and increase moisture in the diaper area and should be avoided.[7] Residual chemicals or laundry detergents in the diaper (cloth or disposable), as well as soaps, medications, or lotions that have been applied directly to the infant's skin, also have roles in the development of diaper rash.

CLINICAL PRESENTATION

Four clinical presentations of dermatitis are associated with diaper wear:

1. A mild, scaling rash in the perianal area
2. A sharply demarcated confluent erythema
3. Ulceration distributed through the diaper area
4. A beefy red confluent erythema with satellite lesions, vesiculopustular lesions, and diffuse involvement of the genitalia

TREATMENT

CASE 104-2

QUESTION 1: K.G., a 3-month-old infant, has had a severe diaper rash for the last 4 days. The very inflamed and tender area is confined to the diaper area, and vesicular satellite lesions are present on the periphery of the erythematous area. K.G.'s mother uses only cloth diapers and has not changed soap or her normal pattern of diaper care since K.G. was born. What is the likely cause of K.G.'s diaper rash and what treatments are appropriate?

K.G.'s rash is consistent with a candidal infection, which typically is beefy red and associated with vesicular satellite lesions. The presence of a rash for longer than 3 days and the diffuse involvement of the genitalia and inguinal folds are also characteristic of this form of diaper rash. K.G.'s rash can be treated with 1% clotrimazole or 2% miconazole cream applied to the inflamed area four times daily until it has resolved. Nystatin (100,000 units/g) ointment can be applied, but often is not as effective as the imidazole antifungals because of increasing resistance of Candida species to nystatin.

CASE 104-2, QUESTION 2: What steps would you recommend for K.G.'s mother to treat her diaper rash and prevent recurrence?

The removal of stool and urine from the diaper area by gentle rinsing with plain water and more frequent diaper changes often help to alleviate diaper rashes. Wiping the baby with diaper wipes that contain alcohol can sting, further irritating the involved area, and should be avoided until the rash has resolved. A good protective agent containing zinc oxide or petrolatum (e.g., Desitin) can be applied with each diaper change to create a barrier to irritants and seal out moisture. Powdered protective agents (e.g., cornstarch and talc) can minimize friction caused by diapers, but should be used cautiously because the infant can aspirate powder particles and develop a chemical pneumonia.[8] When used, powders should be shaken into the diaper or applied close to the body, away from the baby's face. Other prevention and treatment measures appropriate for K.G. include the following:

1. Change the diaper as soon as it is wet or at least every 2 to 4 hours during the day.
2. Keep the diaper area clean (e.g., nightly baths until resolved).
3. Use superabsorbent disposable diapers at night.
4. Expose the diaper area to air as often as possible.
5. Dry the diaper area completely before a new diaper is put on.
6. Apply a barrier cream such as zinc oxide or petrolatum after each diaper change.
7. For cotton diapers, use a bacteriostatic agent in the diaper pail and rinse water or use a diaper service to ensure that diapers are sterile.
8. Apply a low-potency, nonfluorinated topical corticosteroid, such as 0.5% to 1% hydrocortisone, twice daily for no longer than 2 weeks when severe inflammation is present.[7]

Fever

Normal body temperature varies throughout the day, peaking in late afternoon or early evening. Body temperature can be measured rectally, orally, axillary (under the arm), temporally (on the forehead), and tympanically. Rectal temperatures are most reliable in infants younger than 3 months of age. Oral measurements of temperature are not appropriate in children younger than 3 years of age because it is difficult for young children to maintain a tight seal around the thermometer.

Although references differ, fever can be defined as an axillary temperature greater than 37.5°C (99.5°F) or a core temperature greater than 38°C (100.4°F).[9] Rectal and tympanic measurements are typically 0.3°C to 0.6°C (0.5°F to 1°F) higher than an oral reading, whereas axillary measurements are lower by the same amount. (Fahrenheit temperatures can be converted to or from centigrade temperatures by the formula °F = 1.8°C + 32.)

Children with fevers might not have other signs or symptoms of an illness. Any child younger than 2 months of age who develops a fever requires a complete evaluation (e.g., blood culture and urinalysis), because clinical manifestations of a serious infection often are subtle, nonspecific, and not predictive of the extent or severity of illness.[10] In this situation, antibiotic therapy is usually initiated while awaiting laboratory results. Children 3 to 36 months of age with a temperature greater than or equal to 39°C (102.2°F) and white blood cell counts less than 5,000 μL^{-1} or greater than 15,000 μL^{-1} are at increased risk for bacteremia.[10] Children of any age with a temperature greater than 41°C should be evaluated not only for bacteremia, but also for possible meningitis. Blood cultures, lumbar puncture, urinalysis, and chest radiograph should be considered on an individual basis to help determine the etiology of infection. Febrile immunocompromised children and febrile children with functional or anatomic asplenia are at increased risk for sepsis or fulminant infections (e.g., Streptococcus pneumoniae, Salmonella species, and Escherichia coli) and should receive prompt antibiotic therapy.[11]

Febrile Seizures

CASE 104-3

QUESTION 1: R.B., a 12-month-old, 10-kg baby boy, was well yesterday until his mother noticed that he felt warm to her touch later in the afternoon. For the past 24 hours, he has remained warm and is fussy and less active. A rectal temperature 15 minutes ago was 39°C. Because her other two children experienced febrile seizures, his mother is concerned R.B.'s temperature will continue to rise and put R.B. at risk for febrile seizures. Is this a valid concern?

Febrile seizures occur in approximately 2% to 4% of children 6 months to 5 years of age who have temperature elevations greater than 38°C.[12] The etiology and pathogenesis are unknown, and there is no evidence that the rate of temperature increase is important.[13] Genetic predisposition also appears to be a factor because febrile seizures occur with greater frequency among family members.[12] Febrile seizures are of two types: simple and complex. Simple febrile seizures last less than 15 minutes and do not have significant focal features. Complex febrile seizures have a longer duration, occur in series, and are associated with focal changes. Typically, febrile seizures occur within the first 24 hours of a febrile episode.[12,13] Although R.B. is in the age group at greatest risk for having a febrile seizure, he has been febrile for more than 24 hours, and a seizure is unlikely during this illness.

TREATMENT

CASE 104-3, QUESTION 2: How should R.B.'s fever be treated?

Acetaminophen is the most common antipyretic agent used in children. The usual dose, oral or rectal, is 10 to 15 mg/kg/dose administered every 4 to 6 hours as needed to a maximum of 75 mg/kg/day.[14] Ibuprofen is administered as 5 to 10 mg/kg/dose orally every 6 to 8 hours as needed to a maximum of 40 mg/kg/day.

Ibuprofen is as effective as acetaminophen as an antipyretic and is similar in safety.[15] Although renal failure has been reported after ibuprofen use in children, the risk of renal impairment appears greater in children with dehydration, underlying cardiovascular or renal disease, or other nephrotoxic drugs, and children <6 months of age.[15]

Acetaminophen 100 to 150 mg every 4 to 6 hours as needed or ibuprofen 50 to 100 mg every 6 to 8 hours as needed should be effective in lowering R.B.'s fever. Acetaminophen typically has been considered to be a first-line drug in children. Dosing errors have occurred, when teaspoonful quantities of acetaminophen infant drops (80 mg/0.8 mL) were given instead of the liquid formulation (160 mg/5 mL) or when regular-strength tablets (325 mg) have been substituted for chewable children's tablets (80 and 160 mg). To reduce the risk for dosing errors, in 2011, the Consumer Healthcare Products Association (a group of leading manufacturers and distributors of nonprescription medications) voluntarily converted to a single 160 mg/5 mL acetaminophen concentration. In addition, in 2017 manufacturers began transitioning to a single strength of children's chewable acetaminophen tablets (160 mg). However, providers should continue to question caregivers about the dosage form of acetaminophen they have at home, concurrent use of any other products containing acetaminophen, and whether cumulative doses are within the recommended range. Recent data have suggested that ibuprofen may be a more effective alternative to acetaminophen for R.B. and should be used first.[16] It is available in two liquid formulations (infant drops, 40 mg/mL; children's suspension, 100 mg/5 mL) and a chewable tablet (100 mg). Adverse effects are limited when ibuprofen is used in recommended doses for short-term antipyresis. Some data suggest that combination therapy with acetaminophen every 4 to 6 hours and ibuprofen every 6 to 8 hours may be more effective in reducing time with fever in the first 24 hours.[16] However, combination therapy may be associated with medication errors,[15] and recent data suggest an increased risk of acute kidney injury may occur with this combination.[17] Aspirin therapy is not recommended for treatment of fever in children or adolescents with chickenpox, gastroenteritis, or respiratory viral infections because of its link with Reye syndrome.[18,19]

Cough and Cold

Another common diagnosis in children is viral upper respiratory infection or the common cold. Preschool children generally experience between six and eight colds each year.[20] Children with a cold often present with sore throat, nasal congestion, rhinorrhea, sneezing, cough, and irritability.

CLINICAL PRESENTATION AND TREATMENT

CASE 104-4

QUESTION 1: J.K. is a 3-month-old, 5.3-kg infant who began having nasal congestion, rhinorrhea, and cough yesterday. She has had no fever and is eating well, but did not sleep well last evening. J.K.'s mother called her pediatrician and was told that J.K. most likely has a cold caused by a virus. J.K.'s mother would like to know which cold medications would be appropriate to manage J.K.'s symptoms.

A cool-mist humidifier can increase the amount of moisture in room air and decrease irritation in the upper airway when humidity is low. Saline nose drops followed by bulb suctioning can help to clear the nasal passages in J.K. who is younger than 6 months of age. It is especially important to do this before feedings. A decongestant, however, should not be prescribed for J.K. because of her age and the potential for adverse effects. If J.K. was older and a topical nasal decongestant was needed, phenylephrine would be preferred over oxymetazoline and xylometazoline because of its lesser association with toxicity (e.g., sedation, convulsions, insomnia, and coma) in children younger than 6 years of age.[21,22] Neither antihistamines, antitussives, nor guaifenesin should be recommended for J.K.

---

because there is no evidence of their efficacy, and unintentional overdoses are common in this age group. Antihistamines are not effective for rhinorrhea caused by the common cold and should not be recommended. Antitussives are likely not effective and should not be used if the child's cough is productive. Expectorants, such as guaifenesin, are also not effective, and evidence is insufficient to support the use of vitamin C, zinc, or echinacea in children for treatment or prevention of the common cold.

Several hundred over-the-counter medications for upper respiratory symptoms are available, and over 1 billion units of these products are sold each year in the United States.[23] Nevertheless, the safety and effectiveness of these cough and cold medications in children have yet to be proved.[24] The Centers for Disease Control and Prevention (CDC) reported that 1,519 children younger than 2 years of age were admitted to emergency departments in 2004 to 2005 because of overdoses and other problems associated with cough and cold medicines. Furthermore, according to the US Food and Drug Administration (FDA), 54 deaths in children were linked to the use of decongestants (e.g., pseudoephedrine, phenylephrine, and ephedrine) and 69 deaths to antihistamines (e.g., diphenhydramine, brompheniramine, and chlorpheniramine) from 1969 to September 13, 2006. Most of these deaths occurred in children younger than 2 years of age, and some of the fatalities occurred in children who received overdoses that might have been the result of inadvertent administration of multiple medications containing the same ingredient.

In 2008, the FDA issued a public health advisory recommending that over-the-counter cough and cold medications not be used in children younger than 2 years of age.[25] Later that year, the Consumer Healthcare Products Association announced that many manufacturers would voluntarily modify their labels to exclude recommendations for children younger than 4 years of age.[26] Owing to reports of toxicity and death related to over-the-counter cough and cold products, the CDC has recommended that caregivers avoid giving these products to children younger than 2 years of age unless advised by a clinician.[24] If deemed necessary by a physician for older children, nonprescription cough and cold medications containing single ingredients should be selected to minimize the potential for adverse effects and administration of multiple products with similar ingredients. Of note, parents often misunderstand labeling of over-the-counter products, placing the child at risk for dosing errors.[27] It is critical that health care providers educate caregivers on the proper use and administration of these medications to children. Treatment of J.K.'s symptoms should include the use of a cool-mist humidifier in the room and saline nasal drops followed by suctioning before feedings.

Constipation

Chronic constipation is defined as delay or difficulty in stooling for at least 2 weeks' duration.[28,29] It accounts for 3% of annual visits to pediatrician offices, and up to a quarter of referrals to gastroenterologists.[30] Beyond the neonatal period, constipation is most commonly idiopathic or functional and may be related to a diet low in fiber, lack of time or routine for toileting, or passage of a painful stool resulting in a fear of defecating. Other causes of constipation include anatomic (fissures), neurogenic (Hirschsprung disease), hypotonic (cerebral palsy), and endocrine (cystic fibrosis and hypothyroidism) disorders.[30] Medications such as opioids, antacids, and anticonvulsants, among others, can also contribute to constipation. It is important that constipation be managed appropriately because it can have negative effects on growth and development, has been linked to gastrointestinal distress, and adversely impacts quality of life.[30] In addition, constipation in childhood can remain a problem into adulthood.[31]

CLINICAL PRESENTATION AND TREATMENT

CASE 104-5

QUESTION 1: R.J., a 2-year-old, 15-kg boy, has had abdominal pain for 4 weeks. On average, he has one stool weekly, and he cries each time because of pain. R.J. eats regular table food and has two glasses of whole milk each day. After obtaining a thorough history and performing a physical examination, the physician determines that R.J. has functional constipation. What treatment measures are appropriate to relieve and prevent R.J.'s constipation?

Before maintenance therapy can be initiated, disimpaction of the patient is necessary. Although no controlled studies compare efficacy of the oral and rectal routes, oral therapy (mineral oil, polyethylene glycol, and bisacodyl) is preferred because it is less invasive and might lead to better adherence than rectal therapy (phosphate soda enemas, mineral oil enemas, glycerin suppositories in infants, and bisacodyl suppositories in older children).[30] After disimpaction, a combination of behavioral, dietary, and pharmacologic therapies should be initiated to promote regular stool production and prevent reimpaction. Dietary interventions include adequate fluid and fiber intake. The impact of cow's milk on constipation is still controversial. Some data suggest no link,[30] although other recent literature hints at causation through an immune-mediated mechanism.[31,32] Medications such as polyethylene glycol 3350, mineral oil, lactulose, and sorbitol should be titrated to produce one to two soft stools daily. Stimulant laxatives might be needed intermittently in certain cases. Although no clear recommendation for one maintenance medication has been given over others, recent data suggest that polyethylene glycol may be the most effective and best tolerated in children.[33–37] The recommended dosing of medications for treatment of constipation is listed in Table 104-1. Appropriate initial therapy for R.J. could include eliminating or limiting milk intake, behavioral techniques, and polyethylene glycol 0.5 to 1.5 g/kg/day (7.5–15 g). Practically, this would be half to one 17-g packet administered daily in 4 to 8 ounces of water or other beverage.

Vomiting and Diarrhea

Vomiting and diarrhea, two commonly encountered complaints in pediatric practice, are usually self-limiting, but severe cases can result in serious complications such as dehydration, metabolic disturbances, and even death. Infants and young children are particularly susceptible to the more severe complications.

PATHOGENESIS AND PRESENTATION OF VOMITING

Vomiting or emesis is defined as forceful expulsion of gastrointestinal (GI) contents through the mouth or nose, while nonforceful expulsion of GI contents is considered regurgitation. In newborns, regurgitation of small amounts of breast milk or formula after feeding, especially when burping, is common. In most cases, regurgitation usually resolves by 1 to 2 years of age and rarely causes problems.[38] Extensive evaluation of regurgitation is not needed in a child who is growing well. Other causes of vomiting during the newborn period include pyloric stenosis, gastroesophageal reflux (GER), overfeeding, food intolerance, and GI obstruction. Beyond the neonatal period, the most common cause of vomiting is infection. Vomiting in infants and children can also be caused by central nervous system (CNS) disease (e.g., intracranial tumors), metabolic disease (e.g., urea cycle disorder), inflammatory bowel disease, and ulcers. Conditions causing emesis in older infants and children range from viral gastroenteritis to more severe illnesses, such as bowel obstruction or head injury, which require immediate medical attention.[39] Acute vomiting can also result from medication or toxic ingestions. In teenagers, migraine, pregnancy, and psychological disorders, such as bulimia, have been associated with vomiting.

Table 104-1

Medications for the Treatment of Constipation[28,29]

Medication	Initial Dosage	Comments
Osmotic Agents		
Polyethylene glycol 3350	0.2–0.8 g/kg/day	0.5 g/kg initial dose; titrate to effect; do not exceed 17 g/day
Lactulose	1–2 g/kg/day divided once or twice daily	1.5–3 mL/kg/day; do not exceed 60 mL/day
Sorbitol	1–3 mL/kg/day once or twice daily	Less expensive than lactulose
Barley malt extract	2–10 mL/240 mL of milk or juice daily	Useful for infants drinking from a bottle
Magnesium hydroxide	1–3 mL/kg/day using 400 mg/5 mL	Infants are at risk for hypermagnesemia
Phosphate enema	≥2 years of age: 6 mL/kg up to 135 mL	Electrolyte abnormalities more common in children with renal failure or Hirschprung disease. Avoid in children <2 years
Lubricant		
Mineral oil	>1 year of age: Disimpaction: 15–30 mL/year of age up to 240 mL daily	Better tolerated if chilled. Avoid in children <1 year. Lipoid pneumonia may occur if aspirated
	Maintenance: 1–3 mL/kg/day	Maximum daily dose: 90 mL/day
Stimulants		
Senna	2–6 years of age: 2.5–5 mg/day	Not recommended for chronic use
	6–12 years of age: 7.5–10 mg/day	
	>12 years: 15–20 mg/day	
Bisacodyl	3–10 years: 5 mg/day	Not recommended for chronic use
	>10 years: 5–10 mg/day	
Glycerin suppositories	2–5 years: 1 pediatric suppository per dose	Preferred stimulant for children <2 years of age
	≥6 years: 1 adult suppository per dose	

PATHOGENESIS AND PRESENTATION OF DIARRHEA

Diarrhea refers to an increase in frequency, volume, or liquidity of stool when compared with normal bowel movements. In developing countries, diarrhea is a common cause of death in children younger than 5 years of age. In the United States, gastroenteritis accounts for approximately 1 to 2 million physician visits, more than 200,000 hospitalizations, and about 300 deaths each year.[40]

Acute diarrhea in infants and children is generally abrupt in onset, lasts a few days, and is most commonly caused by viruses. (see Chapter 69, Infectious Diarrhea for infectious diarrhea of other origins.) Diarrhea is considered chronic if it is longer than 2 weeks in duration. Chronic diarrhea can be caused by malabsorption, inflammatory disease, infection, alteration of intestinal flora, milk or protein intolerance, drugs, and other causes.[41]

Infants and children are at high risk for morbidity and mortality secondary to diarrhea for several reasons. Dehydration can occur easily because acute net intestinal fluid losses are relatively much greater in young children than in adults. This may result from inefficient transport systems in the developing intestine. In addition, the percentage of total body water in children is higher than in adults; thus, they are more susceptible to body fluid shifts. Total body water changes from 80% of total body weight in premature infants to 70% in term infants and 60% in adults. Finally, the renal capacity to compensate for fluid and electrolyte imbalances in the infant is limited compared with that of adults.[42]

VIRAL GASTROENTERITIS

CASE 104-6

QUESTION 1: J.R., a 15-month-old male 10-kg infant, had one loose stool and began vomiting this morning, but he has not had a fever. On questioning, you discover that many children attending day care with J.R. are experiencing vomiting, diarrhea, and low-grade temperatures. How should J.R.'s vomiting be treated?

Routine use of antiemetics for acute vomiting in children is not recommended because masking of symptoms may delay diagnosis of a treatable illness. In addition, the safety and efficacy of the antiemetics, including metoclopramide, promethazine, trimethobenzamide, and dimenhydrinate, have not been demonstrated.[43] In particular, promethazine is contraindicated in children younger than 2 years of age because of the risk of fatal respiratory depression. Ondansetron does decrease vomiting, increases oral intake and decreases the need for intravenous (IV) rehydration; however, the utility of ondansetron in gastroenteritis needs consideration because this effect may not be sustained, and the drug has not been shown to decrease consistently hospital admission.[44–46]

Parents should be taught the signs and symptoms of gastroenteritis and vomiting that are sufficiently serious to warrant medical attention. The child's primary-care provider should be contacted if the child is toxic appearing, exhibits unusual behavior, exhibits signs of an ear infection, experiences abdominal pain or distension, has red or black vomitus or stool, or if there is a history or suspicion of toxic ingestion or head trauma. Medical evaluation is also necessary for infants younger than 6 months of age, when persistent vomiting or high-volume diarrhea is present, or when chronic medical conditions or prematurity is involved. Because fever can accompany vomiting in viral gastroenteritis, any fever occurring in a neonate warrants medical attention. Fever in older infants and children warrants medical attention, when it becomes prolonged or changes in pattern.

When communicating with a health care provider about a vomiting child, it is helpful if the parents have knowledge of the child's fluid intake, and the frequency and volume of vomiting and urination. The amount of vomitus can be estimated by the following rule of thumb: one tablespoon makes a spot 4 inches wide and a quarter-cup makes a spot approximately 8 inches wide.

Vomiting associated with gastroenteritis usually resolves in 24 to 48 hours. Infants are particularly susceptible to the development of fluid and electrolyte abnormalities; therefore, fluid and electrolyte replacements are critically important.

J.R., who is early in the course of gastroenteritis, must receive sufficient fluids to prevent dehydration. Oral hydration therapy can be successful when given in small volumes, even if J.R. is still vomiting. For example, 5 to 10 mL can be administered every 5 to 10 minutes, with gradual increases in volume as tolerated. Volumes equal to estimated fluid deficit (usually 50–100 mL/kg) should be given over the course of 2 to 4 hours. For each diarrheal stool, an additional 10 mL/kg of oral electrolyte solution should be given. If diarrhea or vomiting recurs, 10 mL/kg and 2 mL/kg of an oral rehydration solution (ORS) can be administered for each stool or emesis, respectively.[46] J.R.'s clinical condition should continue to be monitored by his caregiver. If stool output exceeds 10 mL/kg/hour, ORS might not be sufficient, and the health care provider should be contacted. ORS should only be abandoned in children with intractable vomiting, loss of consciousness, bowel obstruction, or if the child is in shock. Most infants will tolerate oral hydration when small amounts are given frequently. As dehydration is corrected, the frequency of vomiting typically decreases. Once rehydration has been achieved, fluids other than ORS and a diet appropriate for age may be started.[46] Breast milk or formula should be given as tolerated.

Assessment of Dehydration

CASE 104-6, QUESTION 2: On the second day of illness, J.R. develops a mild fever and diarrhea that has increased in frequency and water content. How can the severity of J.R.'s diarrhea be assessed?

To determine the severity of dehydration and whether hospitalization may be needed, consider the following questions:

1. Does the child have any of the following signs and symptoms of severe dehydration: deeply sunken eyes, parched mucous membranes, significantly prolonged capillary refill; cool, mottled extremities; crying without tears; oliguria

or anuria; weak or thready pulses; lethargy; poor oral intake; deep respirations; history of seizures or convulsions; a fever without perspiration; or thirst?

2. Are a large number of copious stools still being produced (>10 mL/kg/hour)? Is bowel obstruction a possibility?
3. Is there a risk of dehydration from inadequate monitoring, or is the parent unable to care for the child? Specific inquiries should be made about the number and consistency of stools in children with diarrhea.

Estimating the degree of dehydration is particularly valuable in assessing the patient with diarrhea, and weight loss is a good criterion. A 3% to 9% weight loss is considered mild to moderate dehydration, whereas more than 9% is considered severe dehydration.[43] (see Chapter 103, Pediatric Fluid, Electrolytes, and Nutrition, for information about IV replacement therapy in children with 10% or more dehydration.)

Oral Replacement Therapy

CASE 104-6, QUESTION 3: J.R. was evaluated by his pediatrician and was not considered to be sufficiently dehydrated to warrant hospitalization. How might J.R.'s fluids and electrolytes be managed on an outpatient basis?

The goal of J.R.'s treatment should be focused on the prevention of dehydration and the restoration and maintenance of adequate fluid and electrolyte balance. Mild to moderate diarrhea without dehydration is generally managed at home by continued age-appropriate feeding. Fluid losses in stools can be replaced with a glucose-containing ORS. Glucose provides calories and enhances salt and water absorption in the small intestine through mechanisms that are usually unimpaired in many toxin-induced diarrheas. Parents formerly were instructed to prepare salt and sugar solutions at home; however, frequent errors in the preparation of these solutions resulted in exacerbation of problems with fluid and electrolyte balance. Commercially available oral glucose–electrolyte formulations, such as Pedialyte, are designed to enhance glucose and sodium absorption and should be used in infants and young children. Carbonated beverages and fruit juices do not contain sufficient sodium to replace diarrheal losses and should not be used. Rehydration and maintenance solutions can be made more palatable with sugar-free flavorings (e.g., Kool-Aid and Crystal Lite).

The World Health Organization (WHO) formerly promoted use of an oral replacement solution (WHO formula) containing sodium (90 mEq/L), potassium (20 mEq/L), bicarbonate (30 mEq/L), chloride (80 mEq/L), and 2% glucose for the widespread management of acute diarrhea in third-world countries. The WHO formula, which had a 90% successful rehydration rate for the management of diarrhea, contained a high concentration of sodium. Although commercially available ORS contain less sodium than the WHO formulation, these preparations were equally effective as the WHO formula, even when used to treat the high-sodium losses associated with cholera. Furthermore, these lower sodium-containing formulations were associated with less vomiting, lower stool output, and reduced need for IV infusions in non–cholera-associated gastroenteritis. As a result, the WHO, in 2002, promoted a new formulation that consists of 75 mEq/L sodium and a total osmolarity of 245 mOsm/L.[43,45] Glucose is added to oral electrolyte solutions to enhance glucose-coupled sodium transport; however, concentrations greater than 3% can impair sodium absorption because the glucose-coupled sodium transport system becomes saturated at this concentration and any additional glucose acts as an osmotically active solute in the bowel lumen. The electrolyte content of commonly used ORS is provided in Table 104-2. Assuming J.R.'s fluid deficit is 50 to 100 mL/kg, he should receive 500 to 1,000 mL of ORS in the course of approximately 4 hours. In addition, he should receive an extra 100 mL for each diarrheal stool and 20 mL for each emesis that occurs. If stool output continues at a pace that cannot be matched with oral replacement, or signs and symptoms of severe dehydration occur, J.R. should be referred to his pediatrician again.

REINSTITUTION OF ORAL FEEDINGS

Previously, feeding during an episode of viral gastroenteritis has been delayed because of the malabsorption that typically occurs during and after these bouts. The malabsorption, however, is self-limiting, and substantial amounts of carbohydrate, protein, and fat can still be absorbed. The reinstitution of a regular diet, therefore, should not adversely affect mild diarrhea and can be beneficial.[46] Parents are encouraged to continue feeding their children using age-appropriate diet while avoiding simple sugars, which can increase osmotic load and worsen diarrhea. Continuation of oral feeding, despite diarrheal episodes, minimizes the development of protein and energy deficits, facilitates the maintenance and repair of intestinal mucosa, promotes recovery of brush border membrane disaccharidases, decreases the duration of illness, and improves nutritional status.[45,46] Although lactose intolerance can occur with viral gastroenteritis, most children with mild diarrhea can tolerate full-strength animal milk, animal milk-based formula, and breast milk. If the child becomes lactose intolerant during this illness, a lactose-free formula may be substituted for 2 to 6 weeks until GI lactase production returns to normal. Specific diets are often recommended during diarrhea (e.g., BRAT [bananas, rice, applesauce, toast]). Although these diets can be occasionally useful, the nutritional value of these foods is relatively low, and they do not provide optimal nutrition compared with complete diets with fats and proteins.[45,46] Once J.R. has been adequately rehydrated, he may resume his normal diet. However, the caregivers must take care to avoid juices and other foods with simple sugars, which may worsen diarrhea.

Table 104-2

Oral Electrolyte Solutions[43]

Solution	Compositions			
	Sodium (mmol/L)	Potassium (mmol/L)	Carbohydrate (mmol/L)	Osmolality
Rehydration				
Rehydralyte	75	20	140	305
WHO formula (1975)	90	20	111	311
WHO formula (2002)	75	20	75	245
Maintenance				
Enfalyte	50	25	167	200
Pedialyte	45	20	139	250
Home Remedies				
Apple juice	0.4	44	667	730
Gatorade	20	3	255	330
Ginger ale	3	1	500	540
Chicken broth	250	8		500
Cola	1.6		622	730

WHO, World Health Organization.

Drug Therapy

Medications play a minor role in the treatment of acute infantile diarrhea because most episodes are self-limiting. Antibiotics are recommended when systemic bacteremia is suspected, when immune defenses are compromised, when a persistent enteric infection is sensitive to antibiotics, or when Shigella, Campylobacter, Vibrio cholerae, Clostridium difficile, and certain Escherichia coli strains are isolated.[46,47] In general, antidiarrheal preparations are not recommended for infants or children because they have little effect on acute diarrhea, are associated with side effects, and direct attention away from the use of oral hydration therapy.[45,46] Drugs such as loperamide that alter GI motility should be avoided, especially in children with high fever, toxemia, or bloody mucoid stools, because they may worsen the clinical course of the bacterial infection. Bismuth subsalicylate preparations, which possess antisecretory and antimicrobial effects, have not been shown to provide clinical benefit and are not recommended.[45] Adsorbents, such as kaolin-pectin or attapulgite, adsorb bacterial toxins and water and lessen the symptoms of diarrhea by producing more formed stools, but there is no evidence of effectiveness, and they are not recommended.[45] Zinc supplementation (10–20 mg for 10–14 days) has been recommended by the WHO for the treatment and prevention of diarrheal disease in children in developing countries; however, its mechanism of action, best method of administration, and efficacy in different populations are not yet well understood.[43,48]

Probiotics, live microbial products containing species of Lactobacillus, Bifidobacterium, Saccharomyces, and Streptococcus, can improve the balance of intestinal flora and diminish the effect of enteric pathogens. These microbes are thought to exert their beneficial effects through various mechanisms, including producing antibacterial chemicals, competing with enteric pathogens, inhibiting the adhesive capabilities of pathogens, altering toxins or toxin receptors, and upregulating interleukin-mediated T-cell response.[48,49] Probiotics are most useful in infectious gastroenteritis when used early in the course of disease. Lactobacilli are the most well-studied species and have been the most consistently effective in clinical trials. It appears that efficacy of the different species may depend on the specific strain, the dose, and the timing of administration, although it is generally accepted that dosage forms with at least 10^6 to 10^9 colony-forming units and above are required.[45,48] The manufacture of probiotics is not regulated by the FDA; therefore, the organism count per dose might be based on the number present at the time of production and not at time of expiration, and the labeling might incorrectly identify the species of organism. Probiotics are not recommended for use in immunocompromised individuals because systemic infections after the use of these products have been reported.[43] For J.R., a Lactobacillus preparation administered for 5 days may provide some modest clinical benefit, although the benefit is most pronounced in rotavirus diarrhea, which has not been documented in his case.

GASTROESOPHAGEAL REFLUX

GER is a common disorder, with 50% to 67% of infants experiencing recurrent vomiting and regurgitation during the first 4 months of life.[50] Most reflux in infants is believed to be caused

by transient relaxations of the lower esophageal sphincter (LES). Infants might also be predisposed to reflux because of their body positioning (e.g., slumped over in a car seat or lying supine), their consumption of a liquid feeding that exceeds the volume capacity of the stomach, and in premature infants, a decrease in peristaltic activity.[51] Infants and young children might also have undiagnosed underlying conditions that predispose them to reflux (e.g., neurologic disorders, hiatal hernia, hypertrophic pyloric stenosis, and cow’s milk protein allergy).[52] Of cases of reflux in infants, 80% are benign and resolve by 18 months of age,[53] and reflux in older children resolves in a timeframe similar to that of adults. If untreated, GER can result in esophageal strictures, GI hemorrhage, or chronic respiratory disease from the aspiration of GI contents. Studies evaluating the relationship between GER disease (GERD) and asthma or Helicobacter pylori have shown mixed results.[54–57]

Clinical Presentation

In infants, the vomiting and regurgitation of GER occur frequently, and other symptoms often are nonspecific (e.g., failure to thrive [FTT], recurrent pneumonia, apnea, dysphagia, reactive airway disease, apparent life-threatening events [ALTE], hematemesis, and anemia).[58,59] A thorough diagnostic workup is generally not necessary in a healthy infant with functional GER presenting as recurrent vomiting. Empiric drug therapy can be initiated after the diagnosis is made based on clinical findings and after other causes of vomiting have been eliminated.[58] Further diagnostic evaluations, however, are indicated for infants and children presenting with additional symptoms of GERD (e.g., FTT, irritability, ALTE, and respiratory difficulties).[53]

Treatment

Because uncomplicated GER usually resolves spontaneously in infants, therapy should focus on providing symptom relief and maintaining normal growth.[53] The goals of therapy are to lessen symptoms, heal esophagitis, and prevent complications in infants and children with pathologic GER, so that surgery can be avoided.[53] Infants and young children with underlying neurologic problems (e.g., cerebral palsy) are unlikely to have spontaneous resolutions of GER and frequently require aggressive antireflux therapies and surgical intervention.

POSITIONAL AND DIETARY MEASURES

CASE 104-7

QUESTION 1: S.B., a 3-month-old, 6-kg, breastfed male infant, has a 2-week history of regurgitation after each feeding. The pediatrician noted that S.B. had not gained weight since his last visit 1 month earlier. The presumptive diagnosis is FTT secondary to GER, and S.B. was referred to a pediatric gastroenterologist. How should S.B. be treated initially?

S.B. can be treated conservatively because he does not present with life-threatening complications.[58,59] First, caregiver feedings should be observed to rule out regurgitation caused either by overfeeding or by inappropriate feeding techniques. Sometimes infants with milk protein allergies can have a similar clinical presentation; therefore, a change to a soy protein formula or hypoallergenic formula should be tried.[58] Interventions to modify an infant’s body positioning or to modify infant feedings with milk thickeners are not proven to be effective, but are reasonable to undertake.[60,61] Maintaining S.B. at a 60-degree angle during the day while sitting and at a 30-degree position at night should be implemented in an effort to promote clearance of acid from the esophagus and to minimize reflux after meals. Milk thickeners (most commonly rice cereal in the United States) and more frequent, smaller feedings are also worthwhile interventions, although thickened formula could lead to increased coughing during feeding. Mild cases of GER often can be treated successfully by dietary measures alone, as well as by propping infants in an upright position during, and 1 hour after, feedings.[59] Although the placement of infants in a face-down prone position during sleep can reduce reflux, the greater risk of sudden infant death syndrome (SIDS) in infants younger than 12 months of age outweighs the benefits of such positioning.[58] Older children and adolescents should follow the recommended dietary guidelines (i.e., avoidance of caffeine, chocolate, and spicy foods) for adults.

DRUG THERAPY

The efficacy of pharmacologic therapy in altering the course of uncomplicated GER in infants has not been proved.[58] In infants or children who present with nonspecific symptoms or complications, such as S.B., acid-suppression therapy or prokinetic therapy is warranted even in the absence of documented esophagitis.[58] When esophagitis is present, acid suppression is always recommended to aid in the healing process; however, these agents alone do not rectify the causes of the GER.[58] The various agents to treat infant GER are listed in Table 104-3.[59,62–73]

Acid-Suppressant Agents

Antacids

Chronic antacid therapy is generally not recommended for the treatment of GER in infants and young children, because infants treated with aluminum-containing antacids can accumulate sufficient aluminum to cause osteopenia and neurotoxicity.[58,62,72] In addition, information on other antacids in infants is limited; nevertheless, antacids can provide short-term relief of symptoms in older children and adults.

Proton-Pump Inhibitors

Proton-pump inhibitors (PPIs) are superior to histamine-2 receptor antagonists (H_2RA) in relieving symptoms and in promoting healing of significant esophagitis from GER in infants, young children, and adults.[58,73,74] PPIs control both basal and meal-stimulated acid secretion, which may in part explain their superior efficacy. The incidence of adverse effects in children from PPI is similar to that reported in adults.[64,75] Despite concerns about the long-term use of PPI, untoward effects have not been observed from their use for up to 11 years.[76] In children, increased metabolism and decreased bioavailability necessitate larger milligram per kilogram doses to maintain acid suppression than adults; thus, titration of dose to response is necessary, particularly for treatment of esophageal erosions.[60,77] Although most clinicians dose PPI once a day, multiple, divided daily doses can prevent acid breakthrough and better promote healing.[73] Omeprazole, lansoprazole, and esomeprazole are available in extended-release capsules, which can be separated, opened, and sprinkled on soft foods. Omeprazole and esomeprazole are also available as granules for an oral suspension. Suspension formulations for both omeprazole and lansoprazole have been extemporaneously compounded and evaluated for stability. Esomeprazole has also been recently approved for use in children with GERD aged 1 to 11 years and has been studied and reviewed extensively.[74,78,79]

Histamine-2 Receptor Antagonists

H_2RA reduce histamine-stimulated acid secretion, but have limited effects on acid secretion by other chemical mediators and other stimuli. In randomized, controlled trials, H_2RA in infants and children relieved symptoms and facilitated the healing of esophageal tissue.[65,66] Tolerance to the acid-suppressant activity of H_2RA for a relatively short time (<30 days), however,[67,68] can limit their use for long-term treatment of esophagitis. Oral liquid formulations are available for most H_2RA. Ranitidine is also available in an effervescent tablet.

Table 104-3

Oral Drugs Used to Treat Gastroesophageal Reflux in Infants[58,59,62–71]

Agent	Mode of Action	Oral Dosage
Acid-Suppressing Agents		
Antacids (aluminum or magnesium hydroxide)	Neutralizes acid	0.5–1.0 mL/kg/dose before and after feeding (maximum, 15 mL/dose)
Proton-Pump Inhibitors		
Omeprazole	Decrease acid secretion via inhibition of gastric hydrogen-potassium adenosine triphosphatase	5 kg–<10 kg: 5 mg daily 10 kg–≤20 kg: 10 mg daily >20 kg: 20 mg daily Alternate dosing: 1 mg/kg daily or twice daily
Esomeprazole		1–11 years: 10 mg daily (>1 mg/kg/day or therapy >8 weeks has not been evaluated) ≥12 years: 20 mg daily
Lansoprazole		Infants ≥3 months: 7.5 mg twice daily or 15 mg once daily 1–11 years: 15 mg (<30 kg)–30 mg (>30 kg) daily

		≥12 years: 15 mg daily
Pantoprazole		<5 years: 1.2 mg/kg/day once daily >5 years: 20 or 40 mg once daily
H_2 Receptor Antagonists		
Cimetidine	Blocks H_2-receptors; ↓ acid secretion	30–40 mg/kg/day divided QID
Famotidine		1 mg/kg/day divided BID
Nizatidine		10 mg/kg/day divided BID
Ranitidine		5–10 mg/kg/day divided BID or TID
Prokinetic Agents		
Bethanechol	Cholinergic agent; stimulates peristalsis ↑ ↑ LES pressure; ↑ gastric emptying; ↑ colonic motility ↑ Gastric emptying; ↑ LES pressure; augments esophageal clearance	0.1–0.2 mg/kg/dose QID given 30–60 minutes before feeding and HS
Metoclopramide	Dopamine antagonist	0.1–0.2 mg/kg/dose QID given 30 minutes before feeding and HS
Erythromycin	Motilin agonist stimulates smooth muscle contraction	3 mg/kg/dose QID; maximum dose: 10 mg/kg or 250 mg
Surface-Active Agents		
Sucralfate	Forms paste and adheres to damaged esophageal mucosa	40–80 mg/kg/day divided QID

BID, 2 times daily; HS, at bedtime; LES, lower esophageal sphincter; QID, 4 times daily; TID, 3 times daily.

Prokinetic Agents

Metoclopramide, a dopamine antagonist with cholinergic and serotonergic effects, accelerates gastric emptying, increases LES pressure, enhances esophageal clearance, and accelerates transit time in the small bowel; however, its effects on vomiting and esophageal pH in children with GER has been equivocal.[69,70] Additionally, metoclopramide has been associated with significant CNS (i.e., restlessness, drowsiness, and extrapyramidal) effects, recently receiving a special alert for a higher risk of extrapyramidal symptoms in those <1 year of age, and rare reports of gynecomastia and galactorrhea.[59] Erythromycin increases GI motility by increasing smooth muscle contractions through its motilin agonistic activity, and it has been used as a prokinetic agent for GER in children, when acid suppression therapy alone was ineffective.[80] Erythromycin-induced development of infantile hypertrophic pyloric stenosis, arrhythmias, and potential changes in bacterial resistance patterns, however, limit its use for GER. The cholinergic agonist, bethanechol, reportedly reduces vomiting episodes in infants with GER[40,58,81]; however, its role in treating GER in infants is limited because of its potential to induce bronchospasm and to stimulate gastric acid secretion. The lack of a suitable commercially available formulation of bethanechol for young infants necessitates its extemporaneous compounding. Baclofen, which decreases transient LES relaxations through its γ-aminobutyric acid agonist actions, could be a future therapeutic option for GER, pending further study.[82] Generally, prokinetic agents only are marginally effective in the management of GER.

Surface-Active Agents

Sucralfate was equally effective as cimetidine for use in esophagitis[83]; however, its use for GER is more limited because of concern about the adverse effects of aluminum-containing products in infants.

CASE 104-7, QUESTION 2: Four weeks after instituting positional and dietary measures, S.B. continues to vomit and still has not been gaining weight. On physical examination, the gastroenterologist notes bilateral wheezes; endoscopy rules out esophagitis. What would be the next step of therapy?

The treatment of S.B. can include acid-suppression therapy. Acid-suppression therapy in children who have complications from GER can be implemented by a step-up approach in which treatment is initiated with an H_2RA followed by a PPI if no improvement is noted, or through a step-down approach involving a PPI followed by an H_2RA for maintenance therapy. However, initial therapy with PPI is preferred,[58,59] and S.B. may be treated with omeprazole 5 mg daily. Granules for suspension may be mixed in 10 mL of water and administered orally.

The effectiveness of acid suppression for managing symptoms of GER in children is not as well documented as it is for healing esophagitis; however, acid suppression is believed to play a useful role for symptom control, particularly for managing the respiratory symptoms.[58] Treatment should be continued for at least 3 to 4 months, although the optimal duration of therapy is unknown. If S.B. requires additional drug therapy to control symptoms of GER beyond 18 months to 2 years of age, surgery should be considered because GER is unlikely to resolve spontaneously after this age.[84] Surgery might be considered earlier if S.B. fails medical therapy or if he develops an esophageal stricture, apnea, or recurrent respiratory disease.[58]

COMMON PEDIATRIC INFECTIONS

Acute Otitis Media

Acute otitis media (AOM) is the most common reason for antimicrobial use in children, and is associated with expenditures of $350 per episode and, cumulatively, almost $3 billion annually.[85] AOM is most common from the ages of 3 months to 3 years, although the highest incidence occurs between 6 and 9 months of age. Most children will have had at least one episode by the time they reach 1 year of age.[86] Incidence is higher in the winter months, concurrent with viral upper respiratory illnesses. Several risk factors for AOM have been identified and include age younger than 2 years, early colonization of pathogens and onset of AOM, day-care attendance, bottle propping, cleft palate, immune compromise, and Down syndrome. Other factors such as smoke exposure, bottle feeding, pacifier use, and ethnicity have not been consistently found to increase risk of AOM.[87,88]

Eustachian tube dysfunction, either from intermittent causes such as upper respiratory infections or permanent causes such as cleft palate, is the primary condition required for the development of AOM. This results in a defect in the eustachian tube's ability to equilibrate middle ear pressure. Thus, nasopharyngeal contents, including bacteria, may be aspirated into the middle ear. This process is more likely in infants and young children who have shorter, flatter eustachian tubes.[87] Changes in pressure can also cause increased vascular permeability, resulting in an effusion. Viral infections contribute by enhancing bacterial transfer from the nasopharynx and adherence to the middle ear.[87]

S. pneumoniae, nontypeable Haemophilus influenzae, and Moraxella catarrhalis colonize the nasopharynx early in childhood, and thus, are the most common pathogens causing AOM.[87] Historically, these pathogens have been implicated in 28% to 54%, 32% to 59%, and up to 63% of cases of AOM, respectively.[89] The introduction of the pneumococcal conjugate vaccine (PCV7) reduced the overall incidence of AOM, the recurrence of AOM, and the need for tympanostomy tube insertion.[85–87] However, the incidence of AOM caused by non-PCV7 serotypes, H. influenzae, and M. catarrhalis increased with the reduction in AOM cases caused by PCV7 serotypes.[85,86,90,91] These studies were used to guide the development of a 13-valent PCV (PCV13), which was approved and licensed to replace the PCV7 in 2010. The PCV13 vaccine includes six of the serotypes that had been shown to produce more than 60% of non-PCV7 vaccine strain invasive infections. The PCV13 vaccine has shown increased protective effects against AOM because of the reduction in nasopharyngeal colonization by emerging serotypes.[92,93] Overall, studies have shown that PCV13 provides a reduction in pneumococcal disease, including AOM, in children.[93]

CASE 104-8

QUESTION 1: C.D. is a 7-month-old, 8-kg infant who during the last 36 hours has developed cough, ear pain, and rhinorrhea, became irritable and at times inconsolable, and now has a temperature of 102.4°F (39.1°C). Physical examination shows bulging, dark, yellow opaque tympanic membranes bilaterally. This is the first time he has had these symptoms and has had no recent courses of antibiotics. What signs and symptoms do C.D. exhibit, which are consistent with AOM, and how should AOM be diagnosed?

Very often, as in this patient case, otitis media is preceded by an upper respiratory tract infection. These viral infections often will produce otitis media with effusion (OME), which typically will cause no more than temporary mild hearing loss. If

AOM develops, more signs and symptoms will usually arise. These symptoms can include otalgia (pain causing infants to pull on or rub the ears), fever, irritability, and otorrhea.[89] Unfortunately, aside from otorrhea, these symptoms are nonspecific and may be present in many children who do not have AOM. As a result, a definitive diagnosis may not be easily obtained with symptoms alone. Diagnosis should be confirmed on visualization of the middle ear.

In 2013, the American Academy of Pediatrics (AAP) published guidelines on the diagnosis and management of AOM that stated that a diagnosis of AOM requires mild bulging of the tympanic membrane and either recent onset of ear pain (<48 hours) or intense erythema of the tympanic membrane.[89] Pneumatic otoscopy should be used to confirm the presence of effusion. Middle ear effusion can be differentiated from AOM in that, whereas both present with bulging tympanic membranes, in AOM, the middle ear fluid is more often dark yellow or red.[87,89] Other diagnostic tools may be used. Tympanometry uses sound waves to measure the compliance of the tympanic membrane. In acoustic reflectometry, the absorption of sound waves by the tympanic membrane provides information about the middle ear in that an effusion will cause more sound to be reflected back than a normal ear.[87] C.D.'s fever and irritability along with fluid in the middle ear and bulging, dark yellow tympanic membranes are consistent with the diagnosis of AOM.

CASE 104-8, QUESTION 2: How should C.D.'s otitis media be treated?

The 2013 AAP recommendations provide for the option to observe without treatment or to treat with antibiotics, depending on the age of the patient and symptoms present.[89] Generally, infants 6 months of age and younger should receive antibiotic therapy in all cases. Infants and children 6 months to 2 years of age can be managed with observation if there is a nonsevere unilateral AOM without otorrhea. Children 2 years of age and older can be managed with observation in bilateral or unilateral nonsevere AOM without otorrhea. Antibiotics are warranted in all cases of AOM with otorrhea or in AOM cases with severe symptoms (e.g., temperature >39°C in past 48 hours).[89]

C.D. appears to have bilateral AOM with severe symptoms based on his fever greater than 39°C, so antibiotic therapy is indicated. Despite pneumococcal penicillin resistance rates, initial therapy in most children who have not received amoxicillin in the last 30 days, would still be amoxicillin at a dose of 80 to 90 mg/kg/day.[89] Amoxicillin is effective against susceptible and intermediately resistant pneumococcus, it is affordable and palatable, and it has a narrow spectrum of activity.[86] Providers should prescribe amoxicillin/clavulanate in children who have received amoxicillin in the last 30 days, have concurrent purulent conjunctivitis, or have a history of recurrent AOM unresponsive to amoxicillin.[89] Oral cephalosporins, including cefdinir, cefuroxime, or cefpodoxime, are options in patients with a non-Type I allergy to penicillin, and macrolides such as azithromycin or clarithromycin may be used in those with Type I allergies to penicillin.

Whichever treatment course is taken in a patient (observation or antibiotic therapy with amoxicillin or amoxicillin/clavulanate), effectiveness is assessed for 48 to 72 hours. If the treatment is effective, the patient should defervesce, irritability should decrease, and normal activity should resume (e.g., eating and sleeping). If the observation is ineffective, treatment with amoxicillin or amoxicillin/clavulanate is recommended. If amoxicillin or amoxicillin/clavulanate is ineffective for C.D., ceftriaxone 400 mg (50 mg/kg) intramuscularly for 1 or 3 days is an option.

CASE 104-8, QUESTION 3: How should C.D.'s otalgia be managed?

Ear pain is a common feature of AOM, and it should be addressed regardless of the decision to use antibiotics or not. Acetaminophen 120 mg (15 mg/kg) or ibuprofen 80 mg (10 mg/kg) can provide adequate relief, and are first-line agents in the management of otalgia.[89] Home remedies such as the application of heat or cold may also be helpful.[89] For example, a washcloth can be soaked with very warm water, wrung out, and placed over the ear for comfort for 15 minutes several times per day.

Acute Pharyngitis

Acute pharyngitis is most common in children 5 to 15 years of age and is rare before 3 years of age. The etiology is typically viral, but bacteria such as group A streptococci (GAS, Streptococcus pyogenes), groups C and G streptococci, Neisseria gonorrhoeae, Mycoplasma pneumoniae, and Chlamydia pneumoniae may also cause pharyngitis in children.[94] The majority of attention is directed toward the detection and management of GAS infections as, untreated, they may lead to rheumatic fever, a complication progressing to permanent heart disease.

CASE 104-9

QUESTION 1: P.J., a 6-year-old boy weighing 23.4 kg, presents to the pediatrician's office complaining of fever, sore throat, and headache. His mother reports that he initially complained of sore throat about 12 hours ago. His oral temperature this morning was 102°F. He takes no medications and has no known drug allergies. Physical examination reveals erythematous tonsils and throat, as well as an enlarged anterior cervical lymph node. Are P.J.'s symptoms more consistent with GAS or viral pharyngitis?

Findings suggestive of GAS tonsillopharyngitis include sudden onset of throat pain, fever, headache, abdominal pain, nausea, vomiting, tonsillopharyngeal edema, enlarged anterior cervical lymph nodes, soft palate petechiae, and a scarlatiniform rash.[94] Symptoms that increase the likelihood of a viral cause include rhinorrhea, cough, conjunctivitis, and viral rash.[94] P.J. is lacking associated symptoms that would suggest a viral cause and has more symptoms of GAS pharyngitis, but confirmatory testing is needed.

DIAGNOSIS

Because clinical and physical findings are not definitive for GAS pharyngitis, confirmatory testing is important to determine the need for antibiotic therapy. A rapid antigen detection test is recommended, and, if positive, treatment is initiated. If negative, a throat culture should also be obtained and treatment initiated if the culture grows GAS. Rheumatic fever can be effectively prevented if treatment is started within 9 days from the start of the illness.[94]

CASE 104-9, QUESTION 2: A rapid antigen detection test for GAS is performed for P.J. and is positive. What treatment should be initiated at this time?

TREATMENT

Penicillins remain the agents of choice for GAS pharyngitis. Either oral penicillin, oral amoxicillin, or intramuscular benzathine penicillin may be used. Amoxicillin suspension is more palatable than penicillin and has the advantage of a once-daily dosing regimen. Intramuscular penicillin is a one-time dose that is helpful in those at risk for nonadherence. In patients with a Type I hypersensitivity to penicillins, azithromycin, clarithromycin, or clindamycin may be used. In those with a non-Type I allergy to penicillin, a first-generation cephalosporin may be considered. Recommended regimens are summarized in Table 104-4.[94,95] Although there is little reported GAS resistance to penicillin, some patients have a decreased clinical response and may respond better to cephalosporins. This is often seen in patients who are GAS carriers and those who may have other bacteria causing infection. Patients are no longer contagious 24 hours after the first antibiotic dose.[95]

Table 104-4

Medication Regimens for the Treatment of Streptococcal Pharyngitis and Prevention of Rheumatic Fever[94,95]

Medication	Dose	Duration
Amoxicillin	50 mg/kg once a day or 25 mg/kg twice a day (maximum 1 g/day)	10 days
Penicillin VK	Children ≤27 kg: 250 mg 2 or 3 times a day Children >27 kg, adolescents: 500 mg 2 or 3 times a day or 250 mg 4 times a day	10 days
Benzathine penicillin G	≤27 kg: 600,000 units IM >27 kg: 1,200,000 units IM	Once
For Patients with Penicillin Allergy		
Cephalexin	20 mg/kg (up to 500 mg) twice a day	10 days
Cefadroxil	30 mg/kg (up to 1 g) once a day	10 days
Clindamycin	7 mg/kg 3 times a day (maximum 300 mg/dose)	10 days

Azithromycin	12 mg/kg once a day (maximum 500 mg)	5 days
Clarithromycin	7.5 mg/kg twice a day (maximum 250 mg/dose)	10 days

IM, intramuscular.

Table 104-5

Medication Regimens for the Prevention of Recurrent Rheumatic Fever[95,96]

Medication	Dose	Frequency
Benzathine penicillin G	≤27 kg: 600,000 units IM >27 kg: 1,200,000 units IM	Every 4 weeks
Penicillin V	250 mg oral	Twice a day
Sulfadiazine	≤27 kg: 0.5 g oral >27 kg: 1 g oral	Once a day
If allergic to above agents		
Erythromycin[96]	250 mg oral	Twice a day

IM, intramuscular.

P.J. should receive amoxicillin (400 mg/5 mL), 12.5 mL (1,000 mg) every 24 hours for 10 days. For pain relief, he may also receive as-needed doses of acetaminophen (160 mg/5 mL), 10 mL every 6 hours, or ibuprofen (100 mg/5 mL), 10 mL every 6 hours.

Those with a history of rheumatic fever, characterized by acute generalized inflammation of the heart, joints, brain, or skin, should receive long-term antibiotic prophylaxis to prevent further complications from streptococcal infections. Recommended medications and dosing regimens are summarized in Table 104-5.[95,96] Patients with acute carditis and residual heart disease should receive treatment for 10 years or until 40 years of age, whichever is longer.[95] Patients with an episode of carditis but without residual heart disease should receive treatment for 10 years or at least until 21 years of age.[95] Patients who had rheumatic fever without carditis should receive treatment for 5 years or at least until 21 years of age.[95]

105

Neonatal Therapy

Donna M. Kraus, Jennifer T. Pham, and Kirsten H. Ohler

CORE PRINCIPLES

RESPIRATORY DISTRESS SYNDROME

CORE PRINCIPLES	CHAPTER CASES
① Respiratory distress syndrome (RDS) is a major cause of morbidity and mortality in preterm neonates, resulting from pulmonary surfactant deficiency; it is characterized by atelectasis, hypoxemia, decreased lung compliance, small airway epithelial damage, and pulmonary edema.	**Case 105-1 (Question 1)**
② Beractant, calfactant, poractant alfa, and lucinactant are exogenous surfactants used in the prevention and treatment of RDS in preterm neonates. These agents have been shown to improve oxygenation and lung compliance and decrease the need for supplemental oxygen and mechanical ventilation.	**Case 105-1 (Questions 2–6)**

BRONCHOPULMONARY DYSPLASIA

CORE PRINCIPLES	CHAPTER CASES
① Bronchopulmonary dysplasia (BPD) is the most common form of chronic pulmonary disease in infants; it is caused by lung immaturity, surfactant deficiency, oxygen toxicity, barotrauma, and inflammation, and is characterized by tachypnea, retractions, and wheezing.	**Case 105-2 (Question 1)**
② The management of BPD includes supplemental oxygen therapy, mechanical ventilation, and pharmacologic interventions including diuretics, bronchodilators, and corticosteroids.	**Case 105-2 (Questions 2, 3)**
③ Infants with BPD are at higher risk for experiencing cardiorespiratory problems including pneumonia, pulmonary hypertension, left ventricular hypertrophy, and neurologic and developmental abnormalities.	**Case 105-2 (Questions 4, 5)**

PATENT DUCTUS ARTERIOSUS

CORE PRINCIPLES	CHAPTER CASES
① Preterm neonates are at high risk for patent ductus arteriosus (PDA), a serious cardiovascular disorder, which may present with tachycardia, wide pulse pressure, bounding pulses, and systolic murmur. Complications of PDA include pulmonary edema and heart failure. PDA places the neonate at high risk for BPD, intraventricular hemorrhage, and necrotizing enterocolitis.	**Case 105-3 (Questions 1–3)**
② Medical management of PDA includes fluid management, correction of anemia, treatment of hypoxia and acidosis, and pharmacologic therapy with prostaglandin inhibitors (indomethacin or ibuprofen) to close the	**Case 105-3 (Questions 4–10)**

ductus.	

NECROTIZING ENTEROCOLITIS

① Necrotizing enterocolitis (NEC) is the most common life-threatening nonrespiratory condition in newborns and is characterized by abdominal distension, bloody stools, metabolic acidosis, and bowel perforation.	**Case 105-4 (Question 1)**
② The management of NEC includes parenteral nutrition, intravenous antibiotics, and bowel resection. Interventions including trophic feedings, breast milk, probiotics, and a strict feeding protocol may be used to decrease the incidence of NEC.	**Case 105-4 (Questions 2–6)**

NEONATAL SEPSIS AND MENINGITIS

① Bacterial sepsis can be classified as early-onset (caused by pathogens colonized from the maternal genital tract) or late-onset sepsis (caused by nosocomial pathogens). Clinical signs can be subtle and nonspecific especially in preterm neonates.	**Case 105-5 (Question 1)**
② Selection of empiric intravenous antibiotics is the same for sepsis and meningitis and will depend on nosocomial pathogens commonly isolated in the neonatal intensive care unit, antibiotic resistance patterns, and underlying neonatal risk factors.	**Case 105-5 (Question 2)**

CONGENITAL INFECTIONS

① Congenital infections including herpes simplex virus, syphilis, and cytomegalovirus may result in fetal death, congenital anomalies, serious central nervous system sequelae, intrauterine growth retardation, or preterm birth; if suspected, appropriate diagnostic tests and treatment should be started immediately.	**Case 105-6 (Question 1)**

APNEA OF PREMATURITY

① Pharmacologic treatment of apnea of prematurity includes the use of methylxanthines, specifically caffeine and theophylline, which decrease apneic episodes via both central and peripheral effects.	**Case 105-7 (Question 1)**
② Caffeine offers several advantages over theophylline for the treatment of apnea including a wider therapeutic index, fewer adverse effects, prolonged half-life, once-daily dosing, and lack of the need for routine serum drug concentration monitoring.	**Case 105-7 (Questions 2, 3)**

NEONATAL SEIZURES

① Neonatal seizure activity is a common manifestation of a life-threatening underlying neurologic process. Initial therapy is focused on the treatment of the underlying cause (e.g., hypoglycemia, hypocalcemia, infection) and may not include antiepileptic drug therapy.	**Case 105-8 (Questions 1–3)**

② Common antiepileptic medications used to treat neonatal seizure activity are phenobarbital, phenytoin, and lorazepam.	**Case 105-8 (Questions 4, 5)**

NEONATAL THERAPY

The rational use of medications in neonates depends on an appreciation of both the physiologic immaturity and the developmental maturation that influence neonatal drug disposition and pharmacologic effects. Much progress has been made to decrease neonatal mortality and improve survival of more premature and lower-birth-weight newborns. Neonates, particularly those of extremely low birth weights (ELBW), pose a pharmacotherapeutic challenge to the clinician. The alterations of body composition, weight, and size, as well as physiologic and pharmacokinetic parameters, which occur with normal growth and maturation during the first few months of life, are greater than at any other time. Although the amount of neonatal drug information is increasing, the overall lack of well-designed pharmacokinetic and pharmacodynamic studies still hinders the clinical use of many drugs in this population. This is especially true for newborns of the lowest birth weights (<750 g). An understanding of common neonatal terminology (Table 105-1) is important because every newborn is evaluated and classified at birth according to birth weight, gestational age, and intrauterine growth status.[1] Pharmacokinetic parameters, pharmacodynamics, and dosing recommendations often are specified according to these terms.[2] Important neonatal pharmacokinetic differences are reviewed in Chapter 102, Pediatric Pharmacotherapy. This chapter focuses on the safe and effective use of medications for common neonatal medical conditions.

RESPIRATORY DISTRESS SYNDROME

Respiratory distress syndrome (RDS) is a major cause of morbidity and mortality in preterm neonates.[3] This clinical syndrome is characterized by respiratory failure with atelectasis, hypoxemia, decreased lung compliance, small airway epithelial damage, and pulmonary edema. The principal cause of RDS is pulmonary surfactant deficiency. Pulmonary surfactant decreases the surface tension at the air–fluid interface in the alveoli and prevents alveolar collapse. Surfactant also facilitates the clearance of pulmonary fluid, prevents pulmonary edema, and stabilizes alveoli during aeration. At birth, the clearance of residual fetal lung fluid is accompanied by an increase in pulmonary blood flow, which facilitates the transition from fetal to adult circulation.[4]

Table 105-1

Common Neonatal Terminology[1,2]

Term	Definition
Gestational age (GA)	By dates: The number of weeks from the onset of the mother's last menstrual period until birth
	By examination: Assessment of gestational maturity by physical and neuromuscular examination; gestational age estimates the time from conception until birth
Postnatal age (PNA)	Chronologic age after birth
Postmenstrual age (PMA)	Gestational age plus postnatal age. Postmenstrual age (rather than postconceptional age) is the preferred term for use in clinical practice. Postmenstrual age is considered to be a more accurate term because gestational age is calculated using the mother's last menstrual period, and the exact date of conception is generally not known.
Postconceptional age (PCA)	Age since conception. This term is not recommended for use in clinical practice and is currently reserved for cases when the exact date of conception is known (i.e., assisted reproductive technology). Older literature may use this term to describe the sum of gestational age plus postnatal age; thus, it is important to know how this term is defined when used.
Corrected age	Postmenstrual age in weeks minus 40; represents postnatal age if neonate had been born at term (40 weeks' gestational age)
Neonate	A full-term newborn 0 to 28 days postnatal age. Some may also apply this term to a preterm neonate who is > 28 days postnatal age, but with a postmenstrual age ≤ 42 to 46 weeks
Preterm	<37 weeks' gestational age at birth
Term	37 weeks' 0 days to 41 weeks' 6 days (average ~ 40 weeks') gestational age at birth
Post-term	≥42 weeks' gestational age at birth
Extremely low birth weight (ELBW)	Birth weight <1 kg
Very low birth weight (VLBW)	Birth weight <1.5 kg
Low birth weight (LBW)	Birth weight <2.5 kg
Small for gestational age (SGA)	Birth weight <10th percentile for gestational age
Appropriate for gestational age (AGA)	Birth weight between 10th and 90th percentiles for gestational age
Large for gestational age (LGA)	Birth weight >90th percentile for gestational age

In the fetus, endogenous cortisol stimulates the synthesis and secretion of pulmonary surfactant at 30 to 32 weeks' gestational age.[4] However, sufficient amounts of pulmonary surfactant for normal lung function are not present before 34 to 36 weeks' gestation.[4,5] Therefore, the incidence and severity of RDS increase as gestational age decreases. RDS occurs in approximately 25% of neonates born at 30 to 31 weeks' gestation, but may occur in as high as 95% to 98% of neonates born at 22 to 24 weeks' gestation.[3]

Without adequate amounts of surfactant, the surface tension within the alveoli is so great that the alveoli collapse (atelectasis), resulting in poor gas exchange (e.g., hypoxemia, hypercapnia). Low lung compliance also results, and large inspiratory pressures are needed to aerate the lungs. Unfortunately, the extremely compliant neonatal chest wall makes it difficult to create the large negative inspiratory pressures necessary to open the alveoli. This results in an increased work of breathing and alterations of ventilation and perfusion.[3,4]

Aeration of the surfactant-deficient lung also results in the cyclic collapse and distension of bronchioles, with resultant bronchiolar epithelial injury and necrosis. This epithelial damage causes pulmonary edema by allowing fluid and proteins to leak from the intravascular space into the airspaces and interstitium of the lung. The necrotic epithelial debris and proteins then form fibrous hyaline membranes.[3] Hyaline membranes and pulmonary edema further impair gas exchange.

The inadequate oxygenation and ventilation and increased work of breathing caused by RDS may result in the need for assisted positive-pressure ventilation. Complications of RDS may be related to mechanical ventilation and include pulmonary barotrauma (e.g., pneumothorax, pulmonary interstitial emphysema [PIE]), intraventricular hemorrhage (IVH), patent ductus arteriosus (PDA), retinopathy of prematurity (ROP), and chronic lung disease or bronchopulmonary dysplasia (BPD).[3]

Clinical Presentation

CASE 105-1

QUESTION 1: L.D., a 680-g male, was born at 25 weeks' gestational age via cesarean section as a result of placenta abruption to a 38-year-old gravida 6 para 5 woman with gestational diabetes. Apgar scores were 3 at 1 minute, 5 at 5 minutes, and 8 at 10 minutes. Thirty minutes after birth, L.D. appears cyanotic and has retracting respirations with grunting and nasal flaring. His heart rate (HR) is 160 beats/minute, and respiratory rate (RR) is 65 breaths/minute. An arterial blood gas (ABG) on 60% oxygen by nasal intermittent positive-pressure ventilation (NIPPV) is as follows:

pH, 7.25
PCO_2, 41 mm Hg
PO_2, 71 mm Hg
Base deficit, 8

Based on the blood gas results, L.D. is intubated immediately and placed on positive-pressure-assisted ventilation. An umbilical arterial catheter is inserted for frequent ABG monitoring, and an umbilical vein catheter is inserted for central venous access. L.D.'s chest radiographic shows RDS (see http://www.adhb.govt.nz/newborn/teachingresources/radiology/CXR/RDS/RDS.jpg for a radiograph of an infant with RDS). Ampicillin 100 mg/kg every 12 hours and gentamicin 5 mg/kg every 48 hours are ordered intravenously (IV) to rule out sepsis. What is an Apgar score? What risk factors does L.D. have for RDS? What signs and laboratory data are consistent with RDS?

An Apgar score is a method of evaluating the physical condition of a newborn infant immediately after birth. It consists of

---

five clinical signs including HR, respiratory effort, muscle tone, skin color, and reflex irritability. Each sign can receive a score of 0 to 2 points with a total possible score of 10 points. A score of 7 to 10 is considered normal, whereas scores of 0 to 3 require immediate resuscitation. The Apgar score is routinely done at 1 and 5 minutes of life and is repeated every 5 minutes until a total score of at least 7 is achieved. (For a video of how to assign an Apgar score to newborns, go to http://online.wsj.com/video/assigning-an-apgar-score-to-newborns/9B7B09A9-1B12-4C65-92BA-D4C6DFA35BBA.html?mod=googlewsj.) L.D.'s Apgar scores of 3 and 5 at 1 and 5 minutes indicate that he may have experienced some perinatal asphyxia, most likely secondary to maternal placenta abruption. L.D.'s risk factors for RDS are prematurity, male sex, perinatal asphyxia, cesarean section, and maternal gestational diabetes. Other risk factors include second-born twins and maternal-fetal hemorrhage.[3] Clinical signs and laboratory data consistent with RDS in L.D. include tachypnea, cyanosis, retracting respirations, grunting, nasal flaring, hypoxemia, hypercapnia, and a mixed respiratory and metabolic acidosis.[3] Clinical manifestations classically present within the first 6 hours of life.

Tachypnea, the first sign of respiratory distress, is an attempt to compensate for the inadequate ventilation, hypercapnia, and acidosis. L.D.'s retracting respirations (the use of intercostal, subcostal, suprasternal, or sternal accessory muscles) reflect the increased work of breathing necessary to maintain ventilation. His nasal flaring decreases resistance during inspiration and increases oxygenation. Grunting is the result of forceful exhalation against a partially closed glottis in an effort to prolong expiration and maximize oxygenation. Grunting also increases intrathoracic pressure during expiration in an attempt to stabilize the alveoli and prevent atelectasis. L.D.'s cyanosis, hypoxemia, hypercapnia, and mixed respiratory and metabolic acidosis are consequences of inadequate oxygenation and poor ventilation and are consistent with RDS.[3]

Treatment

CASE 105-1, QUESTION 2: What treatments should be initiated for L.D.'s respiratory insufficiency?

Before L.D. is treated for RDS, other causes of respiratory distress must be ruled out. For example, infections (particularly group B streptococcal sepsis or pneumonia) often present with respiratory distress. Because it is difficult to distinguish between RDS and infection, all neonates with severe RDS should receive antibiotics. L.D. was started empirically on antibiotics, and a complete evaluation of possible sepsis should be performed.

Neonates should be treated for RDS as soon as possible and may require ventilatory support. Noninvasive ventilator support such as NIPPV or nasal continuous positive airway pressure (CPAP) has been shown to reduce barotrauma, volutrauma, and airway damage compared to intubation with mechanical ventilation.[3] However, some extremely preterm neonates may require intubation with mechanical ventilation due to persistent symptoms of RDS. Because L.D. failed NIPPV and required intubation, exogenous surfactant should be administered intratracheally as soon as possible. Human surfactant is synthesized and secreted by type II alveolar epithelial cells of the lung. It contains 80% phospholipids, 8% neutral lipids, and 12% proteins.[5] The major surface-active component is dipalmitoylphosphatidylcholine (DPPC), also known as colfosceril or lecithin. However, this phospholipid slowly adsorbs to the air–fluid interface in the alveoli. Other phospholipids (e.g., phosphatidylcholine, phosphatidylglycerol) and four surfactant apoproteins (SP-A, SP-B, SP-C, and SP-D) enhance spreadability and surface adsorption.[5] Adsorption and surface spreading of the surfactant in the alveoli are important determinants of surface tension activity. SP-A and SP-D both play a role in immune regulation and providing host defense. SP-A may also help to regulate alveolar surfactant reuptake and metabolism.[5] SP-B and SP-C are the two most important apoproteins responsible for promoting adsorption and surface spreading of the surfactant in the alveoli to form a phospholipid monolayer.[5] SP-B is thought to be the most critical protein for surfactant activity.

Natural surfactants are derived from bovine or porcine lung lipid or lavage extracts. Modified natural surfactants are lung lipid extracts supplemented with phospholipids or other components.[3] Currently, four surfactant products are commercially available for clinical use in the United States (US): beractant (Survanta), calfactant (Infasurf), poractant alfa (Curosurf), and lucinactant (Surfaxin). Beractant, calfactant, and lucinactant are US Food and Drug Administration (FDA)-approved for the prevention (i.e., prophylaxis) of RDS, whereas beractant, calfactant, and poractant alfa are approved for treatment (i.e., rescue therapy). Animal-derived products contain variable amounts of SP-B and SP-C, lipids, and phospholipids. Lucinactant, a new synthetic surfactant, contains not only phospholipids but also high concentrations of sinapultide (KL4), a synthetic peptide that mimics human SP-B. (see Table 105-2 for comparisons).[6–9]

CASE 105-1, QUESTION 3: What are the effects of exogenously administered surfactant that can be expected in L.D.?

Oxygenation and lung compliance rapidly and markedly improve after the administration of surfactant. It should be expected that supplemental oxygen and mechanical ventilation may need to be significantly reduced. The increased lung compliance and decreased need for high inspiratory pressures result in a dramatic decrease in the incidence of pneumothorax and PIE. Survival in treated infants increases by approximately 40% regardless of birth weight or gestational age, and neonatal mortality from RDS is decreased to approximately 20%.[10] Other complications of RDS such as severe BPD, IVH, NEC, ROP, and PDA have not been decreased consistently with surfactant therapy.[11]

CASE 105-1, QUESTION 4: Which surfactant is appropriate and when should it be administered to L.D.?

PRODUCT SELECTION

Trials comparing natural surfactant products (poractant alfa vs. beractant, calfactant vs. beractant, poractant alfa vs. calfactant) have demonstrated that poractant alfa and calfactant result in a significantly faster weaning of supplemental oxygen and mean airway pressure compared to beractant. Furthermore, a lower mortality rate at 36 weeks' PMA was seen with a higher initial dose of poractant alfa 200 mg/kg. No differences were seen with the duration of mechanical ventilation and supplemental oxygen, the incidence of BPD, and other secondary outcomes.[12,13] To date, there is only one trial comparing the three natural surfactant products for the treatment of RDS. Overall, there were no significant differences in the incidence of pneumothorax, PIE, death, and the combined variable of BPD or death among the three surfactant products.[14]

Trials comparing synthetic (lucinactant) to a natural surfactant product (beractant or poractant alfa) found no difference in the incidence of RDS at 24 hours; however, one study reported a significantly higher incidence of RDS-related death by 14 days of life and NEC in the beractant group.[15] In addition, no significant differences were found with mortality, BPD, IVH, PDA, and ROP between synthetic and natural surfactants.[15,16]

Studies assessing the long-term neurodevelopmental outcomes (at 1 year and at 18 to 24 months of corrected age) of infants receiving surfactants (beractant vs. poractant alfa and lucinactant vs. beractant or poractant alfa) for RDS found no significant difference between products.[17,18]

Table 105-2

Comparison of Currently Marketed Surfactant Products[6–9]

Variable	Calfactant (Infasurf)	Poractant Alpha (Curosurf)	Beractant (Survanta)	Lucinactant (Surfaxin)
Type and source	Natural surfactant, calf lung wash	Natural surfactant,	Modified natural surfactant, bovine lung	Synthetic surfactant, protein analog

		porcine lung mince extract	mince extract	
Phospholipids (PL)	Natural DPPC with mixed PL	Natural DPPC with mixed PL	Natural and supplemented DPPC with mixed PL	Synthetic DPPC with mixed PL
Proteins	SP-B and SP-C	SP-B and SP-C	SP-B and SP-C	Sinapultide (KL4 peptide)
Indications	Prophylaxis and rescue therapy	Rescue therapy	Prophylaxis and rescue therapy	Prophylaxis therapy
Criteria for prophylaxis	Premature neonates <29 weeks' GA at high risk for RDS	Not approved	Birth weight <1,250 g or evidence of surfactant deficiency	Premature neonates at high risk for RDS
Recommended dose	3 mL/kg (PL 105 mg/kg)	Initial dose: 2.5 mL/kg (PL 200 mg/kg); Repeat dose: 1.25 mL/kg (PL 100 mg/kg)	4 mL/kg (PL 100 mg/kg)	5.8 mL/kg (PL 175 mg/kg)
Recommended regimen for prophylaxis	Give first dose ASAP after birth, preferably within 30 minutes; repeat every 12 hours up to a total of three doses if infant remains intubated	Not approved	Give first dose ASAP after birth, preferably within 15 minutes; repeat as early as 6 hours up to a total of four doses if infant remains intubated and requires FIO$_2$ ≥0.3 with Pao$_2$ ≤80 mm Hg	Give first dose ASAP after birth; repeat as early as 6 hours up to a total of four doses in first 48 hours of life
Criterion for rescue therapy	Infants ≤72 hours of age with confirmed RDS who require endotracheal intubation	Infants with confirmed RDS who require endotracheal intubation	Infants with confirmed RDS who require endotracheal intubation	Not approved
Recommended regimen for rescue therapy	Give first dose ASAP after RDS diagnosed; repeat every 12 hours up to a total of three doses if infant still remains intubated	Give first dose ASAP after RDS diagnosed; repeat every 12 hours up to a total of three doses if infant remains intubated	Give first dose ASAP after RDS diagnosed, preferably by 8 hours postnatal age; repeat as early as 6 hours up to a total of four doses if infant remains intubated and requires FIO$_2$ ≥0.3 with Pao$_2$ ≤80 mm Hg	Not approved
Recommended administration technique	Administer through side port of ETT adapter via ventilator or through disconnected ETT via 5F catheter, divide dose into two aliquots with position change	Administer through disconnected ETT via 5F catheter, divide dose into two aliquots with position	Administer through disconnected ETT via 5F catheter, divide dose into four aliquots with position change	Administer through side port of ETT adapter via ventilator, divide dose into four aliquots with position change

		change		
Special instructions	Gentle swirling of the vial may be necessary for redispersion; warming to room temperature is not necessary; do not shake	Warm to room temperature before use; do not shake	Warm to room temperature before use; do not shake	Warm for 15 minutes in a preheated dry block heater set at 44°C (111°F); after warming, shake vial vigorously until suspension is uniform and free-flowing. The temperature of product has to be ≤ 37°C (99°F) before administration
Stability	If warmed to room temperature for <24 hours, unopened, unused vials may be returned once to refrigerator; single-use vial contains no preservative, discard unused portion	If warmed to room temperature for <24 hours, unopened, unused vials may be returned only once to refrigerator; single-use vial contains no preservative, discard unused portion	If warmed to room temperature for <24 hours, unopened, unused vials may be returned only once to refrigerator; single-use vial contains no preservative, discard unused portion	If not used immediately after warming, can be stored protected from light at room temperature for up to 2 hours. Do not return to refrigerator after warming; discard if not used within 2 hours of warming or any unused portion
Cost per vial	$455.00 (3 mL), $805.33 (6 mL)[a]	$445.15 (1.5 mL), $877.78 (3 mL)[a]	$459.60 (4 mL), $813.46 (8 mL)[a]	$1032.00 (8.5 mL)[a]

[a] Average wholesale price according to 2015 Red Book.

ASAP, as soon as possible; DPPC, dipalmitoylphosphatidylcholine; ETT, endotracheal tube; F, French; F IO$_2$, fractional inspired oxygen; Pao$_2$, partial pressure of oxygen; PL, phospholipids; RDS, respiratory distress syndrome.

Cost-effectiveness studies of different natural surfactant products for the treatment of RDS reported significant cost savings associated with poractant alfa (due to fewer required additional doses) compared with beractant.[12,13] A recent pharmacoeconomic analysis of costs associated with reintubation in preterm infants treated with either lucinactant, beractant, or poractant alfa utilized data from two multicenter trials. Reintubation rates were significantly lower in the lucinactant-treated group.[19] However, it is important to note that one of the studies compared lucinactant to colfosceril palmitate, a product no longer available in the US. Furthermore, the second trial was terminated before achieving enrollment goal. Therefore, these limitations may have affected respiratory outcomes and healthcare costs associated with reintubation and mechanical ventilation.

Based on these comparative trials, it appears there are no significant differences in the short-term (e.g., air leaks, duration of mechanical ventilation/oxygenation) and long-term outcomes (e.g., death, BPD, and other secondary outcomes) between the four surfactant products. Poractant alfa, given at a dose of 200 mg/kg, may be the favorable surfactant therapy because it resulted in a faster weaning of oxygen and mean airway pressure, a decrease in mortality at 36 weeks' PMA, and a lower cost.

TIME AND METHOD OF ADMINISTRATION

Surfactant therapy can be administered as prophylactic (i.e., within 10–30 minutes after birth) or rescue treatment (given to those with established RDS within 12 hours of life). Early rescue is defined as the administration of surfactant within the first 2 hours of life; late rescue is defined as treatment after more than 2 hours of life. Theoretically, the first dose of surfactant should be given before the newborn's first breath or before positive-pressure ventilation.[10] This would avoid the early lung injury in RDS that can interfere with surfactant distribution, bioavailability, and effectiveness. This strategy, however, increases the cost of care because newborns that might never experience RDS would be intubated and treated unnecessarily. In addition, delivery room treatment may interfere with resuscitation and stabilization of the neonate.[10]

Prophylactic surfactant therapy has been shown to decrease the incidence and severity of RDS, mortality, pneumothorax, and PIE, compared with rescue treatment.[11] However, these findings were reported in studies that were conducted prior to routine clinical use of CPAP for the management of RDS. In studies that utilized routine CPAP as initial management of RDS, a significantly lower incidence of BPD or death was seen in the CPAP group when compared with prophylactic surfactant therapy without CPAP. [11] In contrast, when comparing early versus late rescue therapy (regardless of routine initial use of CPAP), infants treated in the early group had significant decreases in the incidence of mortality, air leak, BPD, and the combined variable of BPD or death.[11] Thus, CPAP should be utilized initially, with selective early rescue surfactant administration in infants in whom symptoms of RDS persist.

Surfactant should be administered by qualified physicians with the presence of nursing and respiratory therapy personnel.[14] (For a video on surfactant administration, go to **http://www.youtube.com/watch?v=hkUdH01sLmA&feature=related**.) Surfactants can be administered through a disconnected endotracheal tube (ETT) via 5F catheter or through a side port of ETT adapter via ventilator, depending on the product (see Table 105-2). Both administrative techniques are effective and are not significantly different with regard to clinical outcomes.[11] Several alternative methods of surfactant administration have been utilized in an effort to avoid mechanical ventilation. The "INSURE" (INtubate–SURfactant–Extubate) technique is a strategy that administers surfactant during a brief intubation followed by immediate extubation to nasal CPAP. This technique was associated with a reduced need for mechanical ventilation and subsequent BPD.[11]

Because surfactant works better if given earlier in the course of RDS, it is important to determine who is at highest risk for RDS. Unfortunately, the exact criteria to clinically determine high-risk newborns are still unclear. Surfactant treatment should be administered as soon as clinical signs of RDS appear. The administration of CPAP after birth with subsequent selective surfactant therapy should be the preferred alternative to prophylactic surfactant therapy. Early therapy avoids progression of the disease and the potential for decreased surfactant effectiveness; therefore, it should be considered in preterm infants born at <30 weeks' gestation who need mechanical ventilation because of severe RDS. Because L.D. has clinical, laboratory, and radiographic findings consistent with RDS, a dose of 2.5 mL/kg (200 mg/kg phospholipid) of poractant alfa should be administered to L.D. intratracheally immediately within 1 hour of age with subsequent extubation to CPAP as soon as possible.

CASE 105-1, QUESTION 5: Within 1 hour of poractant alfa administration, L.D.'s oxygenation improved, and the FIO_2 was weaned from 60% to 40%. Ten hours later, the ABGs revealed the following:

pH, 7.30
PCO_2, 45 mm Hg
PO_2, 50 mm Hg
Base deficit, 2
O_2 saturation, 90% on the following ventilator settings: FIO_2, 0.40; intermittent mechanical ventilation (IMV), 30; PIP, 18; positive end-expiratory pressure (PEEP), +5

Should another dose of poractant alfa be administered?

The response to a single dose of surfactant usually is transient; thus, more than one dose may be needed. Response to surfactant therapy can be variable, especially in preterm newborns or in those who require high oxygen and ventilatory pressures.[3] Reasons for lack of response include surfactant inhibition by proteins that have leaked into the alveolar spaces, inactivation of surfactant by inflammatory mediators (free oxygen radicals, proteases), presence of conditions that can decrease surfactant effectiveness (e.g., pulmonary edema), or poor delivery of surfactant to the alveoli (owing to atelectasis).[3] The degree of responsiveness to surfactant also decreases with increasing postnatal age.[10]

Although the indications for subsequent doses of surfactant vary, persistence of respiratory failure is the major clinical indicator for retreatment. In practice, most infants require only one dose of surfactant. This may be related to advances in neonatal and perinatal management and an increased use of antenatal steroids. However, there are neonates who may be more likely to require more than one dose; these include those who were not exposed to antenatal steroids and/or those with extreme prematurity (<26 weeks' gestation). A second dose of poractant alfa should be given to L.D. because he still requires mechanical ventilation with relatively high inspiratory pressures and supplemental oxygen ($F_{IO_2} \geq 0.3$) to maintain an arterial P_{O_2} of at least 50 mm Hg and oxygen saturation of 90%.

CASE 105-1, QUESTION 6: On rounds, the medical resident asks you about the complications of surfactant treatment in premature infants. Describe the information on adverse effects and their frequency that you would provide for the medical team.

The most common adverse effects of surfactant therapy are related to the method of administration.[11] During administration, L.D. may experience bradycardia and oxygen desaturation

secondary to vagal stimulation and airway obstruction.[6–9] These adverse events might require temporary discontinuation of surfactant administration and increased ventilator support.

The risk of pulmonary hemorrhage, which usually occurs within the first 72 hours of life, can be found in up to 6% of neonates receiving surfactant therapy.[3] However, pulmonary hemorrhage has not been consistently reported in recent studies; thus, the association between surfactant therapy and this disorder is questionable.[3] Furthermore, the benefits of surfactant therapy far outweigh the potential risk of pulmonary hemorrhage.

BRONCHOPULMONARY DYSPLASIA

CASE 105-2

QUESTION 1: J.T. is a 12-week-old, 2-kg female who was born at 25 weeks' gestation. Her medical history includes RDS, episodes of sepsis and pneumonia, and 5 weeks of parenteral nutrition. J.T. has also failed extubation numerous times and is currently requiring mechanical ventilation with an FIO_2 of 0.5. Current vital signs are as follows:

RR, 60 breaths/minute
HR, 150 beats/minute
BP, 80/55 mm Hg
O_2 saturation, 90%

On physical examination, J.T. has intercostal and subcostal retractions, shallow breathing, and an expiratory wheeze. Bilateral diffuse haziness with lung hyperinflation, focal emphysema, atelectasis, and irregular fibrous streaks are seen on chest radiograph. J.T. is currently receiving enteral feedings with a preterm 20-cal/ounce formula at 40 mL every 3 hours. Based on these findings, the diagnosis of BPD is made. What is the pathogenesis of BPD? What risk factors for BPD does J.T. have? What clinical signs and laboratory evidence of BPD are apparent in J.T.?

BPD (also known as chronic lung disease) is the most common form of chronic pulmonary disease in infants. The disease develops in newborns that require supplemental oxygen and positive-pressure ventilation for RDS or other primary lung disorders. A severity-based definition of BPD has been developed by the National Institute of Child Health and Human Development.[21] For infants born at less than 32 weeks' gestational age, assessment of BPD is performed at 36 weeks' PMA or at the time of discharge. Mild BPD is defined as a need for supplemental O_2 in excess of 21% for at least 28 days but not at 36 weeks' PMA or discharge; moderate BPD as a need for supplemental O_2 for at least 28 days plus treatment with less than 30% O_2 at 36 weeks' PMA or discharge; and severe BPD as a need for supplemental O_2 for at least 28 days plus treatment with at least 30% O_2 or positive-pressure ventilation at 36 weeks' PMA or discharge. For infants born at 32 weeks' gestational age or older, the above definitions are different only in that assessments are conducted at 56 days of life rather than 36 weeks' PMA.[21] BPD is a significant cause of infant morbidity and mortality. BPD affects 10,000 to 15,000 infants in the United States each year.[21] The incidence and severity of BPD are inversely related to gestational age and birth weight. Infants born at 23 weeks' gestation have a 73% incidence of BPD compared with a 23% incidence in infants born at 28 weeks' gestation.[21] Similarly, 56% of infants born at 23 weeks' gestation develop severe disease compared with 8% in infants born at 28 weeks' gestation.[21] Overall, from 1993 to 2006, the incidence of BPD has decreased; however, length of hospital stay has increased significantly. This may be due to a change in the definition of BPD and/or an increase in the use of CPAP.[22]

Pathogenesis and Clinical Manifestations

The cause of BPD seems to be multifactorial. Lung immaturity, surfactant deficiency, oxygen toxicity, barotrauma or volutrauma, and inflammation all play important roles. Premature infants, especially those at less than 26 weeks' gestation, are at a higher risk for BPD owing to lung immaturity.[21] Surfactant deficiency and the immature parenchymal structure of the lung and chest wall contribute to the development of BPD. Oxygen therapy, which causes a release of free oxygen radicals, is directly associated with the pathogenesis of BPD. Prolonged exposure to high oxygen concentrations and free oxygen radicals causes tissue damage, alveolar–capillary leaks, and atelectasis with resultant impaired gas exchange and pulmonary edema.[21,23,24] This may lead to the chronic pulmonary fibrotic changes seen in infants with BPD. In term infants, the lungs contain antioxidant enzymes that help to protect the lung from damage produced by free oxygen radicals. However, in preterm infants, the concentration of antioxidant enzymes may be low or absent. Therefore, premature infants are more susceptible to develop BPD than term infants.

Barotrauma secondary to positive-pressure ventilation is also a major factor in the pathogenesis of BPD, independent of oxygen toxicity.[21,23] Barotrauma is caused by repetitive distension of the terminal airways during mechanical ventilation. This results in disruption of the epithelium and an increase in capillary permeability to proteinaceous fluid. The severity of lung injury is related to the amount of positive peak pressure used. Volutrauma is also involved in the pathogenesis of BPD and is caused by high tidal volume ventilation and overdistension. The combined iatrogenic insults of oxygen toxicity and barotrauma or volutrauma, both inflicted on an immature lung for an extended time, can worsen lung damage.

The inflammatory process in the lung is activated by oxygen toxicity, barotrauma or volutrauma, or other injury. This results in the attraction and activation of leukocytes (e.g., neutrophils, macrophages), which may cause further release of inflammatory mediators, elastase, and collagenase.[24] Elevated levels of elastase and collagenase can destroy the elastin and collagen framework of the lung. α_1-Proteinase inhibitor, a major defense against elastase activity, may be inactivated by free oxygen radicals. Therefore, the combined elevated levels of elastase and the decreased activity of α_1-proteinase inhibitor may enhance lung injury and lead to the development of BPD.

Infants who exhibit BPD also have elevated levels of cytokines such as platelet-activating factor, leukotrienes, tumor necrosis factor, and fibronectin.[24] These agents, combined with the activated leukocytes, cause significant lung damage with breakdown of capillary endothelial integrity and capillary leakage. Furthermore, the increased fibronectin levels found in tracheal aspirate samples of infants with early BPD may predispose them to exhibit pulmonary fibrosis.[24]

Infection and nutrient deficiency may also play a role in the pathogenesis of BPD. The presence of chorioamnionitis may increase the infants' risk for BPD, although recent studies failed to report similar findings. Pathogens such as Ureaplasma, Chlamydia, or cytomegalovirus may cause chronic infection and contribute to the development of BPD.[21,23,24] A recent meta-analysis has shown direct correlations between Ureaplasma colonization and the presence of BPD, regardless of gestational age.[25] Deficiencies in nutrients such as vitamin A (retinol) or trace elements such as zinc, copper, and selenium (which are integral components of the antioxidant enzyme structure) may also play a role in the pathogenesis of BPD.

J.T. has two of the most important risk factors for BPD, low birth weight, and decreased gestational age. She is also at risk for

---

BPD owing to mechanical ventilation, oxygen toxicity, and fluid excess (160 mL/kg/day). Other risk factors include male sex, white ethnicity, and persistent PDA.[21,24]

BPD is characterized by tachypnea with shallow breathing, intercostal and subcostal retractions, and expiratory wheezing as demonstrated in J.T. Other signs and symptoms include rales, rhonchi, cough, airflow obstruction, airway hyperreactivity, increased mucus production, hypoxemia, and hypercarbia.[24] J.T.'s chest radiograph shows evidence of BPD, including focal emphysema, atelectasis, bilateral diffuse haziness (interstitial thickening) with increased expansion of the lungs, and irregular fibrous streaks. Mucous plugging, sepsis, and pneumonia can also develop in BPD infants on chronic mechanical ventilation. Infants with severe BPD eventually experience cardiovascular complications such as pulmonary hypertension, cor pulmonale, systemic hypertension, and left ventricular hypertrophy. In addition to chronic respiratory and cardiovascular complications, infants with BPD have significant growth, nutritional, and neurodevelopmental problems.[21,24]

Management

CASE 105-2, QUESTION 2: What nonpharmacologic and therapeutic agents should be used to manage BPD in J.T.?

The medical management of infants with BPD includes supplemental oxygen therapy, mechanical ventilation, fluid restriction, nutritional management, and various pharmacologic interventions. Supplemental oxygen administered via mechanical ventilation, CPAP, or nasal cannula should be provided to maintain an oxygen saturation of 90% to 95% and prevent hypoxemia.[23,24] Fluids should be restricted to 120–130 mL/kg/day to prevent congestive heart disease and pulmonary edema. Because infants with BPD have a 25% increase in caloric expenditure, hypercaloric formulas (e.g., 24 or 27 cal/ounce) may be used to optimize calories while restricting fluid intake.[23,26] If this increased energy is not provided, infants are at risk for undergoing a catabolic state that places them at higher risk of experiencing more severe BPD (inadequate nutrition may potentiate the toxic effects of oxygen toxicity and barotrauma). The goal of nutritional therapy is to produce weight gains of 10 to 30 g/day, which can usually be accomplished by providing 140 to 160 kcal/kg/day.[26] If infants do not tolerate enteral feedings, parenteral nutrition should be substituted until the gastrointestinal (GI) tract becomes more functional. Because J.T. is on a 20-cal/ounce formula, switching her to a hypercaloric formula would help to optimize her weight gain. Her fluids should be restricted to 120–130 mL/kg/day.

PHARMACOLOGIC THERAPY

The treatment of BPD consists of multiple-drug therapy, which includes diuretics, bronchodilators, and corticosteroids.[2,27–32] Despite the advancement of drug therapy, none of these drugs have been shown to reverse pulmonary damage in infants with BPD. Instead, they are used primarily to reduce clinical symptoms and to improve lung function.

Diuretics

Infants with BPD are particularly prone to pulmonary edema from cardiogenic and noncardiogenic factors. Left ventricular failure may worsen the already existing right ventricular failure. Pulmonary vascular permeability is increased because of the disruption of the alveolar–capillary unit and causes an increased amount of fluid in the interstitium. Although the precise mechanism in the treatment of BPD is unknown, diuretics help to reduce interstitial lung water.[24,27] In addition, diuretics lower pulmonary vascular resistance and improve gas exchange, thereby reducing oxygen requirements. The most commonly used diuretics are furosemide, thiazides, and spironolactone. Furosemide is the drug of choice because of its potent diuretic effect. In addition, it increases lymphatic flow and plasma oncotic pressure and decreases pulmonary interstitial edema. The use of furosemide in infants with BPD was associated with short-term improvement in lung compliance and oxygenation, decreased total pulmonary resistance, and facilitation in ventilator weaning.[27,29] However, a meta-analysis did not support all of these findings. Tolerance to furosemide may develop after a few days of therapy; this may be a result of the contraction in extracellular volume, which can lead to a compensatory increase in water and sodium reabsorption in the renal tubules. Furosemide can have significant adverse effects including hypochloremia, hypokalemia, and hyponatremia. Furthermore, volume depletion, hypercalciuria, nephrocalcinosis, osteopenia, and ototoxicity may also occur.[24,29] Excessive fluid loss or hypochloremia may result in metabolic alkalosis and worsen respiratory acidosis. Some of these adverse effects may be reduced by using alternate-day furosemide therapy or nebulized furosemide.[27] Neither of these regimens were associated with electrolyte imbalances, and both were shown to significantly increase lung compliance and decrease pulmonary resistance.[29]

Thiazide diuretics (e.g., hydrochlorothiazide) in combination with a potassium-sparing diuretic (e.g., spironolactone) can improve lung function and decrease oxygen requirements with increased diuresis.[27] Although less potent than furosemide, the combination of these two diuretics can reduce the incidence of hypokalemia commonly associated with loop or thiazide diuretics. Adverse effects commonly seen with this combination include hyponatremia, hyperkalemia or hypokalemia, hypercalciuria, hyperuricemia, hyperglycemia, azotemia, and hypomagnesia.[2] In summary, despite insufficient evidence of long-term efficacy (e.g., decreased oxygen requirement, need for mechanical ventilation, death, severity of BPD) and the potential for adverse effects, diuretics are often used in the management of BPD to provide short-term improvement in pulmonary edema and reduce the need for ventilatory support.

Generally, infants with BPD are treated with furosemide, but are changed to a combination diuretic if long-term treatment is needed to avoid adverse effects. Suggested indications for initiating furosemide therapy include (a) 1-week-old infants with early BPD and ventilator dependency, (b) infants with stable BPD who significantly worsen owing to fluid overload, (c) infants with chronic BPD who do not improve, and (d) infants requiring an increased fluid intake to provide adequate calories.[26] Because J.T. has chronic BPD and is not improving (i.e., she has not been able to be weaned off the ventilator), furosemide 2 mg/kg given every 12 hours enterally may be considered. J.T. should be monitored and treated for electrolyte disturbances while on furosemide.

CASE 105-2, QUESTION 3: One week after starting furosemide, J.T. still requires high ventilatory settings and is unable to be weaned from the ventilator. What other therapeutic agents may be considered to treat J.T.'s BPD?

Inhaled Bronchodilators

Infants in the early stages of BPD generally have airway hyperactivity and smooth muscle hypertrophy. They are also at higher risk for bronchoconstriction owing to increased airway resistance secondary to hypoxia. Therefore, the use of bronchodilators may be helpful in these infants. β_2-Agonists such as albuterol have been shown to provide short-term improvements (4 hours) in lung compliance and pulmonary resistance owing to bronchial smooth muscle relaxation.[17,33] However, inhaled bronchodilators are not effective in all infants with BPD. Infants in the late stages of BPD may have severe pulmonary damage and fibrotic changes.

Only half of these infants demonstrate a decrease in pulmonary resistance after albuterol therapy.[34] In addition, tolerance may develop with prolonged administration.[27] Therefore, inhaled bronchodilators should be reserved for infants who clearly demonstrate improvements during therapy. Currently, there are no well-designed studies evaluating the chronic use or long-term outcome of using inhaled bronchodilators in BPD infants. Despite the lack of meaningful long-term clinical outcomes associated with β_2-agonists and the variable results, their use continues to be very common in preterm infants with BPD. Further studies evaluating the efficacy and safety of long-term inhaled bronchodilator therapy are needed.

Inhaled anticholinergics (e.g., ipratropium bromide) have produced short-term benefits (approximately 4 hours) in infants with BPD by improving pulmonary function.[27] Inhaled anticholinergics, which relax bronchial smooth muscle and decrease mucus secretion, are generally reserved for infants who fail or are intolerant to albuterol, or as an adjunct to albuterol if clinical improvement is not seen.[27] The combined therapy of albuterol and ipratropium may be more effective than either drug alone.[27] The adverse effect profile of ipratropium is minimal because the drug is poorly absorbed.

A major problem with inhaled bronchodilators is their method of administration and drug delivery. Inhaled bronchodilators can be given by jet or ultrasonic nebulization or via a metered-dose inhaler (MDI).[29] For ventilator-dependent infants receiving MDIs, the MDI is connected to an adapter that is attached to the ventilator circuit and ETT. MDIs can also be given through bag ventilation via the ETT. For nonventilated infants, the MDI can be given using a valved holding chamber device and a face mask.

Compared with MDIs, nebulization has several disadvantages including loss or inefficient delivery of drug and cooling of the inspired oxygen mixture. In several neonatal studies, MDIs with a spacer provided more efficient delivery of inhaled bronchodilators and greater improvements in oxygenation and ventilation; smaller doses and a shorter treatment time were also used.[35,36] Furthermore, when comparing the three different devices, the MDI with spacer and the ultrasonic nebulizer are more efficient in delivering aerosols to neonates than the jet nebulizer.[29] In addition, MDIs are less expensive than nebulization. Therefore, the use of MDIs with an appropriate spacing device is preferred for most infants.

Corticosteroids

Corticosteroids, particularly dexamethasone, have been used extensively for the prevention and treatment of BPD. Mechanisms of action of corticosteroids include (a) reduction of polymorphonuclear leukocyte migration to the lung, (b) reduction of lung inflammation, (c) inhibition of prostaglandin, leukotriene, tumor necrosis factor, and interleukin synthesis, (d) reduction of elastase production, (e) stimulation of surfactant synthesis, (f) reduction of vascular permeability and pulmonary edema, (g) enhancement of β-adrenergic receptor activity, (h) reduction of pulmonary fibronectin (which can reduce the risk of interstitial fibrosis), and (i) stimulation of serum retinol concentrations.[2,26]

Systemic dexamethasone is associated with many serious short-term adverse effects, including hyperglycemia, increased BP, hypertrophic cardiomyopathy, GI bleeding, intestinal perforation, pituitary–adrenal suppression, bone demineralization, poor weight gain, and increased risk of infection.[2,24] Serious long-term adverse effects such as cerebral palsy (CP) and neurosensory disability have also been identified in preterm infants who receive systemic corticosteroids.[23,24,27]

Early (within the first week of life) and late (administered after 1 week of life) use of dexamethasone was associated with significant decreases in the incidences of BPD and the combined outcome of death or BPD at 28 days' postnatal age (PNA) and at 36 weeks' PMA.[37,38] Additionally, infants in the late group had a significantly lower incidence of mortality at 28 days' PNA. However, the risk for CP and the combined outcome of death or CP were significantly increased in the early group.[38] Although none of the studies were powered to detect long-term neurologic adverse events, the authors concluded that the benefits of early dexamethasone use do not outweigh the adverse effects and cannot be currently recommended.[38] The use of late dexamethasone should be reserved for infants who are unable to be weaned off the ventilator, and the dose and duration of treatment should be minimized.[37] Recent trials evaluating the adverse long-term neurodevelopmental outcomes associated with dexamethasone reported that low-dose dexamethasone (0.15 mg/kg/day) appeared to be safe and did not increase the risk of CP, whereas high-dose dexamethasone (0.5 mg/kg/day) was associated with significantly increased risk of CP.[39]

Although studies have reported that hydrocortisone may be safer than dexamethasone, a meta-analysis found no effect of hydrocortisone on survival without BPD or mortality.[23,27,40] In addition, an increase in spontaneous GI perforation was found in the hydrocortisone-treated group in the largest trial, resulting in an early termination of three studies.[23,27,39,40] The incidence of GI perforation may have been increased as a result of concomitant treatment with indomethacin. In contrast to studies of high-dose dexamethasone, long-term adverse effects (e.g., CP, neurodevelopmental impairment) of hydrocortisone in patients assessed at 2 to 8 years of age have been reported to be similar to placebo or untreated groups.[39,40] The doses of hydrocortisone used in most of these studies (1 mg/kg/day) were lower than the doses of dexamethasone used in clinical trials. Most infants treated with dexamethasone received a dose of 0.2 to 0.5 mg/kg/day, which is equivalent to hydrocortisone 5 to 15 mg/kg/day. Furthermore, all of these studies initiated hydrocortisone within the first week of life. Currently, there are no trials evaluating the use of hydrocortisone after 1 week of life in infants with established, ventilator-dependent BPD.

Based on these clinical findings, a policy statement from the American Academy of Pediatrics (AAP) does not recommend high-dose dexamethasone (0.5 mg/kg/day or greater) owing to the absence of improved short- and long-term outcomes from randomized trials.[39] It also does not recommend low-dose dexamethasone (<0.2 mg/kg/day) or high-dose hydrocortisone (3–6 mg/kg/day) owing to insufficient evidence. Early low-dose hydrocortisone (1 mg/kg/day) given within the first 2 weeks of life may benefit a specific patient population. Clinicians must weigh the potential risks of BPD with the potential adverse effects associated with glucocorticoids; therapy should be considered in VLBW infants at high risk for experiencing BPD (e.g., those still on mechanical ventilation after 1–2 weeks of age). Parents should be fully informed about the short- and long-term adverse effects of systemic corticosteroids.[39] Despite the AAP recommendation, some clinicians would still consider administering a short course of low-dose systemic corticosteroid to help facilitate extubation. This practice may be supported by a meta-regression analysis demonstrating that the impact of postnatal steroids on the combined outcome of death or CP was modified by the risk of BPD.[24] When postnatal steroids were used in infants with a low risk for BPD (<35%), there was a significant increase in the risk of death or CP. However, when used in infants with a higher risk for BPD (>65%), a significant reduction in the risk of death or CP was found. Overall, infants with a >50% predicted risk of BPD had less harm associated with steroids than those at lower risk of BPD.[24] Dexamethasone 0.2 mg/kg/day in two divided doses (tapered for 5–7 days) may be considered for J.T., even though she is now 13 weeks old. Throughout therapy, J.T. should be monitored for hyperglycemia, hypertension, GI bleeding, and intestinal perforation.

Inhaled steroids such as beclomethasone dipropionate, flunisolide, fluticasone, and budesonide have also been used for the treatment and prevention of BPD.[30,41] When compared to placebo, inhaled corticosteroids have not been shown to decrease the incidence of death or BPD, the combined outcome of death or BPD, and duration of mechanical ventilation and oxygen therapy; however, the use of systemic steroid may be decreased.[30,41] When compared to systemic steroids, no significant differences in mortality or the incidence of BPD were found.[31,32] The use of early inhaled steroids (i.e., prevention) was associated with increased duration of mechanical ventilation and oxygenation. None of these studies evaluated long-term neurodevelopmental outcomes associated with inhaled steroids. Adverse effects of inhaled steroids are less common than with systemic steroids; these include mild adrenal suppression, bronchospasm, tongue hypertrophy, and oral candidiasis.[30–32,41] Inhaled steroids may suppress the pituitary–adrenal axis; however, studies have reported conflicting results. Suppression may vary depending on the type of inhaled steroids, dosing regimen, and other factors such as prematurity.[33] The infant's mouth should be cleaned after each use of inhaled steroid to minimize complications such as oral thrush. As with inhaled bronchodilators, administration is a therapeutic problem with these medications. Further studies evaluating the optimal dose, duration of therapy, time of initiation, delivery technique, most appropriate preparation, and long-term adverse effects (including neurodevelopmental outcome) of corticosteroids are needed before inhaled steroids can be routinely recommended.

Long-Term Sequelae

CASE 105-2, QUESTION 4: Five months have passed, and J.T. is now 4.5 months old (corrected age), weighs 5 kg, and is ready for discharge. During the past several months, ventilation requirements slowly decreased, and J.T. was eventually extubated. However, she still requires supplemental oxygen at an FIO_2 of 30%, 0.25 L/minute via nasal cannula, to maintain an oxygen saturation of 90% to 95%. What are the long-term complications of BPD that can be expected in J.T.?

Infants with BPD have little pulmonary reserve and, therefore, are at higher risk for experiencing frequent respiratory exacerbations. BPD places J.T. at risk for recurrent infections of the lower respiratory tract, and she may require frequent hospitalizations during the first year for bronchiolitis and pneumonia. Approximately 50% of all children with BPD require hospitalization for respiratory exacerbations during early childhood.[21] Respiratory syncytial virus is a common cause of respiratory distress and recurrent atelectasis. With time, most preterm survivors with BPD have an improvement in pulmonary function owing to lung growth; however, many continue to have airway hyper-reactivity. Infants with severe BPD can also experience pulmonary hypertension, cor pulmonale, systemic hypertension, and left ventricular hypertrophy.

In addition, J.T. may be at risk for experiencing bone demineralization and rickets. VLBW infants are born with inadequate stores of vitamin D. In general, these premature infants may not receive an adequate intake of vitamin D, either parenterally or through their diet. Most VLBW infants require prolonged parenteral nutrition, which may cause cholestasis or hepatic failure. Prolonged cholestasis or chronic hepatic congestion owing to heart failure may cause malabsorption of calcium and vitamin D. In addition, furosemide may exacerbate calcium deficiencies by causing hypercalciuria. These combined factors may result in bone demineralization and rickets. Infants with BPD usually have a high catabolism and increased oxygen consumption as a result of an increased work of breathing and chronic hypoxia. Inadequate nutritional support may negatively affect weight gain, growth, and long-term outcome of BPD.

Neurologic and developmental abnormalities such as learning disabilities, speech delays, vision and hearing impairment, and poor attention span can also occur in infants with BPD.[21] BPD itself is not an independent risk factor for neurologic abnormality; related factors include birth weight, gestational age, and socioeconomic status.[21] Long-term follow-up evaluations at 1 to 15 years of age in infants previously treated with high-dose dexamethasone revealed an increase in neurodevelopmental abnormalities such as CP and decreased school performance in some studies.[39] However, it is not known whether these abnormalities were attributable to an adverse effect of dexamethasone on brain development or to an improved survival of infants who may already be at risk for experiencing these abnormalities.

Mortality rates for infants with BPD range from 30% to 40%.[28] Approximately 80% of deaths associated with BPD occur during initial hospitalization and are attributable to respiratory failure, sepsis, pneumonia, cor pulmonale, and congestive heart failure.[28]

Prevention

CASE 105-2, QUESTION 5: What preventive measures could have been used to decrease the likelihood of the development of BPD in J.T.?

Prevention of prematurity and other etiologic factors of RDS is the most effective means of preventing BPD. Although both antenatal steroids and exogenous surfactant therapy have been shown to reduce the incidence of RDS, the incidence of BPD has not been affected.[23] One of the causes of BPD can be vitamin A deficiency, which can predispose infants to BPD owing to impaired lung healing, increased susceptibility to infection and loss of cilia, and decreased number of alveoli.[23] Premature infants, especially VLBW infants, are at greatest risk owing to low body stores, inadequate intake during feedings, and decreased enteral absorption of vitamin A. Intramuscular (IM) vitamin A has been shown to significantly reduce the combined outcome of mortality or BPD; however, no difference was found with mortality, ROP, or sepsis.[23] In contrast, administration of oral vitamin A 5,000 international units/day did not decrease the incidence of BPD, perhaps because of inadequate dose or poor oral absorption.[42] Vitamin A seems to be a relatively safe drug; the incidence of adverse effects was similar between treated and control groups.[23] Although evidence appears to support IM vitamin A in infants with birth weight less than 1,000 g, further studies evaluating the efficacy, safety, and optimal dosage regimen of vitamin A for the prevention of BPD are needed.

Ureaplasma urealyticum colonization of the respiratory tract of premature infants is a significant risk factor for BPD. Several studies evaluated the use of macrolide antibiotics for eradication of Ureaplasma in premature infants at risk for BPD.[23,43] Although erythromycin has not been shown to reduce the incidence of BPD or death, studies evaluating azithromycin and clarithromycin reported variable efficacy results. Azithromycin and clarithromycin have shown to decrease the incidence of BPD, but only in infants positive for Ureaplasma.[43] However, prolonged antibiotic exposure has been linked to an increased rate of NEC or sepsis. Furthermore, erythromycin use has been associated with infantile hypertrophic pyloric stenosis.[2] Therefore, due to these adverse findings as well as conflicting clinical efficacy, routine use of macrolide antibiotics is not recommended.

Optimization of nutritional support may also help to prevent the development of BPD because proper nutrition helps to promote

---

lung maturation, growth, and repair. Excessive fluid administration should be avoided because it may lead to BPD. Fluid restriction decreases both the incidence of BPD and mortality.[24] The early use of caffeine (initiated before 3 days of life) to treat apnea of prematurity in infants with birth weights of 500 to 1,250 g has been shown to decrease the incidence of neurodevelopmental impairment, including CP. In addition, the incidence of BPD was significantly decreased in the caffeine-treated infants, although BPD was one of their secondary outcomes.[23,44] Fluid restriction, the early use of caffeine citrate, and IM vitamin A could have been recommended for J.T. in the early course of her hospitalization to help decrease the likelihood of her experiencing BPD.

PATENT DUCTUS ARTERIOSUS

The fetus has three unique circulatory structures that differ from the adult circulation: (a) the ductus venosus, which permits blood to bypass the liver; (b) the foramen ovale, which allows blood to pass from the right atrium into the left atrium; and (c) the ductus arteriosus, the structure that connects the pulmonary artery to the descending aorta and allows blood to bypass the lungs (Fig. 105-1).[45] In addition to these structural differences, vascular resistance and pressure play important roles in determining the pathway of the fetal circulation. For example, the relative hypoxia that occurs in utero causes pulmonary vasoconstriction. Pulmonary vasoconstriction, along with compression of pulmonary blood vessels by unexpanded fetal lung mass, results in a high pulmonary vascular resistance and decreased pulmonary blood flow. This decreased pulmonary blood flow is acceptable in utero because the lungs essentially are nonfunctional. Large amounts of blood, however, must be pumped through the placenta where gas exchange occurs.

Maximally oxygenated blood (PO_2, 30–35 mm Hg) flows from the placenta to the fetus through the umbilical vein (Fig. 105-1). Approximately 50% of the umbilical venous blood is shunted away from the liver through the ductus venosus and directed into the inferior vena cava. Blood from the inferior vena cava and superior vena cava then enters the right atrium. Most of the blood from the inferior vena cava, which is well oxygenated, is directed in a straight pathway across the right atrium through the foramen ovale directly into the left atrium. It then enters the left ventricle through the mitral valve and is pumped through the ascending aorta and into the vessels of the head and forelimbs. Thus, the fetal brain is preferentially perfused with blood containing a higher amount of oxygen. Deoxygenated blood returning from the head region via the superior vena cava enters the right atrium and is directed through the tricuspid valve into the right ventricle, where it then is pumped into the pulmonary artery. Most of this blood is diverted through the ductus arteriosus into the descending aorta and then through the two umbilical arteries to the placenta. A small percentage of the blood flows to the lower extremities and then is returned to the heart via the inferior vena cava.[45]

Changes at Birth

At birth, major circulatory changes result from umbilical cord clamping, aeration and expansion of the lungs, and an increase in arterial Po_2. These changes are important in the transition from a fetal to an adult circulation. When the umbilical cord is clamped, blood flow decreases through the ductus venosus. Clamping of the umbilical cord also results in a twofold increase in systemic vascular resistance. This increase in systemic vascular resistance increases aortic, left ventricular, and left atrial pressures and cardiac output. Pulmonary pressures and blood flow also change. After the neonate's first breath, the lungs expand, oxygenation improves, and pulmonary vascular resistance immediately drops. This increases pulmonary blood flow, causing a decrease in pulmonary arterial, right ventricular, and right atrial pressures.[45,46]

Closure of the Foramen Ovale

Because of the decreased right atrial pressure and increased left atrial pressure that occur after birth, blood attempts to flow down the pressure gradient from the left atrium through the foramen ovale into the right atrium. This is in the opposite direction from what occurs in fetal life. The small, valve like flap that lies over the foramen ovale on the left side of the atrial septum closes over the foramen ovale opening when the pressure in the left atrium exceeds the pressure in the right atrium. Closure of this flap prevents further flow through the foramen ovale. As long as the pressure in the left atrium is higher than that in the right atrium, the foramen ovale remains functionally closed, until it closes anatomically.

Closure of the Ductus Arteriosus

Closure of the ductus arteriosus is more complex and depends on many factors. In utero, patency of the ductus arteriosus is maintained through the combined vasodilatory effects of a low Po_2 and high concentrations of prostanoids, particularly prostaglandin E_2 (PGE_2) and prostacyclin.[47] After birth, the smooth muscles of the ductus arteriosus constrict as arterial oxygenation increases and concentrations of placentally derived prostaglandins, particularly PGE_2, decrease.[47] In utero, the Po_2 of the ductal blood is 18 to 22 mm Hg, whereas after birth in a term neonate, it is approximately 100 mm Hg. Normally, the ductus arteriosus of a term neonate functionally closes within the first few days of life (i.e., in 82% of infants within 48 hours of life and in 100% of infants within 96 hours of life). Anatomic closure of the ductus occurs within 2 to 3 weeks of life. When the ductus arteriosus fails to close, it is called patent ductus arteriosus (PDA). In a term neonate, a PDA beyond the first few days of life generally is permanent. It usually is secondary to an anatomic defect in the wall of the ductus arteriosus and requires surgical ligation. In contrast, a PDA in a preterm neonate may persist for weeks and still close spontaneously.

When a PDA is present, the direction and amount of shunting through this opening are determined by the pressure gradient between the systemic and pulmonary circulations. Usually, blood flows from the aorta into the pulmonary circulation. Because systemic vascular resistance and aortic pressure are increased, and pulmonary vascular resistance and pulmonary arterial pressure are decreased after birth, blood pumped from the left ventricle into the aorta flows from the aorta (a high-pressure area) through the PDA and into the pulmonary artery (a lower-pressure area). This flow is called left-to-right shunting and is in contrast to the right-to-left shunting that occurs through the PDA during fetal life.

Clinical Presentation

CASE 105-3

QUESTION 1: T.S. is a 750-g female who was born at 25 weeks' gestational age to a 22-year-old gravida 2 para 1 woman. One hour after birth, T.S. exhibited symptoms of RDS, and two doses of beractant were given within the first 24 hours of life. After the second dose of beractant, T.S.'s respiratory function greatly improved, and no further doses of beractant were required. On the third day of life, the nurse noticed that T.S. had tachycardia, a systolic murmur, a hyperactive precordium, and a widened pulse pressure. Her lungs sounded "wet." In addition, the nurse noted that T.S.'s combined IV fluid rates total 160 mL/kg/day instead of the desired fluid intake of 120 mL/kg/day. Current vital signs and ABGs are as follows:

HR, 190 beats/minute
RR, 65 breaths/minute
BP, 55/23 mm Hg
O_2 saturation, 89%
pH, 7.22
PCO_2, 55 mm Hg
PO_2, 77 mm Hg
Base deficit, 10

Ventilator support is increased to compensate for T.S.'s deteriorating respiratory status. Echocardiography is performed and shows a moderate-size PDA with significant left-to-right shunting. The chest radiograph shows pulmonary edema and an enlarged heart. What risk factors for PDA does T.S. have?

T.S. has two major risk factors for developing a symptomatic PDA: prematurity and RDS. The occurrence of a PDA is inversely proportional to gestational age and birth weight. The incidence of PDA is approximately 45% in premature infants with a birth weight of less than 1,750 g, but can be as high as 80% in premature infants with a birth weight of less than 1,200 g.[48] In contrast, the incidence of PDA in term infants is only 0.06%.[48] Preterm neonates are at a higher risk for PDA than term newborns because the smooth muscle of the immature ductus is more sensitive to the dilatory effects of prostaglandins and less sensitive to the constrictive effects of increased oxygen tension. In addition, circulating concentrations of PGE_2 are often elevated in premature infants owing to the decreased pulmonary metabolism of prostaglandins. These factors contribute to the delayed closure of the ductus arteriosus in premature infants. With advanced gestation, the ductus is less responsive to the relaxant effects of prostaglandins and is more sensitive to the constricting effects of oxygen.[49]

RDS also increases the risk for PDA. Exogenous surfactant also may increase the risk and lead to an earlier clinical presentation of symptomatic PDA.[49,50] PDA can further complicate the course of RDS.[49,51] T.S.'s course is typical of a preterm neonate with resolving RDS. T.S.'s pulmonary function improved after surfactant administration. Consequently, pulmonary vascular resistance decreased and the degree of left-to-right shunting across the ductus arteriosus increased, causing a deterioration in respiratory status. In addition, the excess fluid that T.S. received is an iatrogenic factor that may have increased the shunting across the PDA, aggravating the degree of pulmonary congestion.[49]

CASE 105-3, QUESTION 2: How is T.S.'s presentation consistent with that of PDA?

T.S.'s clinical presentation is related to the increased pulmonary blood flow, decreased systemic perfusion, and left ventricular volume overload that resulted from the shunting of left ventricular cardiac output through the PDA into the lungs. To compensate for the inadequate peripheral perfusion, HR increases. This results in an increase in cardiac output and a greater left-to-right shunt through the PDA, creating a vicious cycle. The widened pulse pressure (the difference between systolic and diastolic pressures, 32 mm Hg) is a result of diversion of aortic blood flow through the PDA, which is causing the bounding pulses. The systolic murmur, which is not always present, is the result of turbulent blood flow through the ductus arteriosus occurring because the pulmonary vascular resistance decreases. Tachycardia, hyperactive precordium, and a continuous murmur are results of the left-to-right shunting through the ductus arteriosus during systole.[52]

CASE 105-3, QUESTION 3: What are the potential complications of this hemodynamically significant PDA in T.S.?

The increased pulmonary blood flow and resultant pulmonary edema will worsen T.S.'s respiratory disease and increase the need for ventilatory support. The higher ventilatory settings (increase in MAP and $\mathrm{FIO_2}$) place T.S. at risk for having BPD. If the PDA is left untreated, T.S. may experience congestive heart failure secondary to an increased left ventricular end-diastolic volume. A hemodynamically significant PDA also places T.S. at risk for IVH and NEC.[49]

Treatment

CASE 105-3, QUESTION 4: How should T.S.'s PDA be managed?

The initial medical management for T.S.'s symptomatic PDA is supportive care, which includes fluid management (e.g., fluid restriction and diuretic therapy), correction of anemia, and treatment of hypoxia and acidosis. Although excessive fluid administration may increase the risk of PDA, fluid restriction alone is unlikely to result in ductal closure. T.S.'s fluid intake should be restricted to 100–120 mL/kg/day (approximately 80% of total fluid maintenance requirements) to avoid worsening of her pulmonary edema and to prevent congestive heart failure.[49] Furosemide 1 mg/kg IV push should also be given to T.S. immediately to treat her pulmonary edema. In addition to fluid management, correction of anemia is important. Low concentrations of hemoglobin result in an increased cardiac output, which may worsen the infant's cardiac function. Anemia not only increases the demand of left ventricular output to ensure adequate oxygen delivery to the tissues, but may also increase the magnitude of the left-to-right shunt by decreasing the resistance of blood flow through the pulmonary vascular bed.[49] Maintaining a hematocrit level of more than 40% to 45% is often recommended. Because of T.S.'s gestational age, birth weight, and size of PDA, it is unlikely that she will respond to these general measures alone. Therefore, T.S. requires pharmacologic treatment with indomethacin or ibuprofen.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Both indomethacin and ibuprofen are available in injectable form for the treatment of PDA. These drugs nonspecifically inhibit prostaglandin synthesis, thereby eliminating the vasodilator effects of the PGE series on the ductus arteriosus, allowing the ductus to close. Indomethacin has been used clinically for more than 30 years for the treatment of PDA. However, because of its adverse effects, other prostaglandin inhibitors, such as ibuprofen, have been studied for PDA closure. Results indicate that ibuprofen is as effective as indomethacin in closing the ductus and causes significantly less of a decrease in renal, mesenteric, and cerebral blood flow. In a recent meta-analysis comparing ibuprofen with indomethacin, ibuprofen reduced the risks of NEC and transient adverse effects on renal function (e.g., oliguria, elevations of serum creatinine [SCr]).[53] However, the incidence of mortality, BPD, and IVH were similar for both drugs. Unfortunately, no long-term follow-up studies of ibuprofen exist. These studies are needed to determine whether ibuprofen or indomethacin is the drug of choice for PDA closure.[53] Based on the studies currently available, ibuprofen may be preferred in patients who have or are at risk for decreased renal function. The initial dose of ibuprofen lysine is 10 mg/kg followed by two doses of 5 mg/kg given at 24-hour intervals. If urinary output decreases to less than 0.6 mL/kg/hour, the second or third doses should be held.[2]

Unfortunately, not every infant treated with a nonsteroidal anti-inflammatory drug (NSAID) responds with constriction of the ductus arteriosus; therefore, surgical ligation of the PDA may be required. Ligation generally is reserved for neonates who do not respond to pharmacologic therapy or those in whom drug therapy is contraindicated.[49]

CASE 105-3, QUESTION 5: Due to lower risks of adverse effects on renal function, the attending physician would like to treat T.S. with ibuprofen for closure of her PDA. You explain to the medical team that there is a temporary shortage of ibuprofen, and therefore, T.S. should be treated with indomethacin. The medical team then asks the following: What is the dose of indomethacin for T.S.? and What route should be used for its administration?

The medical team should be told the following information. The route of choice for indomethacin is IV; enteral indomethacin is less effective. This reduced effectiveness may be related to the formulation of the suspension and decreased, erratic enteral absorption. In addition, the use of enteral indomethacin has been associated with NEC.[54]

A large interpatient variability of indomethacin pharmacokinetics occurs in preterm neonates. Serum concentrations do not correlate consistently with therapeutic or adverse effects. Furthermore, the optimal therapeutic serum concentration is not yet defined.[55] Although many dosage regimens have been reported, dosing guidelines from the National Collaborative Study are commonly used.[51] Three indomethacin doses are given in 12- to 24-hour intervals, with the first dose equal to 0.2 mg/kg IV in all neonates. Because indomethacin clearance is directly proportional to postnatal age, the second and third doses are determined by postnatal age at initiation of indomethacin therapy. If onset of treatment was at less than 2 days' PNA, neonates receive 0.1 mg/kg/dose; if initiation of therapy occurred at 2 to 7 days' PNA, neonates receive 0.2 mg/kg/dose; if therapy began at more than 7 days' PNA, neonates receive 0.25 mg/kg/dose. Second and third doses are administered at 12- to 24-hour intervals. No specific guidelines exist regarding which patients receive every-12-hour versus every-24-hour dosing; however, the individual dosing interval generally is determined by the neonate's urine output. If urine output remains greater than 1 mL/kg/hour after an indomethacin dose, then the next dose may be given in 12 hours. If urine output is less than 1 mL/kg/hour but greater than 0.6 mL/kg/hour, then the dosing interval may be extended to 24 hours. Doses should be held if urine output is less than 0.6 mL/kg/hour. T.S. should receive three doses of indomethacin 0.15 mg (0.2 mg/kg/dose) given every 12 hours, as long as her urine output remains greater than 1 mL/kg/hour. If T.S.'s urine output decreases, then the dosing interval should be adjusted as outlined above.

Other indomethacin dosing regimens have been evaluated more recently for the treatment of PDA in preterm infants. An initial dose of 0.2 mg/kg followed by either 0.1 or 0.2 mg/kg for two doses at 12- to 24-hour intervals has been used. In a study measuring serum concentrations, higher doses of indomethacin were required in older neonates (>10 days' PNA).[56] This may be owing to an increased indomethacin clearance in these infants.

Because rapid IV administration of indomethacin can decrease cerebral, mesenteric, and renal blood flow, longer infusion rates of 20 to 30 minutes are recommended.[57]

Response to NSAID therapy can be determined by assessing the clinical signs of PDA such as tachycardia, widened pulse pressure, bounding pulses, heart murmur, and the ability to wean from ventilator support. In certain cases, echocardiography may be performed to confirm closure of a PDA.

CASE 105-3, QUESTION 6: What clinical and laboratory data should be monitored during T.S.'s indomethacin therapy?

Before initiating indomethacin therapy, T.S. should receive an echocardiogram to rule out ductal-dependent congenital heart disease and to confirm the presence of a PDA. In addition, an SCr and blood urea nitrogen (BUN) should be obtained from T.S. before indomethacin therapy because nephrotoxicity is the most common adverse effect. Infants receiving indomethacin can experience transient oliguria with increased SCr. This occurs as a result of indomethacin-induced decreases in renal blood flow and glomerular filtration rate.[51] Dilutional hyponatremia may occur secondary to either decreased urine output or decreased free water diuresis owing to increased antidiuretic hormone activity. Treatment of hyponatremia should be aimed at decreasing free water intake through fluid restriction rather than by sodium supplementation. Typically, renal function normalizes within 72 hours after the last dose of indomethacin. In general, indomethacin therapy is contraindicated in neonates with renal failure, urine output less than 0.6 mL/kg/hour, or an SCr of 1.8 mg/dL or greater.[51]

Furosemide, which increases renal prostaglandin synthesis, has been suggested to help prevent indomethacin-associated renal toxicity. However, by increasing prostaglandins, furosemide may theoretically decrease ductal closure. Currently, studies do not support the routine use of furosemide in preterm neonates who receive indomethacin for the treatment of PDA. Furosemide is also contraindicated in patients who are dehydrated.[58] In addition to monitoring renal function and serum electrolytes, serum concentrations of aminoglycosides, digoxin, and other renally eliminated drugs should be monitored carefully. Indomethacin therapy may decrease renal drug clearance and cause accumulation of these agents, which may require a dosage reduction.[59]

A platelet count should also be obtained from T.S. before therapy because indomethacin may decrease platelet aggregation. Thrombocytopenia (platelet count <50,000/μL) is a contraindication to indomethacin therapy.[51] In cases of thrombocytopenia, indomethacin may be withheld temporarily until platelets can be transfused. Other potential contraindications to indomethacin therapy include active bleeding and clinical evidence of NEC because GI bleeding, perforation, and NEC have been reported with indomethacin use.[49] These GI effects may be related to decreases in intestinal blood flow usually seen with rapid IV infusions. Grades II to IV IVH also are frequently quoted as contraindications to indomethacin therapy; however, indomethacin treatment probably is not associated with progression of IVH. In fact, prophylactic treatment with indomethacin may be associated with a decrease in the incidence of severe IVH (grades III and IV).[49,50]

CASE 105-3, QUESTION 7: When is the best time to initiate an NSAID for symptomatic treatment of T.S.'s PDA?

Conflicting data exist on when to initiate indomethacin or ibuprofen therapy for the treatment of symptomatic PDA. Some centers may opt to treat within the first 2 to 3 days of life (early symptomatic PDA) when infants initially present with clinical signs of PDA (i.e., murmur, widened pulse pressures, tachycardia). Others may not treat until clinical signs of congestive heart failure are present (late symptomatic PDA; 7–10 days of life).[50] Both treatment strategies (early and late) significantly decrease the incidence of PDA, but both cause significant transient reduction of urine output and SCr elevation. In some studies, infants receiving early treatment of indomethacin had significant reductions in the incidence of BPD and NEC and the need for surgical ligation.[50] In contrast, one study found that final PDA closure rates and the need for surgical ligation were comparable in early versus late indomethacin-treated neonates. In fact, spontaneous closure was observed in 43% of the late treatment group, which may indicate unnecessary treatment in the early group. In addition, renal adverse effects and ventilatory requirements were higher in the infants treated early.[60] Thus, early administration of indomethacin should not be used routinely; however, it may be given to preterm neonates at high risk for having a large PDA. Clinically, these recommendations can also be applied to ibuprofen. Because T.S. is an ELBW neonate with RDS, she is at high risk for exhibiting a large PDA. She also has clinical signs of a PDA and, thus, should be treated as soon as possible.

CASE 105-3, QUESTION 8: The physicians were able to decrease T.S.'s ventilator support within the first 12 to 24 hours after starting indomethacin treatment. After 3 to 4 days of gradual and consistent ventilator weaning, the ventilator settings could not be decreased further. During the next 2 to 3 days, T.S.'s respiratory status deteriorates, and she requires increased ventilator support. T.S. now has tachycardia, a widened pulse pressure, bounding pulses, and a hyperactive precordium. Repeat echocardiogram shows a small-to-moderate PDA. Current data include the following:

BUN, 10 mg/dL
SCr, 1.1 mg/dL
Sodium, 134 mEq/L
Potassium, 4.9 mEq/L
Chloride, 97 mEq/L
Urine output, 2.3 mL/kg/hour
Fluid intake, 130 mL/kg/day

Platelets, 180,000/μL

Why did PDA recur in T.S., and how should it be managed?

Successful closure of the PDA with indomethacin occurs in 70% to 90% of infants; however, ductal reopening or recurrence can occur in 20% to 35% of infants who initially respond to indomethacin.[61] Recurrence of PDA occurs especially in lower-birth-weight infants. Several reasons might explain T.S.'s transient response to indomethacin. Recurrence of PDA is inversely proportional to gestational age; the incidence of ductal reopening is significantly higher in infants with 26 weeks' gestational age or younger compared with infants born at 27 weeks' gestation or more (37% vs. 11%, respectively).[62] The higher recurrence in younger gestational age neonates may be related to resumption of PGE_2 production after indomethacin serum concentrations decline and heightened sensitivity of the immature ductus arteriosus to the dilating effects of PGE_2.[49,61] This is particularly important in ventilator-dependent patients such as T.S. because mechanical ventilation increases circulating vasodilating prostaglandins.

Furthermore, the rate of ductal reopening is independent of indomethacin serum concentrations, but seems to be related to the timing of indomethacin therapy, PNA, and the amount of fluid intake 24 hours before indomethacin treatment.[62] The rate of recurrence is lower in infants who were treated with indomethacin earlier in life compared with those who receive treatment later.[49] Because anatomic closure of a PDA may be delayed for a couple of weeks, it is not surprising that the ductus arteriosus reopened in T.S. after her initial response to indomethacin.

Although controversial, prolonged indomethacin therapy may prevent recurrences and allow for permanent closure of the ductus arteriosus. Several prolonged treatment regimens have been successful in preventing ductal reopening.[49,61] One such regimen (indomethacin 0.2 mg/kg/dose IV every 12 hours for three doses, followed by 0.2 mg/kg/dose every 24 hours for five doses) was able to significantly decrease the recurrence of PDA from 47% to 10% in neonates less than 1,500 g without increasing toxicity. The need for surgical ligation also was decreased significantly.[61] However, some studies report an increased mortality in infants receiving prolonged therapy (5 to 7 days) compared with those receiving the short course (three doses).[49] Furthermore, a recent meta-analysis demonstrated that prolonged therapy (six to eight doses) did not improve PDA closure, retreatment, reopening, or surgical ligation rates. Although prolonged courses were shown to decrease transient renal dysfunction, a significantly higher incidence of NEC was observed. Thus, the routine use of prolonged courses of indomethacin is not currently recommended.[63] Select use of prolonged therapy may be used. Individual patient response needs to be considered, especially in ELBW neonates. The optimal duration of indomethacin therapy and dosing regimen need to be identified.

T.S. remains ventilator-dependent and is at increased risk for exhibiting BPD. Because she has no contraindications to indomethacin therapy, a second course of indomethacin (0.1–0.2 mg/kg/dose every 12–24 hours for three to five doses) should be considered.[61,63] If the PDA fails to respond to this prolonged regimen or if it recurs again after an initial response, and T.S. remains ventilator-dependent, surgical ligation most likely will be required to permanently close the PDA.

Prophylactic Administration

CASE 105-3, QUESTION 9: Could prophylactic NSAID administration have prevented the development of a symptomatic PDA in T.S.?

Prophylactic indomethacin therapy is defined as the administration of indomethacin within 24 hours of life to newborns who are at risk of experiencing a symptomatic PDA.[64] However, routine prophylaxis would unnecessarily expose a large number of newborns to indomethacin (and its adverse effects), because PDA closure may occur spontaneously without treatment. Prophylactic use of indomethacin has short-term benefits; it significantly decreases the incidence of PDA and IVH (grades III and IV) and the need for PDA surgical ligation.[64] Unfortunately, most studies have not shown that prophylactic ductal closure with indomethacin decreases the incidence of death, BPD, NEC, or neurodevelopmental disabilities. Additionally, infants receiving prophylactic therapy have a higher incidence of severe oliguria or anuria, albeit transient.[64] Therefore, routine prophylactic administration is usually not warranted. It may be considered, however, in some neonatal units that do not have easy access to cardiac diagnostic and therapeutic services or that have a high incidence of IVH. Typically, preterm neonates, particularly those at high risk for experiencing a large PDA (e.g., ELBW neonates), are treated as soon as clinical signs appear.

Prophylactic ibuprofen therapy (administered at <24 hours of life) significantly decreases the incidence of PDA and the need for rescue pharmacologic treatment and surgical ligation.[65] However, it does not appear to decrease BPD, IVH, NEC, or mortality, and may increase the risk of renal dysfunction and sepsis. Because of the lack of long-term follow-up studies with the current ibuprofen lysine product, prophylactic ibuprofen therapy for the prevention of PDA is not recommended at this time.[65]

Treatment with Acetaminophen

CASE 105-3, QUESTION 10: During multidisciplinary NICU rounds, the advanced nurse practitioner mentions that acetaminophen has been used to treat PDA and may be safer than NSAIDs. Should acetaminophen, rather than indomethacin, have been used to treat the symptomatic PDA in T.S.? What is the evidence to support its use?

The advanced nurse practitioner is partially correct and should be informed of the following information. Several case reports suggest that acetaminophen may be used for the treatment of PDA in neonates who fail or have contraindications to NSAID therapy.[66–68] Similar to NSAIDs, acetaminophen inhibits prostaglandin synthesis. However, in contrast to NSAIDs that inhibit cyclooxygenase-1 and -2 (steps that occur early in the synthesis of prostaglandins), acetaminophen is thought to affect a subsequent step in prostaglandin synthesis by inhibiting the peroxidase site of the enzyme, prostaglandin synthetase. Others suggest that acetaminophen inhibits a yet-unidentified cyclooxygenase-3. Due to the different mechanisms of actions, acetaminophen would be expected to have less serious side effects than NSAIDs.

Two randomized controlled trials compared acetaminophen to ibuprofen for the treatment of PDA in preterm neonates.[67,68] Both trials used acetaminophen doses of 15 mg/kg every 6 hours for 3 days. A recent meta-analysis of these studies found no significant difference in the failure rates for PDA closure or risk of reopening the PDA between the two drugs.[68] No significant differences in secondary outcomes or adverse effects were observed, with two exceptions: The duration of required supplemental oxygen was shorter, and the incidence of hyperbilirubinemia was lower in patients who received acetaminophen. Although these results appear promising, an association of postnatal use of acetaminophen with autism or autism spectrum disorder has recently been identified.[68] In addition, animal studies suggest acetaminophen may affect cognitive function when administered during neonatal brain development. Therefore, further research, including long-term follow-up studies of neurodevelopment, is needed before acetaminophen can be recommended for PDA closure in routine clinical practice.[68] Due to these concerns, acetaminophen should not have been used in place of indomethacin to treat the symptomatic PDA in T.S. After weighing all potential risks and benefits, some clinicians may use acetaminophen before surgical ligation, in select neonates with a significant PDA, who have failed or who have contraindications to NSAID therapy.[67]

NECROTIZING ENTEROCOLITIS

CASE 105-4

QUESTION 1: C.D., a 15-day-old female neonate, was born at 28 weeks' gestational age with a birth weight of 908 g. Her postnatal course has been complicated by RDS, sepsis, and a large PDA for which she required intubation and mechanical ventilation, one dose of beractant, a 7-day course of ampicillin and gentamicin, and indomethacin. Enteral feedings with a standard preterm 24-cal/ounce formula were started on day 4 of life at 5 mL every 3 hours (44 mL/kg/day). Feedings were increased by 5 mL/feed on days 5 through 7 to 20 mL/feed every 3 hours on day 7 of life (176 mL/kg/day). This morning, C.D. exhibited a distended abdomen, bloody stools, multiple episodes of apnea that required reintubation and assisted ventilation, and metabolic acidosis. ABG results revealed the following:

pH, 7.15
PCO_2, 67 mm Hg

PO_2, 55 mm Hg
Base deficit, 10

An abdominal radiograph revealed pneumatosis intestinalis (the presence of gas in the intestinal submucosa). C.D. is to take nothing by mouth (NPO), and gentamicin 4 mg/kg IV infusion every 36 hours and ampicillin 100 mg/kg IV push every 12 hours are restarted. What clinical signs of NEC does C.D. have? What is the pathogenesis of NEC, and what risk factors for NEC does C.D. have?

NEC, a type of acute intestinal necrosis, is the most common neonatal life-threatening nonrespiratory condition. The incidence of NEC ranges from 3% to 11% and is inversely proportional to gestational age and birth weight.[69] Approximately 90% to 95% of NEC occurs in premature infants; however, NEC can infrequently occur in full-term neonates.[70] The age of onset of NEC is also inversely related to gestational age and birth weight; the greater the gestational age at birth, the sooner the onset of NEC. Although NEC is less common in term infants, it usually develops within 3 to 4 days of birth. In contrast, infants born at approximately 30 weeks' gestation acquire NEC at a mean PNA of 20 days. Thus, preterm infants are at a risk for NEC for a longer time.[71,72] Although C.D. is extremely premature, she experienced NEC early (at 15 days of age), most likely because of the aggressive advancement of feedings. The rate of hospitalization associated with NEC is 1.1 per 1,000 live births.[73] The mortality rate of NEC can be as high as 40% to 50%, and approximately 25% of survivors experience long-term complications.[70,71,73] In addition, infants with NEC required longer hospitalizations (60 days longer if surgery is needed and 20 days longer if surgery is not needed) compared with infants without NEC. For infants with medically managed NEC, the estimated hospital cost is $60,000 to $70,000 compared to $200,000 for infants with surgically managed NEC.[70,74]

C.D. has several clinical signs of NEC, including abdominal distension, bloody stools, apnea, metabolic acidosis, and pneumatosis intestinalis on abdominal radiograph. Gastric retention of feedings, respiratory distress, occult blood in stools, lethargy, temperature instability, thrombocytopenia, and neutropenia also may occur. NEC may progress to bowel perforation, peritonitis, sepsis, disseminated intravascular coagulopathy (DIC), and shock. On an abdominal radiograph, the presence of gas in the intestinal mucosa or in the portal venous system is diagnostic of NEC, and free air in the abdomen is observed with bowel perforation. (For images of NEC go to **https://image.slidesharecdn.com/necrotizingenterocolitis-**

150719105818-lva1-app6892/95/necrotizing-enterocolitis-8-638.jpg?cb=1437303559.) Although these radiographic findings confirm the diagnosis of NEC, a lag time may occur between the initial clinical signs of NEC and radiologic confirmation.

NEC can evolve slowly during a period of 24 to 48 hours, from a clinically benign course to an advanced stage of shock, peritonitis, and widespread intestinal necrosis. Although NEC can affect any part of the GI tract, most of the disease is confined to the ileum and colon. A staging system, which categorizes severity according to systemic, intestinal, and radiologic signs, has been developed to permit a more consistent evaluation and treatment of patients.[75] Stages IA and IB NEC include neonates and infants with suspected disease or rule out NEC. These patients may have mild GI problems such as delayed gastric emptying and emesis, temperature instability, apnea, bright red blood from the rectum, or a mild ileus. Infants with stages IIA and IIB have definite NEC and usually present with abdominal distension, bloody stools, and the presence of pneumatosis intestinalis on radiograph. Infants in stage IIB NEC may also exhibit metabolic acidosis and thrombocytopenia. Infants with stages IIIA and IIIB (advanced disease) are severely ill with clinical signs, including peritonitis, ascites, shock, severe metabolic and respiratory acidosis, and DIC. Those with stage IIIB have intestinal perforation. Pneumatosis intestinalis, caused by hydrogen production from bacterial translocation into the bowel wall, is a classic and diagnostic radiographic finding of NEC. Because pneumatosis intestinalis may be hard to detect on radiographs, some infants can experience severe NEC needing surgery without having radiographic findings. Therefore, new criteria including biomarkers of NEC may be needed to help diagnose NEC sooner and prevent its progression. C.D.'s presentation is most consistent with stage IIB NEC.

The pathogenesis of NEC is unknown, but seems to be multifactorial. Most likely, NEC results from the effects of intestinal bacteria and other factors on injured intestinal mucosa. Inflammatory mediators such as platelet-activating factor, tumor necrosis factor-α, interleukin 1β, and interleukin 8 may also contribute to mucosal damage.[70,72] The neonatal intestinal mucosa is prone to injury for the following reasons: (a) increased permeability to potentially harmful substances, such as bacteria and proteins; (b) decreased immunologic host defenses, including low concentrations of immunoglobulin A in intestinal mucosa; and (c) decreased nonimmunologic defenses, such as decreased concentrations of proteases and gastric acid. Furthermore, inappropriate initial microbial colonization may also contribute to the pathogenesis of NEC in preterm neonates, especially because NEC does not occur until after 1 week of life, at a time when the gut has been colonized with anaerobic bacteria. In addition, numerous factors (both prenatal and postnatal) can cause injury to the neonatal intestinal mucosa and increase the risk for NEC.[72,75] Prenatal maternal factors include eclampsia, prolonged rupture of membranes, fetal distress, maternal cocaine use, and cesarean section. Postnatal factors include prematurity, low birth weight, ischemia or hypoxemia, asphyxia, hypothermia, hypotension, respiratory distress, apnea, malnutrition, infection, hemodynamically significant PDA, congenital GI anomalies, cyanotic heart disease, toxins, hyperosmolar substances (e.g., feedings, medications), rapid advancement of enteral feedings, exchange transfusions, blood transfusions, and the presence of umbilical catheters.[72,74,75] Medications such as corticosteroids, indomethacin, and H_2-blockers and prolonged empiric IV antibiotic use have also been associated with an increased risk of NEC.[72,74,75] However, the most significant clinical risk factor for NEC is prematurity.[75]

C.D. has several risks for developing NEC, which include prematurity, ELBW, history of infection, and RDS requiring mechanical ventilation. Furthermore, C.D. not only was given a hyperosmolar formula (24 cal/ounce instead of 20 cal/ounce), but her feedings were advanced aggressively. These two factors may also contribute to the development of NEC. More than 90% of infants with NEC have received enteral feedings, although NEC also occurs in infants who have never been fed.[70] Enteral feedings (breast milk or formulas) serve as substrates for bacterial proliferation in the gut. As a result, reducing substances, organic acids, and hydrogen gas are produced by bacterial fermentation of these nutrients. Although studies have shown that rapid advancements in the volume of feeds (30 mL/kg/day vs. 15–20 mL/kg/day) were associated with an increased risk of NEC, a systematic review reported that infants advanced at a rate of 30 to 35 mL/kg/day reach full enteral intake and regain birth weight significantly earlier than infants advanced at 10 to 20 mL/kg/day without increasing the risk of NEC or NEC with perforation.[73] Similarly, older studies reported that early initiation of feeds might increase the risk of NEC; however, a recent review failed to confirm these findings. In fact, infants who were fed earlier (within 4 days of birth) had a significant reduction in the number of days on parenteral nutrition.[73] C.D. was started at a much higher initial feeding volume (44 mL/kg/day) and aggressively increased by 44 mL/kg/day, which may have increased the risk

---

of NEC. If C.D. were appropriately fed, she would have reached full feedings in 7 to 14 days instead of 4 days. Last, the presence of PDA and the use of indomethacin for the treatment of PDA may also have contributed to NEC in C.D. through decreased mesenteric blood flow with resultant ischemia and intestinal mucosal injury.[71]

Treatment

CASE 105-4, QUESTION 2: How should C.D. be managed?

Significant abdominal distension may compromise respiratory function and blood flow to the intestines. Therefore, as soon as NEC is suspected, feedings should be stopped immediately and an orogastric tube with low intermittent suction placed to decompress the abdomen. C.D.'s vital signs and abdominal circumference should be closely monitored for disease progression. A complete blood count and platelet count should be obtained frequently to monitor for neutropenia and thrombocytopenia. Blood and urine cultures should be obtained, and parenteral antibiotics should be started as soon as possible; 20% to 30% of infants with NEC have associated bacteremia. Radiographic examinations should be routinely performed at least every 4 to 8 hours or as needed to evaluate the progression of the disease. In infants with stage I NEC, antibiotic therapy is usually given for 3 days pending culture results and clinical signs. Once the diagnosis of NEC is ruled out, antibiotics may be discontinued. Enteral feedings can then be initiated slowly. However, if the diagnosis of NEC is made (i.e., stages II or III), antibiotics are continued and parenteral nutrition is initiated at that time. Infants require bowel rest (NPO) for at least 7 to 14 days. The length of antibiotic therapy and bowel rest in infants with documented NEC is determined by the severity of systemic illness (e.g., metabolic acidosis, thrombocytopenia). In general, infants with NEC stage II require at least 7 to 10 days of antibiotic therapy and bowel rest whereas those with NEC stage III may require at least 10 to 14 days. C.D. has stage IIB disease and needs to be NPO for at least 7 to 10 days; she requires total parenteral nutrition during that time, and the surgery team should be notified at this point. Infants with stage III disease may also require fluid resuscitation, administration of inotropic agents such as dopamine and dobutamine, and surgical intervention, especially for those with perforated NEC.[70,71] Up to 40% of infants treated for medically managed NEC may require surgical intervention (either primary peritoneal drainage or exploratory laparotomy), with the absolute indication for surgery being intestinal perforation.[73] Despite the type of surgical intervention, up to 50% of ELBW infants who require surgery will die.[72]

CASE 105-4, QUESTION 3: C.D. just completed a 7-day course of ampicillin and gentamicin. Is it appropriate to restart these antibiotics?

The selection of antibiotics for NEC depends on the common microorganisms observed in an individual neonatal unit and their sensitivities. Many organisms have been implicated in NEC, including Enterobacteriaceae (e.g., Escherichia coli, Klebsiella species), Pseudomonas, Staphylococcus aureus (in rare cases, methicillin resistant), Staphylococcus epidermidis, Clostridium, enteroviruses, and rotaviruses.[76] For most cases of NEC, treatment with a broad-spectrum penicillin, such as ampicillin, and an aminoglycoside (e.g., gentamicin) is appropriate.

Due to an increase in S. epidermidis-associated NEC, vancomycin and an aminoglycoside may be used as routine treatment in some nurseries or in specific patients at risk for Staphylococcus infections (e.g., neonates with central catheters or prolonged ICU stays). Vancomycin may be more appropriate than ampicillin because vancomycin has coverage against methicillin-resistant S. epidermidis, as well as enterococcal and streptococcal species. Because C.D. has been hospitalized for longer than 1 week and weighs less than 1,000 g, vancomycin and gentamicin may be more appropriate, especially if her neonatal ICU has a high incidence of staphylococcal nosocomial infections. C.D. should be treated with parenteral antibiotics for 7 to 10 days.

Other antibiotic combinations used to treat NEC include cefotaxime and vancomycin, and cefotaxime and ampicillin. The combination of cefotaxime and vancomycin has been shown to prevent severe peritonitis and death and reduce the need for surgery in less than 2,200-g birth-weight neonates with NEC, whereas gentamicin and ampicillin have not. Suppression of aerobic fecal flora by the combination of cefotaxime and vancomycin, but not by ampicillin and gentamicin, may explain these findings.[76] Therefore, if C.D. is not responding to vancomycin and gentamicin, consideration should be made to replace gentamicin with cefotaxime.

CASE 105-4, QUESTION 4: Two days later, C.D. exhibits peritonitis with ascites (NEC stage III), hypotension, worsening metabolic acidosis, neutropenia, and DIC. IV fluids and dopamine are administered for the hypotension, fresh-frozen plasma and whole blood are given to treat the coagulopathy, and a fentanyl continuous infusion at 1 mcg/kg/hour is started for pain control. Free air in the abdomen is observed on abdominal radiograph. Blood and urine cultures have had no growth for 48 hours. What additional antimicrobial coverage should be provided?

The use of empiric anaerobic coverage in infants with definite NEC, stage II or III, remains controversial; however, many institutions have added anaerobic coverage to routine antibiotic regimens.[76] The two most commonly used agents are clindamycin and metronidazole. Routine use of clindamycin in the treatment of NEC has not decreased the incidence of intestinal gangrene, perforation, or death. In addition, it has been associated with an increased incidence of abdominal strictures.[76] There are no studies to demonstrate the efficacy of metronidazole in this patient population, but the lack of reports documenting adverse effects in preterm infants has made it the agent of choice in some hospitals. A recent study reported no significant difference in the incidence of the combined outcome of death or intestinal strictures in infants with NEC stages II and III treated with or without anaerobic coverage.[77] Furthermore, anaerobic antibiotic therapy did not prevent the progression to death within 7 days of NEC diagnosis or to surgical NEC. However, a higher risk of strictures was found in all infants receiving anaerobic antibiotic therapy. Furthermore, in those with surgical NEC, a lower mortality rate was found in the anaerobic antibiotic-exposed infants.[77] Based on this study, it might be prudent to consider weighing the risk versus benefit when deciding to add anaerobic antibiotic therapy in the treatment of medically managed NEC. In contrast, infants with peritonitis secondary to intestinal perforation (i.e., those needing surgery) require both aerobic and anaerobic coverage. Therefore, an antimicrobial agent with anaerobic activity such as metronidazole should be added to C.D.'s current regimen.

Complications and Prognosis

CASE 105-4, QUESTION 5: C.D. is taken urgently to the operating room, and 40 cm of necrotic ileum is removed along with the ileocecal valve. What long-term nutritional problems is C.D. likely to have?

The most common postoperative complications of NEC are intestinal strictures (up to 25%) and short-bowel syndrome (11%).[70]

C.D. is at risk of experiencing short-bowel syndrome, a condition of malabsorption and malnutrition that results from surgical removal of a significant portion of the small intestine. The most important factors that determine short-bowel syndrome are the length of the remaining small intestine and the presence of the ileocecal valve. Because C.D. has had a majority of her ileum and her ileocecal valve removed, she most likely will suffer from short-bowel syndrome.

Because the terminal ileum is an important site for absorption of vitamins, trace minerals, and nutrients, C.D. will be at risk for decreased absorption of these substances. C.D. also will have a faster GI transit time and diarrhea because her ileocecal valve was removed. (The ileocecal valve plays a major role in controlling intestinal transit time.) Absorption of enterally administered medications also may be decreased in patients with short-bowel syndrome. When C.D. starts to receive most of her nutrition enterally, she should be monitored for fat malabsorption and other nutritional deficiencies (e.g., deficiencies in vitamins A, B_{12}, D, E, and K), and supplemented accordingly.

Despite advances in earlier diagnosis and aggressive treatment, approximately 15% to 50% of all infants with NEC die, with the highest mortality in those with birth weight <750 g and with surgical NEC.[69,70,74,75] Furthermore, infants with NEC are significantly more likely to have neurodevelopmental impairment (e.g., CP); those requiring surgical management are at higher risk.[73]

Prevention

CASE 105-4, QUESTION 6: What could have been done to prevent NEC in C.D.?

Several interventions may decrease the incidence of NEC. Enteral feedings in preterm infants can be withheld for several weeks and parenteral nutrition initiated. Intestinal priming or trophic feeding (i.e., using a small amount of full-strength formula or breast milk for several days to stimulate GI mucosal development) has been shown to decrease the incidence of NEC compared with infants with advancement of feedings.[73] Because breast milk provides antibodies, growth factors, and cellular immune factors, it may reduce the incidence of NEC. Infants fed with human milk had a significantly lower incidence of NEC than those fed with formula.[74,75] In a recent study, a significant decrease in the incidence of NEC and surgical NEC was observed in infants who were exclusively fed with a human milk-based diet compared with a combination of human milk- and formula-based diets.[74] In contrast, the use of hyperosmolar formulas or medications can cause osmotic injury to the bowel and may result in NEC. Maternal steroids (commonly used to accelerate fetal lung maturation) can decrease the incidence of NEC owing to a maturational effect on the microvillous membranes.

Although prophylactic enteral administration of antibiotics (i.e., gentamicin or vancomycin) has been shown to decrease the incidence of NEC, its routine use is not recommended.[74] In addition, prophylactic use of these antibiotics has been associated with the emergence of resistant organisms, especially with long and repeated courses.[72,74]

Probiotics are live, nonpathogenic microbial preparations that colonize the intestine and have a beneficial effect on the health of the host. Probiotic microorganisms commonly used are strains of Lactobacillus and Bifidobacterium. In a recent Cochrane review, enteral administration of probiotics significantly decreased the risk of severe NEC and death and shortened the time to full feedings in VLBW infants.[78] Furthermore, recent studies evaluating the long-term effects of probiotics (assessed at 18–22 months up to 3 years corrected age) reported no adverse effects on growth or neurodevelopmental outcomes.[78] One major concern is that exposing immunologically immature VLBW infants to probiotics may potentially increase the risk for infections. Although the Cochrane review did not find an increased risk for infections in neonates receiving probiotics, cases of systemic infections, especially in ELBW neonates, have been reported.[78] The lack of probiotic-associated sepsis could be due to failure of the laboratory to isolate these strains in blood cultures by the use of conventional culture-based techniques. Other controversies exist. Most studies did not evaluate the effects of probiotics in ELBW infants, the population at greatest risk for NEC. The optimal type of probiotic (species, strains, single or combined, live or killed) and the timing, dosage, and duration of therapy are still unknown. Little is known regarding the benefits of probiotics in infants who are exclusively or partially fed breast milk. Furthermore, none of the studies were conducted in the United States and most of the trials did not utilize US commercially available probiotics. Lastly, currently no product in the United States has the appropriate regulatory mechanisms in place to ensure the quality of the product. Therefore, clinical studies are needed to address these issues, and if probiotics are administered to VLBW infants for the prevention of NEC, careful surveillance of mortality, NEC, and emergence of resistant strains will be necessary. When C.D. is ready to be fed, breast milk (if available) should be used in place of formula to help prevent future risk of NEC. Although probiotics have been shown to significantly decrease the incidence of NEC, their use cannot be recommended for C.D. at this time.

NEONATAL SEPSIS AND MENINGITIS

CASE 105-5

QUESTION 1: J.E., a 28-week gestation, 850-g male, was born to a mother with prolonged rupture of membranes (>72 hours). The newborn's mother is diagnosed with chorioamnionitis. J.E. had Apgar scores of 3 at 1 minute, 4 at 5 minutes, and 7 at 10 minutes after birth. Mechanical ventilation was instituted, and J.E. was admitted to the neonatal ICU. Vital signs on admission were as follows:

HR, 190 beats/minute
Temperature, 35.8°C
BP, 56/33 mm Hg

Blood and urine cultures are pending. Significant laboratory data include the following:

WBC 2,400 cells/μL with a differential of 25% segmented neutrophils, 15% bands, 45% lymphocytes, 10% monocytes, 4% eosinophils, and 1% basophils
Platelets, 45,000/μL
C-reactive protein (CRP), 5 mg/dL

What is the etiology and pathogenesis of neonatal sepsis? What risk factors for sepsis does J.E. have? What clinical signs and laboratory evidence of sepsis are apparent in J.E.?

Bacterial sepsis significantly contributes to neonatal morbidity and mortality. Neonates, especially preterm newborns, are at increased risk for infections and should be considered immunocompromised. The neonate's decreased immune function (e.g., immature function of neutrophils, lower amounts of immunoglobulin) also results in a reduced ability to localize infections. Once a tissue site becomes infected, bacteria can spread easily, resulting in disseminated disease. In addition, the lack of opsonic antibodies in preterm infants such as J.E. increases the susceptibility to infections caused by bacteria with polysaccharide capsules (e.g., group B streptococcus, E. coli, Haemophilus influenzae type B).[79]

The incidence of neonatal sepsis is inversely proportional to birth weight and gestational age, and ranges from 6 to 9 cases per 1,000 live births. However, the incidence is much higher in VLBW neonates (~25%).[80] Risk factors (as demonstrated in J.E.) include prematurity, low birth weight, male sex, and predisposing maternal conditions (e.g., prolonged rupture of membranes, maternal fever, elevated maternal WBC or left shift, chorioamnionitis, and urinary tract infection).[81,82] Despite treatment, mortality rates for neonatal sepsis can be as high as 30% to 50%, with the highest mortality observed in newborns less than 1,500 g.[83] Meningitis occurs as a complication of bacterial sepsis in 10% to 30% of septic neonates[83] and has a mortality rate of 20% to 50%, depending on the pathogen.[81] Long-term sequelae of meningitis have been reported in about 20% to 60% of survivors and include hearing loss, abnormal behavior, developmental delay, cerebral palsy, focal motor disability, seizure disorders, and hydrocephalus.[79,84]

Common Pathogens

The fetal environment within the amniotic membranes is normally sterile until the onset of labor and delivery. Once the membranes are ruptured, the infant may be at risk for colonization of microorganisms from the maternal genital tract. Many of these organisms do not cause infection in the mother, but may be detrimental to the infant. Early-onset neonatal sepsis (sepsis that presents during the first 72 hours of life) usually is caused by organisms acquired from the maternal genital tract. The most common pathogens found in early-onset neonatal sepsis are group B streptococcus (50%) and E. coli (20%). Other primary pathogens include Listeria monocytogenes, Enterococcus, and other gram-negative bacilli (e.g., H. influenzae, Klebsiella pneumoniae).[84,85]

Late-onset sepsis (sepsis presenting after 3 days' PNA) usually is caused by these primary organisms or by nosocomial pathogens, such as coagulase-negative staphylococci (CONS), particularly S. epidermidis, S. aureus, Pseudomonas species, anaerobes, and Candida species.[84,86] The presence of IV catheters (umbilical or central) and duration of parenteral hyperalimentation are major risk factors for nosocomial septicemia.[86,87] Other risk factors include prematurity, low birth weight, prolonged hospital stay, prior antibiotic use, lipid emulsion, use of H_2-blockers, invasive procedures, GI disease (including NEC), the presence of other indwelling devices (e.g., ETTs, ventriculoperitoneal shunts), and nasal CPAP. [80,87] Seventy percent of late-onset sepsis in VLBW infants is caused by gram-positive organisms, with CONS being the most common pathogen (68%); S. aureus, Enterococcus species, and group B streptococcus account for the remainder.[88] Clinically, before continuation of antibiotic therapy, it is important to distinguish whether patient isolates of CONS are the result of colonization of the catheters or IV tubing or represent true bacteremia.

Neonatal sepsis may present with nonspecific or subtle signs, especially in VLBW infants.[81] The most common signs are poor feeding, temperature instability, lethargy, or apnea.[81,83] Other signs of neonatal sepsis include glucose instability (hypoglycemia or hyperglycemia), tachycardia, dyspnea or cyanosis, tachypnea, diarrhea, vomiting, feeding intolerance, abdominal distension, metabolic acidosis, and abnormal WBC.[81] Clinical signs and laboratory evidence of neonatal sepsis observed in J.E. include tachycardia (HR, 190 beats/minute), hypothermia (temperature 35.8°C), leukopenia (WBC, $2.4 \times 10^3/\mu L$), neutropenia (absolute neutrophil count of 960/μL), a left shift in the differential (i.e., an immature-to-total neutrophil ratio [I/T] of 0.38), thrombocytopenia (platelets, 45,000/μL), and an elevated CRP (5 mg/dL). Hypothermia is more common than fever in neonatal sepsis, especially in preterm newborns. However, if fever is present, it is strongly associated with bacterial infection. Neutropenia, especially with a left shift (as seen in J.E.), can be a sign of WBC depletion from bone marrow owing to overwhelming sepsis. An elevated WBC also can indicate a neonatal infection, but may be less specific. The I/T ratio, defined as band forms plus any earlier cells divided by the total neutrophil count (including early cells), has been shown to be useful in diagnosing neonatal sepsis. An I/T ratio of less than 0.3 is normal.[82] CRP, an acute-phase reactant protein associated with tissue injury in response to an inflammatory process, may also be included as part of a sepsis workup. A CRP level of more than 1 mg/dL indicates inflammation and possible infection.[82] In infants with bacterial infection, serum CRP levels begin to increase from 6 to 8 hours after the onset of the illness and peak after 2 to 3 days.[89] Therefore, because of the delayed response, the use of CRP for detection of early-onset sepsis is not of great value. Serial CRP levels obtained during 2 to 3 days of illness may aid in the determination of duration of empiric antibiotic therapy. Empiric antibiotic therapy may be discontinued in infants with normal serial CRP levels in the absence of any clinical signs suggestive of sepsis. However, elevated CRP levels can be found in other clinical conditions such as viral infection, ischemic tissue injuries, hemolysis, or chorioamnionitis. Procalcitonin, another acute-phase reactant, rises more quickly than CRP in the presence of bacteria so it may be more useful for early detection. However, there are also limitations to its routine use for the evaluation of neonatal sepsis including nonspecificity (i.e., noninfectious conditions can cause elevation of procalcitonin levels) and a lack of age-specific reference ranges.[89] Therefore, CRP and procalcitonin levels should be used with caution as the sole diagnostic criteria for sepsis or bacteremia. Late signs of neonatal infection include jaundice, hepatosplenomegaly, and petechiae.[81] A bulging fontanel, posturing, or seizures indicate meningitis, although these CNS signs are not always present when meningitis exists.

Bacterial meningitis should always be considered in infants with neonatal sepsis.[79] The major pathogens causing neonatal sepsis are also the primary pathogens that cause neonatal meningitis.[83] The definitive diagnostic method for bacterial meningitis is lumbar puncture. Lumbar puncture should be performed in infants with a positive blood culture, abnormal neurologic signs, an elevated WBC or left shift, or the presence of bacteria in the urine.[90] A lumbar puncture is not needed in neonates receiving empiric antibiotics solely because of maternal risk factors.[89] However, it is important to note that a negative blood culture does not dictate the absence of bacterial meningitis. Approximately 1 of every 4,000 live births has culture-proven bacterial meningitis, and 15% to 50% of infants with bacterial meningitis may have a negative blood culture.[89] The cerebrospinal fluid (CSF) should be tested with a Gram stain, cell counts with differential, glucose and protein levels, and bacterial culture.

Normal CSF cell counts and protein concentrations are different for neonates compared with older children and adults. For example, the CSF protein concentration in a healthy neonate is about 2 to 3 times that of an adult and decreases with age; preterm infants may have higher levels.[79] Neonatal CSF cell counts are also difficult to interpret because values observed with meningitis may overlap with normal neonatal values. The diagnosis of neonatal sepsis is confirmed by isolation of the pathogen from blood, urine, CSF, or other body sites.

Treatment of Sepsis and Meningitis

CASE 105-5, QUESTION 2: What antibiotic regimen should be prescribed for J.E.?

Empiric treatment with appropriate IV antibiotics must be initiated immediately in J.E. Significant morbidity or fatality would occur if antibiotics were withheld until a diagnosis was confirmed by culture results (in 24–72 hours). This is especially true in patients in whom meningitis is suspected. The initial empiric antibiotic treatment of choice for early-onset neonatal sepsis and meningitis is ampicillin plus an aminoglycoside (Tables 105-3, 105-4).[2,91–93] These antibiotics are used because they (a) are bactericidal against the common neonatal pathogens; (b) penetrate into the CNS; (c) are relatively safe; and (d) have proven clinical efficacy. If the culture is positive for group B streptococcus, ampicillin should be replaced with high-dose penicillin G because of its higher activity against group B streptococcus. If meningitis is highly suspected, gentamicin may be replaced by a third-generation cephalosporin (i.e., cefotaxime) owing to greater CSF penetration compared with aminoglycosides.

Table 105-3

Gentamicin Dosing Guidelines for Neonates and Infants[2,96]

Age	Extended-Interval Dosing Regimen[a]
PMA <32 weeks	4–5 mg/kg/dose every 36–48 hours
PMA 32–36 weeks	4–5 mg/kg/dose every 36 hours
PMA ≥37 weeks	4–5 mg/kg/dose every 24 hours

[a] Some institutions empirically adjust dosing interval based on clinical factors that may affect renal drug clearance (e.g., birth depression, hypotension requiring vasopressor support, or congenital heart defects resulting in decreased peripheral perfusion).

PMA, postmenstrual age.

Therefore, ampicillin 85 mg every 12 hours IV plus an aminoglycoside (e.g., gentamicin 4.2 mg every 48 hours IV) should be started in J.E. for suspected neonatal sepsis and possible meningitis. Meningitic doses of ampicillin should be used in J.E. until meningitis can be ruled out. Ampicillin is active against group B streptococci, Enterococcus, Listeria, and some strains of E. coli. Aminoglycoside antibiotics (e.g., gentamicin or tobramycin) usually are active against gram-negative bacilli. In addition, aminoglycosides may provide synergy with ampicillin against Listeria and group B streptococci.[82] Selection of the specific aminoglycoside should be determined by antibiotic resistance patterns within the neonatal ICU. Amikacin should be reserved for gram-negative organisms resistant to gentamicin and tobramycin. Aminoglycoside regimens need to be designed to achieve safe and therapeutic serum concentrations (traditional dosing regimens: gentamicin and tobramycin, peak 6–8 mcg/mL, trough <2 mcg/mL; amikacin peak 20–30 mcg/mL, trough <10 mcg/mL) and to aim for a peak concentration that is more than 8 times greater than the minimum inhibitory concentration (MIC) of the organism being treated.[94] If extended-interval aminoglycoside dosing is used, peak gentamicin and tobramycin serum concentrations of 10 to 12 mcg/mL and trough concentrations of less than 1 mcg/mL may be reasonable, depending on the MIC.

Traditionally, aminoglycosides were administered to neonates in multiple daily doses (e.g., gentamicin 2.5 mg/kg/dose 2 or 3 times a day). This dosing strategy frequently resulted in peak serum concentrations below and trough concentrations above the respective target ranges especially in preterm neonates. Evolution of the understanding of developmental pharmacokinetics resulted in knowledge that neonates have a larger volume of distribution for water-soluble drugs and a slower renal elimination of aminoglycosides compared to infants, older children, and adults.[95] Thus, many institutions now use higher mg/kg doses of aminoglycosides (e.g., gentamicin 4–5 mg/kg) administered at prolonged dosing intervals (every 24, 36, or 48 hours; commonly determined by GA or PMA).[96,97] A Cochrane review concluded that administering higher mg/kg aminoglycoside doses at prolonged intervals to neonates was as effective as multiple daily doses without evidence of increased toxicity. Serum peak and trough concentrations also were more likely to be in the target range.[98]

Table 105-4

Antimicrobial Dosage Regimens for Neonates: Dosages and Intervals of Administration[2,91–93]

	Weight <1,200 g	Weight 1,200–2,000 g		Weight >2,000 g	
Drug	0–4 weeks PNA (mg/kg)[a]	0–7 days PNA (mg/kg)[a]	8–28 days PNA (mg/kg)[a]	0–7 days PNA (mg/kg)[a]	8–28 days PNA (mg/kg)[a]
Amphotericin B					
Deoxycholate	1 every 24	1 every 24	1 every 24	1 every 24	1 every 24

	hours	hours	hours	hours	hours
Lipid complex/Liposomal	5 every 24 hours	5 every 24 hours	5 every 24 hours	5 every 24 hours	5 every 24 hours
Ampicillin					
Meningitis	100 every 12 hours	100 every 8 hours	75 every 6 hours	100 every 8 hours	75 every 6 hours
Other diseases	50 every 12 hours	50 every 12 hours	50 every 8 hours	50 every 8 hours	50 every 6 hours
Cefotaxime[b]	50 every 12 hours	50 every 12 hours	50 every 8 hours	50 every 12 hours	50 every 8 hours
Fluconazole	6 every 72 hours	12 every 24 hours	12 every 24 hours	12 every 24 hours	12 every 24 hours
Metronidazole	7.5 every 48 hours	7.5 every 24 hours	15 every 24 hours	15 every 24 hours	15 every 12 hours
Oxacillin/Nafcillin[b]	25 every 12 hours	25 every 12 hours	25 every 8 hours	25 every 8 hours	25 every 6 hours
Penicillin G crystalline					
Meningitis[c]	50,000 units every 12 hours	100,000 units every 12 hours	100,000 units every 8 hours	100,000 units every 8 hours	100,000 units every 6 hours
Other diseases	25,000–50,000 units every 12 hours	25,000–50,000 units every 12 hours	25,000–50,000 units every 8 hours	25,000–50,000 units every 12 hours	25,000–50,000 units every 8 hours
Vancomycin	15 every 24 hours	15 every 12–18 hours	15 every 8–12 hours	15 every 8–12 hours	15 every 6–8 hours

[a] PNA = postnatal age.

[b] Higher dosage may be needed for meningitis.

[c] Doses listed are for treatment of group B streptococcal meningitis.

This dosing strategy (of giving higher mg/kg/doses at prolonged intervals) in neonates is commonly referred to as extended-interval aminoglycoside dosing; however, it should not be confused with the adult dosing method of the same name.[95] Extended-interval aminoglycoside dosing (also known in adults as once-daily dosing or single-daily dosing) has been widely used in the adult population. Aminoglycoside antibiotics display concentration-dependent killing of bacteria. Rationale for the use of extended-interval aminoglycoside dosing include (a) enhancement of bacterial killing by providing a higher peak serum concentration to MIC ratio, (b) provision of a prolonged post-antibiotic effect, and (c) minimization of adaptive postexposure microbial resistance by achieving a drug-free period at the end of the dosing interval.[99] Key differences between this approach to aminoglycoside dosing in adults and the use of higher mg/kg doses given at prolonged intervals to neonates include the following: (a) Peak concentrations of ~20 to 25 mcg/mL are targeted in adults compared to 8 to 12 mcg/mL in neonates, (b) a drug-free period occurs at the end of the dosing interval in adults, while acceptably low, but measurable trough concentrations are commonly observed in neonates, and (c) a standardized dosing nomogram allows for interval adjustments based on a single serum concentration (drawn 8–12 hours postdose) in adults; however, routine peak and trough concentration monitoring is recommended for neonates.[95,99,100]

In some nurseries, a third-generation cephalosporin (e.g., cefotaxime), instead of an aminoglycoside, is added to ampicillin for initial empiric treatment of early-onset neonatal sepsis and meningitis.[80,87,94] The spectrum of activity of these third-generation cephalosporins includes many gram-negative organisms and group B streptococci. Ceftriaxone should be avoided in neonates with hyperbilirubinemia owing to bilirubin displacement from albumin-binding sites. Ceftriaxone has also been associated with sludging in the gallbladder and cholestasis.[2,94] The resultant increase in serum free bilirubin concentrations and decrease in bilirubin elimination can place the neonate at risk for kernicterus. In addition, calcium–ceftriaxone precipitates have been found in the lungs and kidneys of neonates when ceftriaxone was administered with calcium-containing solutions. Several fatalities have been reported; ceftriaxone should not be administered within 48 hours of calcium-containing solutions or products.[94] Hence, cefotaxime is the preferred cephalosporin for neonatal use.

The third-generation cephalosporins have advantages over the aminoglycosides, including better CNS penetration, the elimination of serum concentration measurements, and less nephrotoxicity. However, these cephalosporins do not significantly improve clinical or microbiologic end points compared with the standard ampicillin and gentamicin regimen. In fact, overuse of cefotaxime during the first few days of life has been associated with an increased risk of death compared with the use of gentamicin.[94] Furthermore, extensive use of the third-generation cephalosporins in neonatal ICUs may lead to rapid emergence of resistant gram-negative bacilli (e.g., Enterobacter cloacae, Pseudomonas aeruginosa, and Serratia species) and vancomycin resistance in enterococci. Also, prolonged treatment has been associated with an increased risk of neonatal candidiasis.[94] In contrast, only rare cases of gentamicin resistance have been reported.[80] Thus, combinations such as ampicillin and cefotaxime should be reserved for the following situations: (a) neonatal ICUs in which aminoglycoside resistance to gram-negative enteric bacilli is of concern, (b) neonatal ICUs in which serum concentrations of aminoglycosides cannot be measured, and (c) specific neonates in whom aminoglycoside therapy could be of concern (e.g., neonates with known renal failure).

Therapy for late-onset sepsis or meningitis is directed toward nosocomial pathogens plus the primary pathogens of early-onset infection. Selection of initial antibiotic therapy should consider the specific neonatal ICU's nosocomial pathogen and antibiotic resistance patterns, as well as the neonate's risk factors, clinical condition, and previous antibiotic therapy. CONS is now the most common pathogen of late-onset neonatal nosocomial septicemia.[101] Because of the high incidence of methicillin-resistant CONS, vancomycin has been used as the drug of choice for empiric therapy for suspected late-onset neonatal sepsis. However, widespread use of vancomycin has led to the emergence of vancomycin-resistant Enterococcus and S. aureus. Therefore, the routine use of vancomycin as empiric therapy for nosocomial neonatal sepsis should be discouraged. The highly selective use of vancomycin for neonatal CONS septicemia results in low morbidity and mortality, while significantly reducing vancomycin use. Guidelines for the selective use of vancomycin should be tailored according to individual neonatal ICU's nosocomial pathogens, susceptibility patterns, and patient risk factors, clinical condition, and antibiotic history. Therefore, if J.E. had a central venous catheter and presented with a late-onset sepsis, initial antibiotic therapy should include an aminoglycoside (for gram-negative coverage) plus either an antistaphylococcal penicillin (e.g., nafcillin, methicillin) or vancomycin (for activity against S. aureus and S. epidermidis). Vancomycin is used in place of the antistaphylococcal penicillin in neonatal units with methicillin-resistant S. aureus and for selective use to cover S. epidermidis (a CONS) as outlined.[101]

For systemic fungal infections, amphotericin B is considered the initial treatment of choice.[83] Because of the high incidence of Candida species colonization (up to 60%), with up to 20% progressing to invasive fungal infections in VLBW infants, prophylactic fluconazole may be used to prevent Candida colonization and infection in these infants.[102] Infants of 27 weeks' gestational age or less and weighing less than 1,000 g benefited most from prophylactic fluconazole. Despite potential benefits, routine use of prophylactic fluconazole is not recommended and should be reserved for those units with a high incidence of fungal infections. Because uncommon organisms are not suspected in J.E., the regimen of ampicillin 85 mg IV every 12 hours plus gentamicin 4.2 mg IV every 48 hours is appropriate.

Once a pathogen is isolated, the antimicrobial susceptibilities should be evaluated and the drug therapy modified appropriately. Blood, CSF, or urine cultures should be repeated to document bacterial sterilization after 24 to 48 hours of appropriate therapy. J.E. should be evaluated carefully for the development of serious bacterial complications such as meningitis, osteomyelitis, abscess formation, or endocarditis.

DURATION OF THERAPY

As long as there is no evidence of meningitis or other focal infection (e.g., abscess formation), the duration of therapy for most systemic bacterial infections is 7 to 10 days (or approximately 5–7 days after significant clinical improvement). Antibiotic therapy may need to be continued for 14 to 21 days if the neonate's clinical response is slow or if multiple organ systems are involved.[84] If cultures are negative at 48 hours and the infant does not have any clinical or laboratory signs of sepsis, antibiotics can be discontinued. In neonates presenting with signs of severe infection followed by improvement after initiation of antibiotics, therapy may be continued despite negative cultures.[85]

If CSF cultures are positive, repeat CSF cultures should be obtained daily or every other day in J.E. to document when the CSF becomes sterilized. The duration of therapy for neonatal meningitis depends on the clinical response and duration of positive CSF cultures after therapy is initiated. Appropriate antibiotics should be continued for a minimum of 14 days after the CSF is sterilized. This is equivalent to a duration of antibiotic therapy for a minimum of 21 days for gram-negative organisms and at least 14 days for gram-positive pathogens.[81,83] As a general rule, it takes longer to sterilize the CSF of neonates infected by gram-negative enteric bacilli (72 hours) than those infected by gram-positive bacteria (36–48 hours).[81]

CONGENITAL INFECTIONS

TORCH Titers

CASE 105-6

QUESTION 1: S.Y., a 2,000-g female, was born at 34 weeks' gestational age by vaginal delivery. S.Y.'s birth was complicated by prolonged rupture of membranes (>72 hours), and fetal distress requiring a fetal scalp monitor. On physical examination, S.Y. is an extremely irritable newborn with a RR of 60 breaths/minute. Several vesicular skin lesions located on the scalp and around the eyes are noted. Conjunctivitis is also present. S.Y. is placed on supplemental oxygen, and ABGs are obtained. Blood, CSF, and urine were cultured for bacteria and fungus, and S.Y. was started on ampicillin 200 mg IV every 12 hours and gentamicin 9 mg IV every 36 hours to rule out sepsis. Antimicrobial therapy will not be altered until culture results are available. What other tests and information are needed for S.Y. at this time?

Certain bacteria, viruses, and protozoa can cause fetal infections that may result in fetal death, congenital anomalies, serious CNS sequelae, intrauterine growth retardation, or preterm birth.[99] The primary organisms that cause these infections can be remembered by the acronym, TORCH: toxoplasmosis; other (i.e., syphilis, gonorrhea, hepatitis B, listeria); rubella; cytomegalovirus; and herpes simplex. Because of the potential severity of these diseases, newborns who display any signs of infection (e.g., irritability, fever, thrombocytopenia, hepatosplenomegaly) need to be evaluated for these intrauterine and perinatally acquired infections. The diagnosis of each of these infections should be considered separately. A complete infectious disease workup should include specific antibody titer measurements or polymerase chain reaction (PCR) to the suspected organisms rather than sending a single serum sample for TORCH titer measurement.[103]

Primary clinical manifestations and treatment for selected congenital infections are listed in Table 105-5.[2,84,103–106] The clinical signs of these infections may overlap, and concurrent infection with two or more microorganisms is possible. The detection of congenital infections often is difficult because many neonates are asymptomatic at birth. Therefore, prenatal maternal screening and accurate evaluation of maternal history for risk factors are very important. Other organisms that can cause congenitally acquired infections include human immunodeficiency virus, human parvovirus, varicella-zoster virus, and measles virus.[103]

When congenital infections are suspected, appropriate diagnostic tests for each suspected organism should be performed. Viral cultures of the urine, oropharynx, nasopharynx, stool, and conjunctiva, and a complete maternal history along with the results of recent maternal vaginal cultures also should be obtained.[103] Measurements of immunoglobulin M levels specific for each possible organism under consideration are also recommended. S.Y. has signs of a congenital infection (respiratory distress, skin rash, and conjunctivitis). Because of the nature of S.Y.'s skin rash (i.e., vesicular), infection with the herpes simplex virus (HSV) should be highly suspected. Skin vesicles, conjunctiva, oropharynx, nasopharynx, rectum, urine, and CSF should be cultured for HSV and other organisms known to cause congenital infections. Rapid diagnostic testing using tissue scrapings from vesicles and fluorescein-conjugated monoclonal HSV antibody can also be performed. Other appropriate tests for the diagnosis and workup of suspected congenital infections should also be performed (e.g., liver enzymes, prothrombin time, partial thromboplastin time, electroencephalogram [EEG], computed tomography scan, or magnetic resonance imaging).[103]

Table 105-5

Selected Congenital and Perinatal Infections in the Neonate[2,84,103–106]

Organism	Primary Clinical Manifestations	Treatment of Proven or Highly Probable Disease[a]
Herpes simplex	Cutaneous vesicles, keratoconjunctivitis, microcephaly, CNS infection, hepatitis, pneumonitis, prematurity, respiratory distress, sepsis, convulsion, chorioretinitis	Acyclovir Ocular involvement: Add topical therapy: 1%–2% trifluridine, 1% iododeoxyuridine, or 3% vidarabine
Toxoplasmosis	Chorioretinitis, ventriculomegaly, microcephaly, hydrocephaly, intracranial calcifications, ascites, hepatosplenomegaly, lymphadenopathy, jaundice, anemia, mental retardation	Sulfadiazine and pyrimethamine and leucovorin (folinic acid)
Treponema pallidum	Early: Osteochondritis, periostitis, hepatosplenomegaly, skin rash (maculopapular or vesiculobullous), rhinitis, meningitis, IUGR,	Aqueous crystalline penicillin G

	jaundice, hepatitis, anemia, thrombocytopenia, chorioretinitis	
	Late: Hutchinson triad (interstitial keratitis, VIIIth-nerve deafness, Hutchinson teeth), mental retardation, hydrocephalus, saddle nose, mulberry molars	
Hepatitis B	Prematurity; usually asymptomatic; long-term effects include chronic hepatitis, cirrhosis, liver failure, hepatocellular carcinoma	Perinatal exposure (maternal HbsAg-positive): HBIG and hepatitis B vaccine
Rubella	Early: IUGR, retinopathy, hypotonia, hepatosplenomegaly, thrombocytopenic purpura, bone lesions, cardiac effects Late: Hearing loss, mental retardation, diabetes Rare: Myocarditis, glaucoma, microcephaly, hepatitis, anemia	Supportive care
Cytomegalovirus	Petechiae, hepatosplenomegaly, jaundice, prematurity, IUGR, increased liver enzymes, hyperbilirubinemia, anemia, thrombocytopenia, interstitial pneumonitis, microcephaly, chorioretinitis, intracranial calcifications Late: Hearing loss, mental retardation, learning and motor abnormalities, visual disturbances	Ganciclovir
Neisseria gonorrhoeae	Ophthalmia neonatorum, scalp abscess, sepsis, arthritis, meningitis, endocarditis	Ceftriaxone Use cefotaxime if hyperbilirubinemic

[a] See references 2 and 84 for dosing and recommended treatment duration.

CNS, central nervous system; HBIG, hepatitis B immune globulin; HbsAg, hepatitis B surface antigen; IUGR, intrauterine growth retardation.

APNEA OF PREMATURITY

Apnea in neonates is a life-threatening condition that occurs more frequently in premature newborns and newborns of lower birth weights. Only 7% of infants of 34 to 35 weeks' gestational age have apnea.[107] In contrast, the incidence of apnea has been reported to be 78% in infants of 26 to 27 weeks' gestational age and 84% in infants with birth weights less than 1,000 g.[108] Although several definitions exist, clinically significant apnea may be defined as cessation of breathing for at least 15 seconds, or less, if accompanied by bradycardia (HR <100 beats/minute), significant hypoxemia, or cyanosis.[107,109,110] Pallor or hypotonia also may occur.

In neonates, apnea may be caused by a severe underlying illness (e.g., infection, metabolic disorders, intracranial pathology), drugs, or prematurity itself.[110] Appropriate patient history, physical examination, and laboratory tests must be evaluated to rule out other causes of apnea before the diagnosis of apnea of prematurity can be made.[109] It is especially important to rule out sepsis before apnea of prematurity is presumed. If an etiology other than prematurity is identified, therapy would be directed toward that specific cause. For example, antibiotics are used to treat neonatal sepsis with secondary apnea.

Apnea of prematurity is classified into three types: central, obstructive, and mixed.

Approximately 40% of apneic episodes are of central origin (i.e., no respiratory effort), 10% are caused by obstruction, and 50% are attributable to both (i.e., mixed events).[109] Although these terms imply separate mechanisms, obstruction and airway closure may be important in all three types (even "central"). Treatment of apnea of prematurity includes the use of supplemental oxygen, gentle tactile stimulation, environmental temperature control, methylxanthines, nasal CPAP, and positive-pressure ventilation.

CASE 105-7

QUESTION 1: S.M., a premature male newborn of 29 weeks' gestational age, had a birth weight of 995 g. On day 2 of life, he experienced seven episodes of apnea followed by bradycardia with HR as low as 85 beats/minute. These episodes lasted 20 to 30 seconds and required administration of oxygen and tactile stimulation. Three prolonged episodes required bag-and-mask ventilation. Between apneic spells, the newborn seemed well; physical examination and laboratory tests were normal for gestational age. Appropriate cultures were drawn for a septic workup, and ampicillin and gentamicin were initiated. How should S.M.'s apnea be managed?

Methylxanthines, specifically caffeine and theophylline (or aminophylline), are widely accepted as the initial pharmacologic approach for the treatment of idiopathic apnea of prematurity.[107,109] These agents decrease apneic episodes via both central and peripheral effects. Methylxanthines stimulate the medullary respiratory center and increase receptor responsiveness to carbon dioxide. This results in an increase in respiratory drive and minute ventilation. Central stimulatory effects may be mediated by adenosine receptor blockade. Adenosine is a known inhibitor of respiration, and both theophylline and caffeine competitively inhibit adenosine at the receptor level.[107] Peripherally, methylxanthines increase diaphragmatic contractility, decrease diaphragmatic fatigue, and improve respiratory muscle contraction. In addition, methylxanthines increase catecholamine release and metabolic rate. This may improve cardiac output and oxygenation, lessen hypoxic episodes, and decrease apneic spells.

Methylxanthine therapy generally is initiated for apnea of prematurity when apneic episodes are frequent, prolonged for 20 seconds or greater, are accompanied by significant bradycardia or cyanosis, or are not controlled by nonpharmacologic means. S.M. has had prolonged apneas with bradycardia that have required supplemental oxygenation. Initiation of a methylxanthine would be appropriate at this point.

CASE 105-7, QUESTION 2: On rounds, the NICU medical team asks you how does caffeine compare with theophylline with regard to its pharmacokinetics, efficacy, and toxicity? What treatment and dose should be selected for S.M.? How do you reply to the team?

The plasma clearance of caffeine is considerably lower, and the half-life is extremely prolonged in the premature newborn (72–96 hours).[2] The low clearance is a reflection of the decreased neonatal hepatic metabolism and a resultant dependence of elimination on the slow urinary excretion.[111] As a result, caffeine can be dosed once daily (every 24 hours) in the neonate. The half-life of caffeine decreases with increasing PMA,[112] and plasma clearance reaches adult levels after 3 to 4.5 months of life.[113] As a result of the maturational changes, doses usually need to be adjusted after 38 weeks' PMA; however, most infants no longer require treatment of apnea beyond 36 weeks' PMA.

Protein binding of theophylline is decreased in term newborns compared with adults.[114] The decreased protein binding along with an increased tissue distribution results in a larger volume of distribution of theophylline in neonates. This larger volume of distribution results in larger loading-dose requirements to attain similar serum concentrations. Like caffeine, theophylline clearance in preterm newborns is much slower than that observed in young children of 1 to 4 years of age.[114] As a result, smaller theophylline maintenance doses are required in neonates. Theophylline clearance and therefore maintenance doses increase with increasing PMA. Adjustment of maintenance doses is especially important in infants at 40 to 50 weeks' PMA when the greatest maturational changes in theophylline clearance occur.[115]

In adults, theophylline is eliminated primarily via hepatic metabolism.[116,117] In contrast, the primary route of theophylline elimination in neonates is renal excretion of unchanged drug (55%).[115] Hepatic metabolism of theophylline (especially N-demethylation) is decreased in the neonate. As in adults, theophylline is methylated to caffeine in the neonate. The neonate's decreased demethylation pathway, however, results in a decrease in caffeine elimination and significant serum caffeine accumulation. On average, serum caffeine concentrations can be 40% of the serum theophylline concentration.[115] The theophylline-derived caffeine may contribute to the pharmacologic and toxic effects seen in neonates receiving theophylline. After 50 weeks' PMA, the theophylline-derived serum caffeine concentrations become insignificant.

Comparative studies have found similar efficacy for theophylline and caffeine in the control of apnea of prematurity. Caffeine, however, has several advantages over theophylline, including a wider therapeutic index. Adverse effects such as tachycardia, CNS excitation, and feeding intolerance are reported more frequently with theophylline than with caffeine. Because the half-life is prolonged and dosing requirements do not change quickly with time, caffeine serum concentrations do not need to be routinely monitored. The great majority of preterm neonates achieve caffeine plasma concentrations within the therapeutic range (5–20 mcg/mL) if they receive standard doses.[113] Caffeine serum concentrations may be obtained in select neonates (e.g., patients with clinical signs of toxicity or with intractable apnea). IV loading doses of 20 mg/kg caffeine citrate (10 mg/kg caffeine base), followed 24 hours later by maintenance doses of 5 to 8 mg/kg caffeine citrate (2.5–4 mg/kg caffeine base) given daily, are recommended. Loading doses of caffeine citrate should be given IV for 30 minutes using a syringe infusion pump. Maintenance doses can be administered IV for 10 minutes or given orally.[2] Because of the longer half-life, infants receiving caffeine must be monitored for a longer time (e.g., for 7–10 days) for adverse effects if toxicities occur and for apnea recurrence once the medication is discontinued. It is important to remember that another IV caffeine product is marketed in the United States as the sodium benzoate salt. Benzoic acid has been associated with the gasping syndrome and may also displace bilirubin from albumin-binding sites.[2] Because of these toxicities, the caffeine sodium benzoate product should not be used in neonates.

The short- and long-term safety and efficacy of caffeine to treat apnea of prematurity in VLBW infants were studied in a large, randomized, placebo-controlled trial.[45,118] Caffeine significantly decreased the frequency of BPD.[45] Infants who received caffeine were able to have positive airway pressure discontinued 1 week sooner than those receiving placebo. Although caffeine reduced weight gain, the effect was only temporary (during the first 3 weeks of therapy). In a follow-up study at 18 to 21 months' corrected age, caffeine significantly improved the rates of survival without neurodevelopmental disability (e.g., CP, cognitive delay).[118] These benefits were not sustained at 5-year follow-up.[119] Although oral theophylline (aminophylline) and caffeine are considered to be well absorbed in the neonate, many neonates initially have feeding problems when apnea and bradycardia are present. Therefore, therapy is usually initiated with the IV route, and an oral solution can be used when the neonate is stable and tolerating enteral feedings. It should also be remembered that, depending on the specific product used, aminophylline is a salt containing 80% to 85% theophylline.

The generally accepted therapeutic range of theophylline for apnea of prematurity is 6 to 12 mcg/mL. This range is lower than that which is normally accepted for the treatment of asthma (5–15 mcg/mL) for several reasons: (a) The higher free fraction of theophylline found in neonates results in a higher free concentration at any given total concentration; (b) there is a significant accumulation of the unmeasured active metabolite, caffeine; and (c) a different mechanism of action for theophylline is being exploited for apnea (i.e., central stimulation vs. bronchodilation for asthma). Aminophylline IV loading doses and maintenance doses of aminophylline and theophylline can be found in appropriate pediatric references.[2] However, a large variation in serum theophylline concentrations has been observed with some dosing regimens.[120] Concomitant drug therapy and disease states (e.g., hepatic or renal dysfunction) should also be taken into consideration when selecting initial theophylline doses.

Serum theophylline concentrations should be monitored 72 hours after initiation of therapy or after a change in dosage. Serum concentrations of theophylline should also be measured if the infant experiences an increase in the number of apneic episodes, signs or symptoms of toxicity, or a significant increase in weight. In asymptomatic neonates, once steady state levels are obtained, theophylline concentrations may be monitored every 2 weeks.

Because of the many advantages of caffeine over theophylline, S.M. should be given 20 mg of caffeine citrate (10 mg caffeine base) as an IV loading dose for 30 minutes. Maintenance doses of 5 mg of caffeine citrate (2.5 mg caffeine base) every 24 hours should be started 24 hours after the loading dose.

CASE 105-7, QUESTION 3: The NICU medical resident asks you to outline a pharmacotherapeutic monitoring plan for S.M. that includes monitoring parameters for efficacy and toxicity and duration of therapy. What would you tell her?

The goal of methylxanthine therapy for S.M. is to decrease the number of episodes of apnea and bradycardia. Continuous monitoring of HR and RR is required for proper evaluation. The time, duration, and severity of episodes, activity of the infant, and any necessary intervention performed should be documented. Relationships between the apneic episodes and the feeding schedule and volume of feeds, as well as the dosing schedule, should be examined. Apnea of prematurity usually resolves by 34 to 36 weeks' PMA; however, it may persist in some infants up to or beyond 40 weeks' PMA.[107,109] Methylxanthine therapy usually is discontinued at 34 to 36 weeks' PMA provided that the infant has not been having apneic spells. Infants requiring therapy for longer periods may be discharged home on methylxanthines with apnea monitors; however, this occurs very rarely.

Methylxanthine toxicities noted in neonates include tachycardia, agitation, irritability, hyperglycemia, feeding intolerance, gastroesophageal reflux, and emesis or occasional spitting up of food. Tachycardia is the most common toxicity and usually responds to a downward adjustment of the dose. Tachycardia may persist for 1 to 3 days after dosage reductions owing to the decreased elimination of caffeine. Seizures have also been reported with accidental overdoses. Methylxanthine toxicity can be minimized with careful dosing and appropriate monitoring of theophylline serum concentrations.

NEONATAL SEIZURES

CASE 105-8

QUESTION 1: F.H., a term female newborn (weight 3.5 kg), has a history of perinatal asphyxia. Apgar scores were 0, 1, 4, and 7 at 1, 5, 10, and 15 minutes, respectively. Maternal history is negative for drug abuse. Twenty-four hours after birth, F.H. begins to have rhythmic clonic twitching of the right hand, repetitive chewing movements, fluttering of the eyelids, and occasional pendulum-like movements of the extremities that resemble swimming motions. How should F.H.'s seizure activity be evaluated?

Seizure activity may be difficult to recognize in the term or premature neonate. Because of the immaturity of the cortex, neonatal seizures rarely are generalized tonic-clonic events, but can be clonic (focal or multifocal), tonic (focal or generalized), myoclonic (focal, multifocal, or generalized), or subtle in nature.[121,122]

For videos of neonatal seizures, go to **https://www.youtube.com/watch?v=Igj1HBT6oCQ**.

Subtle seizures include activities such as abnormal oral-buccal- lingual movements; ocular movements; swimming, pedaling, or stepping movements; and occasionally apnea. In addition, autonomic nervous system signs such as changes in HR, BP, respirations,

---

skin color, oxygenation, salivation, or pupil size may occur.[121,122] Clinical neonatal seizures may or may not be associated with EEG changes. In addition, electrographic seizure activity may occur in neonates without clinical manifestations (i.e., subclinical seizures).

Neonatal seizure activity is a common manifestation of a life-threatening underlying neurologic process. Etiologies may include metabolic or electrolyte imbalances (e.g., alterations in glucose, calcium, magnesium, or sodium), cerebrovascular injury, CNS infection, genetic disorders, or drug-related causes (e.g., withdrawal after maternal drug use or adverse effects from drugs administered before, during, or after delivery).[121–126] Therefore, initial efforts may not include antiepileptic drug therapy. Definitive treatment is directed toward specific identified etiologies. The acute evaluation of neonatal seizures includes assessment of the infant's airway, breathing, and circulation and a review of the infant's history, physical examination, and laboratory studies. Every neonate with seizure activity should have a bedside determination of glucose; laboratory determinations of serum electrolytes, including sodium, BUN, glucose, calcium, and magnesium; blood gases; bilirubin; and an infectious disease workup, including complete blood cell count with platelets, CRP level, blood culture, urine culture, lumbar puncture with CSF analysis (cell count, protein, glucose), and CSF culture.[121–124] Treatment with antiepileptic drugs is indicated after correction of known electrolyte abnormalities. Antiepileptic drug therapy can be initiated while laboratory test results are pending, as long as hypoglycemia has been corrected.

If these tests do not reveal any abnormalities, an EEG, metabolic disease workup (e.g., serum ammonia, lactate, and pyruvate; serum and urine amino and organic acids), and screening of blood and urine for drugs can be performed.[121–124] Intrauterine infections associated with congenital neurologic abnormalities and seizures can be identified by obtainment of TORCH titers or PCR for specific viruses (e.g., CMV, HSV). Cranial ultrasounds, computed tomography scans, and magnetic resonance images may be obtained to identify infarcts, hemorrhages, calcifications, or cerebral malformations that may cause seizure activity.[121,122,124]

CASE 105-8, QUESTION 2: F.H. is found to have adequate ventilation and circulation. An IV line is established; blood cultures and serum chemistries, including calcium and magnesium, are obtained. A bedside blood glucose determination reveals a blood glucose of 20 mg/dL. What is your assessment and recommendation at this time?

Hypoglycemia seems to be the cause of F.H.'s seizure activity. Hypoxic ischemic encephalopathy secondary to asphyxia, however, is the most common cause of neonatal seizures.[121,123] Hypoxic ischemic encephalopathy can be associated with metabolic abnormalities such as hypoglycemia, hypocalcemia, and hyponatremia (owing to inappropriate secretion of antidiuretic hormone). The definition of clinically significant hypoglycemia in neonates remains controversial, because normal blood glucose depends on a variety of factors, including gestational age, birth weight, feeding status, body stores, and other disease states.[125] Historically, hypoglycemia was defined as a whole blood glucose less than 20 mg/dL for premature infants and less than 30 mg/dL for term infants during the first 72 hours of life and less than 40 mg/dL for any neonate after 72 hours of age. However, in clinical practice, a blood glucose less than 40 mg/dL in a neonate of any age would be treated.[121] F.H. should receive an IV bolus dose of 7 mL (2 mL/kg) of dextrose 10% (200 mg/kg) given in 2 to 3 minutes, followed by a continuous infusion of dextrose 10% at an initial dose of 12.6 to 16.8 mL/hour (6–8 mg/kg/minute or 3.6–4.8 mL/kg/hour).[121,125] Serum glucose levels should be monitored, and the dextrose infusion should be titrated as needed. If hypoglycemia persists, possible causes such as islet tumor of the pancreas, adrenal insufficiency, and inborn errors of metabolism should be investigated. Corticosteroids, glucagon, diazoxide, and octreotide have been used to treat persistent hypoglycemia.[125]

Treatment of Hypocalcemia and Hypomagnesemia

CASE 105-8, QUESTION 3: F.H. receives 7 mL (700 mg) of 10% dextrose solution IV, and an IV infusion of glucose at 8 mg/kg/minute is initiated. A repeat bedside blood glucose determination reveals a blood glucose of 80 mg/dL, but F.H. continues to have seizure activity. F.H.'s laboratory results come back with the following results:

Sodium, 137 mEq/L
Potassium, 4.3 mEq/L
CO_2, 22 mEq/L
Chloride, 104 mEq/L
BUN, 7 mg/dL
SCr, 0.7 mg/dL
Glucose, 25 mg/dL
Magnesium, 1.0 mEq/L
Calcium, 6.5 mg/dL

What should be done next to control F.H.'s seizures?

F.H. also has hypocalcemia and hypomagnesemia, both of which may cause seizure activity. Neonatal hypocalcemia is defined as a serum calcium less than 7.5 mg/dL in preterm and less than 8 mg/dL in term infants[123] or an ionized serum calcium less than 3 mg/dL. Hypomagnesemia (defined as a serum magnesium <1.5 mEq/L) is rare but may coexist with hypocalcemia. Hypomagnesemia should be suspected when hypocalcemia cannot be corrected despite large doses of calcium.

F.H. should receive calcium gluconate 700 mg (200 mg/kg) given slowly IV as a 10% solution[121,123] and magnesium sulfate 25 to 50 mg/kg/dose (0.2–0.4 mEq/kg/dose) IM as a 20% solution or IV as a dilute solution (maximal concentration, 100 mg/mL) administered for 2 to 4 hours.[2] Doses of calcium gluconate and magnesium sulfate may be repeated based on serum determinations. If IV calcium is administered too quickly, vasodilation, hypotension, bradycardia, cardiac arrhythmias, and cardiac arrest may occur. Calcium gluconate may be administered slowly IV at a maximal rate of 50 mg/minute while monitoring HR, BP, and electrocardiogram.[2] The IV site should be closely monitored for signs of infiltration because extravasation may result in severe dermal necrosis.

Treatment with Antiepileptic Drugs

CASE 105-8, QUESTION 4: Despite normalization of her laboratory tests, F.H. continues to have seizure activity. Phenobarbital 35 mg IV push for 1 minute is administered. Ten minutes later, F.H. continues to have intermittent seizure activity. Describe a pharmacotherapeutic plan to control F.H.'s seizure activity.

Phenobarbital is the initial antiepileptic drug of choice for neonatal seizures; phenytoin and lorazepam usually are considered the second and third drugs of choice.[121,124,126–130] Because of the large volume of distribution of phenobarbital in neonates (0.8–1 L/kg), large initial loading doses of 20 mg/kg are required to produce therapeutic serum concentrations.[2,121,124] Because F.H. received only a 10-mg/kg dose (35 mg) of phenobarbital, an additional 10 mg/kg should be given now. Phenobarbital should be administered IV at a rate of 1 mg/kg/minute or less,[2]

---

so a 35-mg dose should be given for at least 10 minutes, not in 1 minute. Rapid administration of phenobarbital may cause respiratory depression, apnea, or hypotension. If F.H. continues to have seizure activity after a total phenobarbital loading dose of 20 mg/kg, additional 5- to 10-mg/kg loading doses may be given every 15 to 20 minutes as needed up to a total loading dose of 40 mg/kg. Ventilatory support may be required when using these higher doses, and serum phenobarbital concentrations should be monitored. Phenobarbital's therapeutic effect of controlling neonatal seizures plateaus at serum concentrations of 40 mcg/mL; adverse effects increase at higher serum concentrations.[131]

If seizure activity is not controlled in F.H. (despite optimal phenobarbital loading doses), a phenytoin loading dose of 70 mg (20 mg/kg) should be administered IV at a rate of 0.5 to 1 mg/kg/minute or less.[2,121,124] Rapid IV administration of phenytoin may cause cardiac arrhythmias, bradycardia, or hypotension. Phenytoin may cause severe damage to tissues if extravasation occurs. Therefore, BP, HR, electrocardiogram, and the IV site of infusion should be monitored. Fosphenytoin, the diphosphate ester salt of phenytoin, is available in the United States for IV and IM use in adults.[2] Fosphenytoin is a water-soluble prodrug of phenytoin that undergoes conversion by plasma and tissue esterases to phenytoin, phosphate, and formaldehyde. Because of its greater water solubility, the IV preparation does not contain propylene glycol, and thus fosphenytoin may have fewer cardiovascular adverse effects associated with IV administration. In addition, it can be safely administered intramuscularly and may cause less dermal necrosis if extravasated. Unfortunately, appropriate clinical studies of fosphenytoin in neonates have not yet been conducted. Unanswered concerns about the neonatal handling of formaldehyde also exist. Despite the lack of neonatal studies, some clinicians prefer to use fosphenytoin instead of phenytoin, due to the aforementioned advantages. Studies assessing the safety, efficacy, and optimal dosing of fosphenytoin in neonates are needed.

Lorazepam IV (0.05 to 0.1 mg/kg) should be used to treat F.H.'s seizures if they are unresponsive to phenobarbital and phenytoin.[2,126,127] Lorazepam is preferred over diazepam owing to its longer duration of effect and fewer pharmaceutical adjuvants. Lorazepam (especially in combination with phenobarbital) may cause respiratory and CNS depression. RR, BP, and HR should be monitored. Doses should be diluted with an equal volume of 5% dextrose in water, normal saline, or sterile water for injection before IV use and administered slowly for 2 to 5 minutes.[2]

If seizure activity continues in F.H., continuous IV infusion of midazolam or IV or oral levetiracetam should be considered.[121,124,128–130,132] Levetiracetam may be preferred over continuous infusion midazolam due to less adverse neurologic effects. In fact, some clinicians prefer levetiracetam to phenytoin as a second-line agent. Although the IV formulation of levetiracetam is not approved for use in neonates, some neonatal centers use the pediatric oral dosing recommendations for the IV route because the two forms are bioequivalent.[2] However, the optimal neonatal dose of levetiracetam has not been established. Neonatal reports have used doses based on studies in pediatric patients.[128] Given that levetiracetam is primarily excreted via the kidney (66% of a dose is excreted as unchanged drug in the urine) and that the renal function of neonates is decreased compared with that of older infants, one would expect a lower clearance and the use of lower levetiracetam doses in neonates. However, recent neonatal pharmacokinetic studies [124,129,130] have identified a larger volume of distribution per kg (compared to children) and a more rapid clearance than expected based on immature renal function. A significant increase in levetiracetam clearance also occurred during the first week of life, reaching the clearance seen in children. These findings indicate that in neonates, larger loading doses and maintenance doses, with an adjustment of maintenance doses after the first 7 days of life, would be required. Phase 2 trials of higher doses have not yet been completed.[124,129] Thus, currently the clinical use of levetiracetam in neonates requires careful dose titration and close monitoring of adverse effects. Oral carbamazepine, clonazepam, lamotrigine, topiramate, and valproic acid (IV, oral) have also been used to treat refractory neonatal seizures in limited numbers of patients.[121,124,126,129] Because the risk of valproic acid-associated hepatotoxicity is higher for patients younger than 2 years of age, this drug is not a preferred agent for use in neonates.[2] IV pyridoxine (50 to 100 mg) should be considered when seizure activity persists. Pyridoxine is a cofactor required for the synthesis of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). Patients with pyridoxine dependency require higher amounts of pyridoxine for proper GABA synthesis. Pyridoxine dependency is a rare disorder, but should be considered in neonates with seizure activity unresponsive to antiepileptic drug therapy. Lifelong supplementation of pyridoxine is required in these patients.[123]

CASE 105-8, QUESTION 5: F.H.'s seizure activity stopped after receiving a total loading dose of 105 mg of phenobarbital and 70 mg of phenytoin. A serum phenobarbital concentration of 35 mcg/mL and a phenytoin concentration of 17 mcg/mL were measured 1 hour after the phenytoin loading dose (2 hours after the last phenobarbital loading dose). How should maintenance doses of antiepileptic drugs be instituted in F.H.?

It is not surprising that F.H. required both phenobarbital and phenytoin to control her seizures. Although phenobarbital and phenytoin are equally effective, neonatal seizures are controlled in fewer than 50% of neonates with either agent alone. When both agents are used together, neonatal seizures are controlled in approximately 60% of neonates.[133]

F.H. should be placed on maintenance doses of both phenobarbital and phenytoin because both drugs were needed to control her seizure activity. Because the half-life of phenobarbital is prolonged in neonates (about 100–150 hours), maintenance doses can be instituted 24 hours after the loading dose at 3 to 4 mg/kg/day[2,123,134] as a single daily dose. Although this newborn is term, she should receive a lower dose of phenobarbital (2.5– 3 mg/kg/day) because of her history of asphyxia. Asphyxiated neonates have impaired phenobarbital clearance and therefore require lower maintenance doses than nonasphyxiated neonates to achieve similar phenobarbital serum concentrations.[135] Maintenance doses of phenytoin (3–4 mg/kg/day given in divided doses every 12 hours) may be initiated 12 to 24 hours after the loading dose. Serum concentrations of these agents should be monitored periodically because maintenance dose requirements increase with time, usually by weeks 2 to 4 of therapy.[134] This may be related to a normal maturation of hepatic enzyme systems with age or induction of cytochrome P-450 enzymes. In neonates, oral phenytoin is poorly absorbed and should be avoided in the acute setting. A routine 25% increase in the dose is needed when converting IV phenytoin to oral to attain similar serum concentrations. In addition, after 2 to 4 weeks of age, dosing intervals of every 8 hours may be needed.

It should be remembered that phenytoin is a highly protein-bound drug. In neonates, protein binding of phenytoin is decreased. This results in an increased free fraction and suggests that total phenytoin therapeutic serum concentrations in newborns should be 8 to 15 mcg/mL rather than the 10 to 20 mcg/mL as accepted in children and adults.[2] In addition, bilirubin can displace phenytoin from albumin binding sites. A positive correlation between total bilirubin concentrations and free fraction of phenytoin has been described. Unbound phenytoin was reported to be approximately 20% in neonates when bilirubin concentrations were 20 mg/dL (compared with 10% normally).[136] Thus, total phenytoin serum concentrations must be interpreted carefully in neonates, and measurement of unbound phenytoin may be required in neonates with hyperbilirubinemia.

The optimal duration of anticonvulsant treatment of neonatal seizures has not been clearly established. Because of the potential long-term toxicities of these medications and the low risk of seizure recurrence, anticonvulsants are generally discontinued before discharge if the neonate's neurologic examination and EEG are normal. Neonates who continue receiving anticonvulsants are reassessed periodically after discharge (e.g., at 1 and 3 months of age and then every 3 months). Thus, the duration of anticonvulsant medications is individualized based on the infant's neurologic examination and EEG.

Care of the Critically Ill Child

Elizabeth Anne Farrington and Marcia L. Buck

	CORE PRINCIPLES	CHAPTER CASES
1	The most frequent cause of cardiac arrest in pediatric patients is a terminal result of respiratory failure or shock, not a primary cardiac event.	**Case 106-1 (Question 1)**
2	Developmental changes and immaturity of the respiratory system make respiratory distress the most common reason for hospital admission in the first year of life. Nasal flaring and grunting are unique features of the respiratory examination in infants that indicate respiratory distress. The normal respiratory rate in children changes over time; therefore, the respiratory rate that would be of concern varies based on the age of the patient.	**Case 106-2 (Questions 1, 2)**
3	Oxygen should be administered immediately in a child where respiratory difficulty is suspected. Once the decision is made to intubate the patient, the choices for pharmacotherapy of intubation vary based on the cardiovascular stability of the patient, whether the stomach is empty or full, and the underlying cause of the respiratory distress.	**Case 106-2 (Questions 3, 4)**
4	Hypovolemic shock is the most common type of shock seen in pediatric patients. Septic shock, obstructive shock, and cardiogenic shock occur in children but are less common. The initial treatment of all forms of shock is the same. A pediatric patient can present with compensated or decompensated shock. There are physiologic differences in the pediatric patient's response to hypovolemia, with hypotension being the last physiologic change during decompensation.	**Case 106-3 (Questions 1, 2)**
5	Infants have low glycogen stores, so are at high risk for the development of hypoglycemia when they have poor oral intake or during conditions of stress. Because hypoglycemia may cause seizures and is linked to poor neurologic outcome, all critically ill infants should have point-of-care glucose testing on presentation. If identified, hypoglycemia must be treated promptly.	**Case 106-3 (Question 3)**
6	Due to the immature immune system in the infant, the incidence of septic shock is the highest in the first year of life. Patients with underlying medical conditions have a higher mortality rate than previously healthy children who experience sepsis.	**Case 106-4 (Question 1)**

7	Due to physiologic changes during childhood, the definitions of sepsis and systemic inflammatory response syndrome (SIRS) are different in children and adults. Tachycardia and tachypnea, pivotal to the adult definition of SIRS, are common presenting symptoms of many pediatric disease processes and are not solely indicative of sepsis. Unlike adult guidelines, temperature variation and leukocyte abnormalities are included in the pediatric definitions. There are also specific definitions based on patient age: newborn, neonate, infant, toddler and preschool-aged child, school-aged child, and adolescent.	**Case 106-4 (Question 2)**
8	Septic shock can be further defined by the patient's response to fluid resuscitation and catecholamine administration. These factors, as well as physiologic differences in neonatal and pediatric cardiovascular physiology compared with adults, affect not only the choice of therapy but also drug dosing and monitoring.	**Case 106-4 (Questions 3–6)**

9	Neonates with ductal-dependent congenital heart disease (CHD) may not be diagnosed immediately after birth. These patients may present with symptoms of being either in respiratory distress, in cardiogenic or obstructive shock, or in a combination of both. It is essential to consider CHD in any neonate who presents with these symptoms.	**Case 106-5 (Question 1)**
10	Traumatic brain injury (TBI) is the leading cause of mortality in children and leads to significant morbidity among survivors. The anatomic differences of the child's brain render it more susceptible to certain types of injuries after head trauma. Causes vary by age, with nonaccidental trauma seen most commonly in the first year of life. Quick assessment of the patient on presentation to emergency services is needed for appropriate diagnosis, stabilization, and treatment.	**Case 106-6 (Questions 1–3)**
11	Placement of a ventriculostomy will allow for measurement of intracranial pressure (ICP) and drainage of cerebral spinal fluid. The ability to measure ICP will assist in the evaluation of the efficacy of treatments. Cerebral perfusion pressure (CPP) also must be monitored closely in patients with TBI. Goal CPP values vary by age. Standard therapies to reduce ICP include CSF drainage, medically induced hypertension, and hyperosmolar therapy with mannitol or hypertonic saline. When standard therapies fail, barbiturate coma, therapeutic hypothermia, or decompressive craniectomy may be considered.	**Case 106-6 (Questions 4–6)**
12	Treatment and/or prevention of early post-traumatic seizures has been shown to improve outcomes, but long-term use of anticonvulsant medications (greater than 7 days) has not been shown to improve outcomes and is associated with adverse effects.	**Case 106-7 (Question 1)**

Much of pediatric practice is dedicated to assisting the child in making the transition from the intrauterine environment through infancy, childhood, and adolescence to adulthood. One of the greatest challenges in managing pediatric patients is recognizing the numerous physiologic changes that take place during this time and understanding how they affect assessment and management of the patient. The definition and presentation of many disease states encountered in the critical care setting, including respiratory depression, supraventricular tachycardia, hypotension, and shock, vary based on the age of the patient as a result of these physiologic variations. There are also newborn emergencies that are unique to the physiologic transitions that occur in the first month of life.

Pediatric healthcare providers practicing in critical care settings such as the emergency department or pediatric intensive care unit (PICU) must be adept at incorporating these physiologic differences into medication selection, dosing, and monitoring to optimize patient care.

The epidemiology of patients admitted to either the pediatric emergency department or PICU differs from that typically seen in adult critical care settings.[1,2] In an evaluation of 361 children presenting to an emergency department, the most common medial reasons for admission were cardiocirculatory causes (32%), neurologic conditions (26%), and respiratory causes (23%).[1] Cardiocirculatory causes included hypovolemic, septic, cardiac, and anaphylactic shock. Neurologic conditions consisted primarily of seizures, status epilepticus, and meningitis or encephalitis. The most common respiratory cause for admission was respiratory syncytial virus (RSV) bronchiolitis, followed by pneumonia, pleural effusions, and croup. Eighteen percent (18%) of the patients were admitted after trauma. Diabetic ketoacidosis accounted for 6% of admissions. Other diagnoses included intoxications, near drowning, snake bites, and burns. Assessment of the most common causes for PICU admission has provided similar results. In a review of 1,149 children admitted during a 2-year period to the PICU of a university-affiliated children's hospital, the majority (38%) were diagnosed with cardiovascular diseases, followed by respiratory illnesses (28%), other medical causes (10%), neurologic illness (8%), and trauma (8%). Another 7% were admitted for postoperative care.[2] When comparing admissions to pediatric intensive care from 1982, 1995, and 2005 to 2006, the most common medical diagnostic categories have remained unchanged. However, fewer children were admitted after accidents, with croup or with epiglottitis.[2] These changes can be explained by mandatory car seats for children, administration of dexamethasone in the emergency department to patients with croup and the conjugate Haemophilus influenza type b immunization. During the same time period, the proportion of patients that died decreased from 11% to 4.8%; however, the proportion of survivors with moderate or severe disability increased significantly from 8.4% to 17.9%.[2] With the low rate of mortality in the PICU, the focus of our research should investigate how to improve patient outcomes.

PEDIATRIC CARDIOPULMONARY RESUSCITATION

In marked contrast to pediatric cardiac arrest, adult cardiac arrest studies have focused on the diagnosis and treatment of ventricular fibrillation (VF) in both inpatient and out-of-hospital cardiac arrest. Studies showed that VF was the most common initial dysrhythmia in adults with sudden death; in some reports, the prevalence of VF was 60% to 85%. Cardiac arrest due to VF or pulseless ventricular tachycardia as the initial cardiac rhythm occurs in only 5% to 15% of pediatric patients in hospital and out-of hospital cardiac arrest.[3] In contrast to adults, cardiac arrest in infants and children does not usually result from a primary cardiac cause; more often it is the terminal result of progressive respiratory failure or shock. Therefore, it is essential to recognize and treat pediatric patients admitted with respiratory distress, pneumonia, and shock aggressively to prevent the development of systemic hypoxemia, hypercapnia, and acidosis that may then progress to bradycardia, hypotension, and eventually cardiorespiratory arrest.

CASE 106-1

QUESTION 1: Paramedics are transporting C.W., a 5-month-old, 5-kg infant with respiratory distress who stops breathing en route to the hospital. The patient is bag-mask-ventilated with cardiopulmonary resuscitation in progress. On arrival in the emergency department, the patient is apneic, asystolic, and pulseless. The infant has no intravenous (IV) access. After brief bag-mask ventilation, the patient is intubated with an endotracheal tube (ETT). A colorimetric carbon dioxide capnometer detector device confirms proper ETT placement. Findings now include breath sounds that are equal bilaterally and good chest movement with ventilation, although there is still no pulse palpable without chest compressions and no heart sounds are heard. An electrocardiogram shows asystole. Oxygen saturation is not obtainable. What medication is needed for C.W. at this point in his resuscitation and what would the appropriate dose be?

Epinephrine is the drug of choice for the management of pediatric asystole.[3] Ventilation and chest compressions should be continued for C.W., and while one responder is attempting IV access, another may administer the first dose of epinephrine down the ETT using a higher dose of 0.5 mg (0.1 mg/kg prepared from the 1:1,000 or 1 mg/mL concentration) to account for reduced absorption. If two attempts at IV line placement are unsuccessful, an intraosseous (IO) catheter should be inserted into the proximal tibia. Blood may be obtained through the IO needle to perform a rapid glucose check and sent for further studies. After reassessment of the airway, ventilation and chest compressions should be continued. Subsequent doses of epinephrine can be administered every 3 to 5 minutes through the IO line, using the appropriate IV/IO dose of 0.05 mg (0.01 mg/kg using the 1:10,000 or 0.1 mg/mL concentration).

RESPIRATORY DISTRESS

Respiratory distress, related to problems at all levels of the respiratory tract from the nose to the lungs, is a frequent occurrence in children.[4] (For a video that shows some of the signs of respiratory distress in an infant, go to http://www.youtube.com/watch?v=42jJ18fkZ0Y.) The nose provides nearly half the total airway resistance in children. Infants under 2 months are obligate nasal breathers, and their nose is short, soft, and small with nearly circular nares. The nares will double in size from birth to 6 months but they can easily be occluded from edema, secretions, or external pressure. Simply clearing the nasal passageways with saline and bulb suctioning can significantly improve an infant's respiratory condition. Other physiologic reasons for a high incidence of respiratory failure in infants and children are small and collapsible airways, an unstable chest wall, inadequate collateral ventilation for alveoli, poor control (tone) of the upper airway (particularly during sleep), tendency for the respiratory muscles to fatigue, reactivity of the pulmonary vascular bed (increased sensitivity of the vasculature, particularly in young infants), an inefficient immune system, genetic disorders or syndromes, and residual problems related to premature birth such as bronchopulmonary dysplasia.

CASE 106-2

QUESTION 1: T.F. is a 7-month-old, previously healthy 12-kg infant who presents to the emergency room with a 3-day history of upper respiratory tract symptoms. His mother states that he is having increasing difficulty breathing and has not wanted to drink or eat. On examination, he has a respiratory rate of 70 breaths/minute, an O_2 saturation of 90% on 100% FIO_2 via nasal cannula, nasal flaring and grunting, and both intercostal and suprasternal retractions. Initial viral screening reveals positive results for RSV, and his chest X-ray is consistent with RSV bronchiolitis. He was agitated and fussy at first presentation, but during the last 30 minutes his respiratory rate has decreased to 40 breaths/minute with a reduction in retractions and he has become somnolent. What developmental changes in the lung explain why a routine viral infection could result in the need for an emergency room visit in a 7-month-old previously healthy child?

The most common reason for admission to the hospital in the first year of life is respiratory distress. This can be explained by the numerous physiologic differences seen in an infant. Although all the conducting airways are present at birth and the airway branching pattern is complete, the airways are small.[5] The airways will increase in size and length throughout childhood. Not only are the airways smaller in an infant but supporting airway cartilage and elastic tissue are not developed until school age. For these reasons, the child's airways are susceptible to collapse and may easily become obstructed as a result of laryngospasm, bronchospasm, and edema or mucus accumulation. Normal airway resistance is the highest in infants because it is inversely proportional to $1/\text{radius}^4$. Therefore, any airway narrowing from bronchospasm, edema, or mucus accumulation will significantly increase the airway resistance and increase the infant's work of breathing. The cartilaginous ribs of the infant and young child are twice as compliant as the bony ribs of the older child or adult. During episodes of respiratory distress, the infant's chest wall will retract further than a patient with a bony ribcage. This will reduce the patient's ability to maintain functional residual capacity (FRC) or increase tidal volume, thus further increasing the patient's work of breathing.

The respiratory muscles consist of muscles of the upper airway, the lower airway, and the diaphragm. They contribute to expansion of the lung and maintenance of airway patency. Lack of development of the small airway muscles may render young infants less responsive than older children to bronchodilator therapy. Lastly, the intercostal muscles are not fully developed until school age, so they act primarily to stabilize the chest wall during the first years of life. Because the intercostal muscles have neither the leverage nor the strength to lift the rib cage in the young child, the diaphragm is responsible for the generation of tidal volume. Therefore, anything that impedes diaphragm movement, such as a large stomach bubble, abdominal distension, or peritonitis, can result in respiratory failure in the young child.

CASE 106-2, QUESTION 2: What respiratory signs and symptoms are present in T.F. and how do they define the patient's respiratory status? What are potential causes of T.F.'s respiratory distress?

To assess a patient for respiratory distress, one should evaluate four areas: respiratory rate and effort, work of breathing, quality and magnitude of breath sounds, and the patient's mental status. Normal respiratory rates vary with age (Table 106-1). A respiratory rate greater than 60 breaths/minute is abnormal in a child of any age, but most concerning in an older child. An abnormally slow or decreasing respiratory rate may herald respiratory failure. Intercostal, subcostal, and supracostal retractions increase with increasing respiratory distress. Although increased retractions are seen in infants, they have decreased efficiency of respiratory muscle function during the first years of life; therefore, the benefit in infants is reduced. Decreasing respiratory rate and diminished retractions in a child with a history of distress may signal severe fatigue. Nasal flaring is an effort to increase airway diameter and is often seen with hypoxemia. T.F. demonstrates all of these physiologic signs of respiratory distress. In addition to these findings, some infants will exhibit an expiratory grunting noise. This noise is produced by the child's involuntary effort to counter the loss of FRC by closing their glottis on active exhalation. Grunting produces positive end-expiratory pressure (PEEP) in an effort to prevent airway collapse. An expiratory grunt is mechanistically similar to "pursed lip breathing" in adults with chronic dyspnea. An expiratory grunt is classically seen in the presence of extensive alveolar pathology and is considered a sign of serious disease.

Table 106-1

Normal Respiratory Rates and Definition of Tachypnea for Children, by Age

Age	Respiratory Rate (breaths/minute)	Tachypnea (breaths/minute)
Newborn–2 months	30–60	>60
2–12 months	25–40	>50
1–3 years	20–30	>40
3–6 years	16–22	>40
7–12 years	14–20	>40
>12 years	12–20	>40

There are numerous causes of respiratory distress in infants and children. Table 106-2 summarizes common respiratory noises in children and their site of origin which may provide clues to the clinical cause. The most common causes of respiratory failure in infants and children are infectious diseases, asthma, malignancies, trauma (both accidental and nonaccidental), poisonings, foreign body aspiration, anatomic upper airway obstruction, cardiogenic shock, and untreated left-to-right intracardiac shunts. Respiratory syncytial virus is among the most common causes of respiratory distress in infants and young children, leading to an estimated 90,000 hospitalizations each year.[6] Although RSV can occur at any age, it is most severe in children under 2 years of age such as T.F. Prematurity, as well as chronic respiratory disease and congenital heart disease, increases the risk for severe RSV bronchiolitis requiring hospitalization.

CASE 106-2, QUESTION 3: T.F. is no longer consistently maintaining oxygen saturation values above 90% on nasal cannula O_2. How should T.F. be managed?

Oxygen should be administered immediately in any patient where respiratory difficulty is suspected. Infants and children consume 2 to 3 times more oxygen per kilogram of body weight than adults under normal conditions and even more when they are ill or distressed. T.F. responded well to oxygen administered via nasal cannula in the emergency department, but is now increasingly somnolent and has a decreased respiratory rate along with decreased oxygen saturation values—all signs of impending respiratory failure. The specific indications for intubation in infants and children are as follows:

Table 106-2

Common Airway Noises, Site of Origin, and Clinical Causes in Children

Respiratory Noise	Definition	Site of Origin	Common Clinical Causes	
			Acute	Persistent
Wheeze	A high-pitched, continuous musical noise, often associated with prolonged expiration (can occur with inspiration or expiration)	Intrathoracic airways	Intermittent asthma/viral-induced wheeze	Persistent asthma

Rattle	This sound is the result of excessive secretions in the large airways, which are presumably moving with normal respirations	Either or both intrathoracic and extrathoracic airways	Acute viral bronchitis	Chronic sputum retention (neuromuscular disorders)
Stridor	This is predominately an inspiratory noise and indicates obstruction to airflow in the extrathoracic airways (upper airways obstruction) (can occur with inspiration or expiration)	Extrathoracic airways	Acute laryngotracheobronchitis (or viral croup)	Laryngomalacia
Snore	The noise arises from an increase to airflow through the upper airways, predominately in the region of the nasopharynx and oropharynx; it is more obvious during inspiration, but may be audible throughout the respiratory cycle	Oronasopharyngeal airway	Acute tonsillitis/pharyngitis	Chronically enlarged tonsils and adenoids, obstructive sleep apnea
Snuffle/Snort	These terms describe respiratory noises emanating from the nasal passages; these noises are audible in both inspiration and expiration and are often associated with visible secretions from the nares	Nasal passage/nasopharynx	Acute viral head cold	Allergic rhinitis
Grunt	This sound occurs with closure of the glottis during active exhalation	Alveoli/lung parenchyma	Any alveolar pathology in infants and small children	None

For examples of some of these airway noises, go to the following web links:

- Wheeze: http://www.youtube.com/watch?v=YG0-ukhU1xE&feature=related
- Rattle/rhonchi: http://www.youtube.com/watch?v=QPBZOohj2a0&feature=related
- Stridor

Toddler: http://www.youtube.com/watch?v=Zkau4yHsLLM&feature=related

Infant: http://www.youtube.com/watch?v=73zUjcCzgqA&NR=1

- Grunt: http://www.youtube.com/watch?v=aptwttJ6y_4

1. Apnea
2. Acute respiratory failure (Pao_2 <50 mm Hg in patient with FIO_2 >0.5 and Paco_2 >5 mm Hg acutely)
3. Need to control oxygen delivery, with institution of PEEP or to provide accurate delivery of FIO_2 greater than 0.5
4. Need to control ventilation to decrease work of breathing, control Paco_2, or to administer neuromuscular blocking agents

5. Inadequate chest wall function, as in patients with neuromuscular disorders such as Guillain–Barré syndrome, spinal muscular atrophy, or muscular dystrophy
6. Upper airway obstruction
7. Protection of the airway of a patient whose protective reflexes are absent, such as those with head trauma

Based on the diagnosis of acute respiratory failure and the need to control oxygen delivery, T.F. should be intubated and placed on mechanical ventilation.

MEDICATIONS FOR INTUBATION AND MECHANICAL VENTILATION

CASE 106-2, QUESTION 4: What pharmacologic agents are recommended when intubating a pediatric patient? Develop a plan for the medications to be used during intubation of T.F.

After the decision is made to proceed with intubation, the next decision needs to be whether pharmacologic agents are appropriate. Most pediatric patients require sedation before laryngoscopy and intubation. The goal is to depress the infant or child's level of consciousness sufficiently to produce appropriate conditions for intubation. Pharmacologic therapy is used to produce adequate sedation, analgesia, and amnesia plus a blunting of the physiologic response to airway manipulation. Intubation in the awake state can elicit protective reflexes that trigger tachycardia, bradycardia, and elevation of blood pressure, increased intracranial pressure, intraocular pressure, cough, and bronchospasm. Pharmacologic control promotes a smoother intubation with less physiologic stress for the patient who often is already in a compromised state. Ideally, this should be accomplished while producing minimal hemodynamic compromise.[7]

There are many factors to be considered when choosing agents for intubation: the onset of action of the agent, the patient's hemodynamic status, the need to prevent increased intraocular or intracranial pressure that may be caused with intubation, and whether the stomach is full or empty. A wide variety of medications may be used for pediatric sedation, each with its own risk and benefits (Table 106-3).[7] In general, agents that act rapidly and are eliminated quickly are ideal. Often drug choices are made based on the clinician's experience with a particular drug and the immediate availability of the drug. Most importantly, the drug regimen chosen must be based on the patient's physiologic state. Agents with adverse effects that would exacerbate any underlying medical conditions must be avoided. Narcotics used in combination with anxiolytics are used commonly. To produce optimal conditions for intubation, T.F. could be given 12 mcg of fentanyl (1 mcg/kg) and 1.2 mg of midazolam (0.1 mg/kg) IV before the procedure to provide sedation and analgesia. Both agents are relatively short-acting and reversible if difficulties arise with ETT placement.

Patients with inadequate relaxation despite adequate sedation may require neuromuscular blockade, although these agents are not without risk. In a patient with a partial airway obstruction, neuromuscular blockade may worsen pharyngeal collapse, potentially resulting in complete airway obstruction. Therefore, neuromuscular blocking agents should only be used if the clinician is absolutely certain that adequate ventilation can be provided or that the patient can be intubated. If adequate chest rise and oxygen saturation cannot be readily maintained with bag-mask ventilation, neuromuscular blockers should not be used. Infants and children younger than 5 years have a high vagal tone; therefore, they are more likely to exhibit bradycardia when intubated. Instrumentation of the airway can directly stimulate vagal receptors and induce bradycardia. In these patients, it is prudent to administer atropine 0.02 mg/kg before intubation to blunt the autonomic response. Lidocaine (1–1.5 mg/kg/dose with a maximum dose of 100 mg) may be administered intravenously to blunt the airway protective reflexes elicited by instrumentation. This may be particularly useful in a patient with elevated intracranial pressure (ICP).

In the asthmatic patient, drugs that release histamine (e.g., morphine, atracurium, or thiopental) and have the potential to produce laryngospasm or bronchospasm should be avoided. The beneficial bronchodilatory side effects of ketamine, however, make it a useful choice in these patients. In a child with increased ICP, the choice of pharmacologic agent depends on the hemodynamic status of the patient. Thiopental or pentobarbital is an excellent choice in the hemodynamically stable patient whereas etomidate is preferred if the patient is unstable or hypovolemia is suspected. Etomidate should not be used routinely in pediatric patients because a single dose administered for intubation has the potential to produce adrenal inhibition.[8] In children and adults with septic shock, etomidate administration is associated with a higher mortality rate.[8–10]

In all cases of intubation, preoxygenation is carried out to increase the available oxygen in the lungs during the procedure, thus giving the practitioner some buffer time to intubate the patient. However, in patients with an elevated ICP or pulmonary vascular hypertension, hyperventilation is recommended to also produce hypocarbia. A summary of specific patient conditions and recommended agents for intubation can be found in Table 106-4. In an infant or child with a full stomach, the risk of aspiration of gastric contents is high. Rapid sequence intubation (RSI) is used when there is an aspiration risk, such as the child with a full stomach, and there is no concern of a difficult intubation.[11] The goal of RSI is to gain airway control with an ETT as quickly as possible to prevent aspiration. The patient is preoxygenated via face mask and bag-mask ventilation cannot be used because it causes gastric distension. Once all necessary intubation equipment is ready, rapidly acting sedative, analgesic, and paralytic medications are administered simultaneously. Cricoid pressure must be maintained until the ETT is in place and confirmed to provide adequate protection from aspiration. An end-tidal CO_2 detector should be attached to the ETT after intubation to confirm proper placement in the trachea. Colorimetric end-tidal CO_2 devices change color from purple to yellow to confirm the presence of exhaled CO_2 and tracheal placement.

Endotracheal intubation and mechanical ventilation can be painful, frightening, and anxiety provoking, especially in a young child. To improve patient comfort, relieve anxiety, and lessen the work of breathing, anxiolytics, sedatives, and analgesics are frequently administered once the patient is intubated and mechanically ventilated. Maintenance of adequate sedation is essential. Selection of appropriate agents is based on the physiology of the patient. Guidelines for the use of continuous infusions are outlined in Table 106-3. In the paralyzed patient, neuromuscular blockade neither alters consciousness nor provides analgesia; therefore, adequate sedation and analgesia are essential. Providing effective analgesia and sedation to the pediatric patient depends on accurate ongoing efforts to assess the intensity of the patient’s pain or anxiety. The assessment of pain and anxiety in infants and critically ill children who are unable to communicate relies heavily on physiologic and behavioral responses. A number of pain and sedation tools have been developed and validated specifically for use in children.[12] No single standard measure gives a complete qualitative or quantitative measure. Selection of an appropriate tool is based on the child’s age, underlying medical condition, and cognition level. It is essential that these tools are utilized to evaluate the adequacy of the ICU sedation. Policies and procedures need to be in place for the appropriate selection and use of each tool, in addition to training of all healthcare professionals to appropriately use each tool. The goal is to use the minimum amount of sedation needed to adequately sedate the intubated child, while minimizing adverse effects.

Table 106-3

Pharmacologic Agents Used for Pediatric Intubation and Continuous Sedation

Drug	Route	Dose	Onset	Duration	Benefits	Adverse Effects
Narcotics						
Morphine	IV	0.1 mg/kg/dose (max: initial dose 2 mg) may repeat to a maximum total dose of 15 mg Neonates: 0.05 mg/kg/dose **Continuous infusion** Children: 20–50 mcg/kg/hour	Peak: 20 minutes	2–4 hours in neonates	Reversible (naloxone)	Histamine release. Respiratory depression hypotension, peripheral vasodilatation, euphoria, dysphoria, itching, central nausea and

		Neonates: 15 mcg/kg/hour Premature neonates: 10 mcg/kg/hour				vomiting, decreased response to hypercarbia
Fentanyl	IV	1–3 mcg/kg/dose (max: initial dose 100 mcg, may repeat to a total dose of 5 mcg/kg or 250 mcg) **Continuous infusion** 1–3 mcg/kg/hour (max: initial dose 50–100 mcg/hour) CHD patient with an open chest: 5 mcg/kg/hour	1–3 minutes	30–90 minutes	Rapid onset, short acting, reversible (naloxone), relatively stable hemodynamic profile	Bradycardia, respiratory depression, decreased response to hypercarbia, acute chest wall rigidity, itching
Benzodiazepines						
Diazepam	IV	0.05 mg/kg/dose (max: 5 mg) may repeat in 0.05-mg/kg increments (max: 1 mg) to a total maximum dose of 10 mg	0.5–2 minutes	3 hours	Reversible (flumazenil)	Respiratory depression, lacks analgesic properties, hypotension and bradycardia, Local irritation, pain
Lorazepam	IV	0.05–0.15 mg/kg/dose (max: 4 mg)	15–30 minutes	0.5–3 hours	Reversible (flumazenil)	Respiratory depression, lacks analgesic properties, hypotension and bradycardia
Midazolam	IV/IM	0.05–0.15 mg/kg/dose (max: initial dose 2 mg, may repeat in 1-mg increments to a total dose of 5 mg) **Continuous infusion** 0.05–0.1 mg/kg/hour (max: initial dose 2 mg/hour)	1–5 minutes	20–30 minutes	Rapid onset, short acting, provides amnesia, reversible (flumazenil)	Respiratory depression, lacks analgesic properties, hypotension and bradycardia
	Intranasal	0.1–0.3 mg/kg/dose (max: 10 mg) Use the 5-mg/mL concentration	2–5 minutes	30–60 minutes		
	PO	0.5–0.75 mg/kg/dose (max:10–20 mg)	30 minutes	2–6 hours		

Barbiturates						
Pentobarbital	IV	2 mg/kg/dose (max: 100 mg). May repeat in 1-mg/kg/dose increments to a total dose of 7 mg/kg. Do not exceed 200 mg total dose **Continuous infusion** 0.5–1 mg/kg/hour	1 minute	15 minutes	Decreases intracranial pressure	Cardiovascular and respiratory depression
	IM/PO/PR	2–6 mg/kg/dose	IM: 10–15 minutes PR/PO: 15–60 minutes	1–4 hours		

Miscellaneous						
Ketamine	IV	1 mg/kg/dose every 5 minutes titrated to effect **Continuous infusion** 0.5–1 mg/kg/hour	1–2 minutes	10–30 minutes	Rapid onset, airway protective reflexes stay intact, no hypotension or bradycardia Bronchodilation is useful to intubate asthmatics	Increases airway secretions and laryngospasm (blunted with atropine). Elevated intracranial and intraocular pressure. Emergence reactions are possible.
	IM	4–5 mg/kg/dose	3–5 minutes	12–25 minutes		
	PO	6–10 mg/kg (mixed in cola or other beverage)	30 minutes	30–60 minutes		
Etomidate	IV	0.3 mg/kg/dose initially, then 0.1 mg/kg/dose every 5 minutes to titrate to effect	10–20 seconds	4–10 minutes	Rapid onset Short acting Stable hemodynamic profile, decreased ICP	Potential for adrenal inhibition, nausea, and vomiting on emergence
Propofol	IV	1–2 mg/kg/dose initially, then 0.5–2 mg/kg/dose every 3–5 minutes to	30–60 seconds	5–10 minutes	Intravenous general anesthetic, rapid onset and	Cardiovascular and respiratory depression (propofol-

		titrate to effect **Continuous infusion** Infants and children: 50–150 mcg/kg/minute Adolescents: 10–50 mcg/kg/minute			recovery	related infusion syndrome), contraindicated in patients with egg allergy, pain on injection
Dexmedetomidine	IV	0.5–1 mg/kg/dose **Continuous infusion** 0.4–0.7 mcg/kg/hour Doses as high as 2.5 mcg/kg/hour have been used	30 minutes	4 hours	Minimal to no respiratory depression	Hypotension and bradycardia Use with caution in patients with advanced heart block
Neuromuscular Blockers						
Succinylcholine	IV	1 mg/kg/dose	30–60 seconds	4–7 minutes	Rapid onset Short duration	Potentiates hyperkalemia. Contraindicated in head trauma (↑ ICP), crush injury, burns, hyperkalemia. May induce neuroleptic malignant syndrome
Vecuronium	IV	0.1 mg/kg/dose **Continuous infusion:** 0.1 mg/kg/hour	1–3 minutes	30–40 minutes	Cardiovascular stable	Slower onset Longer duration of action
Rocuronium	IV/IM	0.6–1 mg/kg/dose	60–75 seconds	20–30 minutes	Cardiovascular stable	
Reversal Agents						
Naloxone	IV	For opioid overdose: 0.1 mg/kg/dose (max: 2 mg) For reversal of mild respiratory depression: 0.01–0.02 mg/kg/dose (max: 0.4 mg) may repeat every 2–3 minutes	2 minutes	20–60 minutes	Rapid onset	Shorter duration than most opioids, therefore repeated doses may be needed
Flumazenil	IV	0.01 mg/kg/dose (max: 0.2 mg), may repeat 0.005 mg/kg/dose at 1-minute intervals to	1–3 minutes	6–10 minutes	Rapid onset	Shorter duration than most benzodiazepines, therefore repeated doses

		a max total dose of 1 mg				may be needed

Table 106-4

Management Examples of Specific Patient Cases

Condition	Treatment Goal During Intubation	Medications
Full stomach	Prevent passive regurgitation and aspiration after airway protective reflexes lost	Rocuronium, succinylcholine
Bronchospasm	Eliminate or treat stimuli that would induce or increase bronchospasm	Ketamine, vecuronium, lidocaine, atropine
Increased intracranial pressure	No increase in heart rate or blood pressure	Thiopental/pentobarbital, etomidate, vecuronium, rocuronium, lidocaine
Pulmonary vascular hypertension	Avoid decreased pulmonary blood flow	Midazolam, fentanyl, vecuronium
Hypokalemia or depressed cardiac output	Maintain blood pressure without heart rate changes	Etomidate or midazolam with fentanyl

PEDIATRIC SHOCK

CASE 106-3

QUESTION 1: M.M., a 3-month-old, 6-kg male infant, presents with a history of decreased oral intake and progressive lethargy. Physical examination revealed an irritable infant with a respiratory rate of 50 breaths/minute, heart rate of 150 beats/minute, blood pressure of 80/50 mm Hg, and temperature of 39°C. He has cool extremities with a capillary refill of 3 seconds. The mother reports that her baby has had no wet diapers for the last 4 hours. A small purpuric rash has appeared on his trunk in the last half hour because the parents left home to bring him to the emergency room. Initial electrolytes obtained in the emergency room on placement of IV access were as follows:

Sodium, 136 mEq/L
Potassium, 4.9 mEq/L
Chloride, 111 mEq/L
CO_2 content, 13 mEq/L
Blood urea nitrogen, 31 mg/dL
Serum creatinine, 0.8 mg/dL
Serum glucose, 50 mg/dL

What type of shock might M.M. be experiencing?

Shock may be classified as hypovolemic, distributive, cardiogenic, or obstructive. Based on his presentation, M.M. is most likely presenting with hypovolemic shock, the most frequent type of shock seen in pediatric patients. Hypovolemic shock occurs when circulating intravascular volume decreases to a point at which adequate tissue perfusion can no longer be maintained. Hypovolemia causes a decrease in preload and adversely affects cardiac output. Initially, hypovolemia activates peripheral and central baroreceptors that cause catecholamine-mediated vasoconstriction and tachycardia. This initial response can maintain adequate circulation and blood pressure even after acute loss of as much as 15% of the circulating blood volume. Shock results from inadequate blood flow and oxygen delivery to meet the metabolic demands of the tissues.[3] Shock will progress from an initial compensated state to decompensated state. Typical signs of compensated shock include tachycardia, cool and pale distal extremities, prolonged (>2 seconds) capillary refill, weak peripheral pulses compared with central pulses, and normal systolic blood pressure. As shock progresses, the patient will exhaust his ability to compensate. The patient will exhibit signs of inadequate end-organ perfusion, including depressed mental status, decreased urine output, metabolic acidosis, tachypnea, weak central pulses, and mottling of extremities. M.M. shows evidence of having progressed to this later stage, with lethargy and decreased urine output.

CASE 106-3, QUESTION 2: How should M.M. be initially managed and monitored?

All patients presenting with shock should be placed on high-flow oxygen while their initial evaluation is being performed. Initial volume resuscitation in all forms of shock is the same. It is recommended to push isotonic crystalloid fluid (normal saline or lactated Ringer's solution) in 20 mL/kg boluses administered over 5-10 minutes. Immediately reassess the patient for signs of improved perfusion, using clinical criteria such as reduction in heart rate, improvement of blood pressure, capillary refill, quality of pulses, and mental status. If the clinical signs of shock persist, another 20 mL/kg of isotonic fluid should be administered, reaching, if necessary, at least 60 mL/kg within the first 15 to 30 minutes of treatment.[3,13] Therapeutic end points of fluid resuscitation in patients with shock are capillary refill less than 2 seconds, normal pulses with no difference between central and peripheral pulses, warm limbs, urine output greater than 1 mL/kg/hour, normal mental status, decreased lactate as measured on arterial blood gases (ABG), and increased base deficit. Children normally have a lower blood pressure than adults and are better able to preserve adequate blood pressure by vasoconstriction and increasing heart rate; therefore, blood pressure by itself is not a reliable end point for evaluating the adequacy of resuscitation. Hypotension is the last thing to occur in pediatric shock states. The definition of hypotension, defined as the 5% for systolic blood pressure for

---

age in the 2015 Pediatric Advanced Life Support guidelines[3], is as follows:

- less than 60 mm Hg in term neonates (0–28 days)
- less than 70 mm Hg in infants (1–12 months)
- less than 70 mm Hg + (2 × age in years) in children 1 to 10 years of age
- less than 90 mm Hg in children older than or equal to 10 years of age

Fluid resuscitation should be continued until clinical improvement is clear or there is clinical evidence of hypervolemic state as evidenced by rales, a gallop rhythm, or hepatomegaly. Further discussion of the management of hypovolemia and dehydration in children can be found in Chapter 103, Pediatric Fluid, Electrolytes, and Nutrition. M.M. should receive a bolus 120 mL normal saline IV infused over 5 minutes, followed by assessment of perfusion status to ascertain improvement. If he has not demonstrated significant improvement, the fluid bolus should be repeated until adequate perfusion is seen and blood pressure is stable at greater than 70 mm Hg.

CASE 106-3, QUESTION 3: As noted earlier in the case, M.M. is hypoglycemic with a blood glucose of only 50 mg/dL. What are the concerns associated with hypoglycemia during pediatric shock and how should M.M be managed?

Hypoglycemia often develops in infants during episodes of stress, including shock, seizures, and sepsis. Infants have high glucose needs and low glycogen stores, which make hypoglycemia a risk in a critically ill infant, especially one with poor enteral intake. Point-of-care glucose testing should be performed in any critically ill infant with a history of poor oral intake. One should not wait to obtain serum chemistries. Aggressive fluid resuscitation recommended for hypovolemia and shock will only exacerbate hypoglycemia. Most importantly, hypoglycemia needs to be prevented during cardiopulmonary and trauma resuscitation because it may cause seizures and has been linked with poor neurologic outcome.[3,13] Hypoglycemia in pediatric patients must always be promptly identified and treated. After diagnosis, the patient should be managed with a bolus of 0.5 to 1 g/kg of glucose or 5 to 10 mL/kg of a 10% dextrose solution as required to achieve a serum glucose greater than 100 mg/dL. Neonates, especially premature neonates, are more prone to intraventricular hemorrhage with rapid changes in serum osmolarity than older infants and children; therefore, 0.2 g/kg or 2 mL/kg of 10% dextrose is recommended in this population until the target serum glucose is achieved. M.M. should be given 30 mL (5 mL/kg) of 10% dextrose IV for 1 to 2 minutes, followed by reassessment of his serum glucose. Treatment may be continued until his serum glucose is within the normal range for his age (60–105 mg/dL). After stabilization, maintenance therapy should be initiated with fluids containing 10% dextrose.

SEPSIS AND SEPTIC SHOCK IN INFANTS AND

CHILDREN

Septic shock can be a mixture of hypovolemic, cardiogenic, and distributive shock. In a recent population-based study of children in the United States with severe sepsis (defined as bacterial or fungal infection with at least one acute organ dysfunction), Hartman et al.[14] reported an increase in the incidence of severe sepsis from 2000 to 2005 and from 0.56 to 0.89 cases per 1,000 children. The increase reported in newborns was from 4.5 to 9.7 cases per 1,000. This increase was led by sepsis in very low birthweight neonates. The second increase was reported in children from 15 to 19 years of age with a reported increase from 0.37 to 0.48 cases per 1,000. The mortality rate in this study was 8.9%, unchanged from 2000, but significantly lower than that reported for adult patients with severe sepsis and septic shock (approximately 30% and 50%, respectively). This dramatic improvement in outcome has been attained through a better understanding of the physiology of shock. The use of aggressive fluid resuscitation and the implementation of time-sensitive goal-directed therapies, as well as the application of technologic advances in respiratory, cardiovascular, renal, and nutritional support, and improved antibacterial, antiviral, and antifungal therapy, has resulted in improved survival in infants and children with septic shock and the resultant multisystem organ failure.[3,15–20]

Infants and young children are at a higher risk of severe systemic illness after infection than adults. Despite new developments in vaccine technology, rates of sepsis have not declined. This phenomenon is most likely as a result of cases occurring in infants before complete immunization. Infants are particularly vulnerable to infections for several reasons.[20] Passive immunity is normally conveyed from the mother to the fetus through transmission of immunoglobulins during the last trimester. As a result, premature neonates are immunoglobulin-deficient. Even the full-term neonate has decreased polymorphonuclear leukocyte (PMN) function and small PMN storage pools compared with older children and adults, as well as decreased ability to synthesize new antibodies. Lastly, neonates cannot make and deliver adequate amounts of phagocytes to sites of infection. Low immunoglobulin levels also make the infant susceptible to viral infections. Stores of maternal immunoglobulin are depleted at approximately 2 to 5 months of age. Adult levels of immunoglobulin are not typically achieved until 4 to 7 years of age. As the result of these physiologic differences, as well as differences in bacterial resistance patterns, the list of most likely pathogens in children with sepsis differs from those of adults. Table 106-5 lists common pediatric pathogens and appropriate empiric antibiotic coverage. Antibiotics should be administered within 1 hour of diagnosis, after the collection of appropriate cultures.[13]

As in adults, baseline health status also affects the likelihood of a child exhibiting severe sepsis. Watson et al. found that 49% of cases of sepsis occurred in children who had underlying illnesses which may place them at risk of higher morbidity and mortality.[14] At the Children’s Hospital of Pittsburgh, the mortality rate for children who were previously healthy was 2% compared with 12% in children with chronic illnesses.[21]

CASE 106-4

QUESTION 1: J.B., a 6-year-old, 20-kg girl, presented to the pediatric emergency department in acute distress. She was stabilized with oxygen via nasal cannula and fluid resuscitation before being transferred to the PICU for further management. On presentation to the PICU, she is lethargic and unable to follow commands, with warm, dry, slightly mottled skin and sluggish capillary return. She is febrile to 39.5°C and has a respiratory rate of 21 breaths/minute, a heart rate of 154 beats/minute, and a blood pressure of 76/55 mm Hg. Initial laboratory values are notable for a white blood cell count of 21×10^3 µL. Her parents report that she has not urinated since the previous evening. Does J.B. meet the criteria for septic shock?

In an effort to develop a consensus definition of the pediatric sepsis continuum including systemic inflammatory response syndrome (SIRS), infection, sepsis, severe sepsis, septic shock, and multisystem organ dysfunction syndrome, a group of international experts in the fields of adult and pediatric sepsis and clinical research gathered in 2002. A panel was chosen consisting of published pediatric critical care physicians and scientists with clinical research experience in pediatric sepsis.[16] Because the clinical variables used to define SIRS and organ dysfunction are greatly affected by the normal physiologic changes that occur as children age, the group first defined six clinically and physiologic age categories for defining SIRS criteria (Table 106-6). Premature infants were not included because their care occurs primarily in neonatal intensive care units and not in PICUs. Before discussing treatment, it is important that the practitioner should understand the terms used to define sepsis. In 1992, SIRS was proposed by the American College of Chest Physicians and the Society of Critical Care Medicine (SCCM) to describe the nonspecific inflammatory process occurring in adults after trauma, infection, burns, pancreatitis, and other diseases.[22,23] Sepsis was defined as SIRS associated with infection. The SIRS criteria were developed for use in adults; it was not until 2005 that a consensus definition was published for SIRS in children (Table 106-7).[24] A separate pediatric definition for SIRS was essential. Tachycardia and tachypnea, pivotal to the adult definition of SIRS, are common presenting symptoms of many pediatric disease processes. To better distinguish SIRS from other diseases, the pediatric definition also includes temperature and leukocyte abnormalities as criteria. Numeric values for each criterion were also established to account for the different physiology in children. Table 106-8 gives the age-specific cutoffs for each criterion.

Table 106-5

Causative Pathogens and Recommended Treatments for Pediatric Sepsis

Age or Risk Factor	Microorganism	Empiric Antibiotic Coverage
Age <30 days	Listeria monocytogenes Escherichia coli Group B Streptococcus Gram-negative enteric organisms	Ampicillin + aminoglycoside or ampicillin + cefotaxime acyclovir (if patient presents with seizures, until HSV ruled out)
Age 1 to 3 months	L. monocytogenes E. coli Group B Streptococcus Haemophilus influenzae Streptococcus pneumoniae Neisseria meningiditis	Ampicillin + TGC ± vancomycin[a]
Age >3 months	H. influenzae S. pneumoniae N. meningiditis	TGC ± vancomycin[a]
Immunocompromised child	Pseudomonas aeruginosa Staphylococcus aureus Staphylococcus epidermidis	Ceftazidime or cefepime or piperacillin/tazobactam + vancomycin[a]
Child with a ventriculoperitoneal shunt	S. aureus S. epidermidis Gram-negative enteric organisms	TGC ± vancomycin[a]

[a] Dosed to maintain trough vancomycin serum concentrations of 15 to 20 mcg/mL.

HSV, herpes simplex virus; TGC, third-generation cephalosporin (i.e., cefotaxime, ceftriaxone, or ceftizoxime).

Table 106-6

Pediatric Age Group Definitions for Severe Sepsis

Age Category	Definition
Newborn	0 day–1 week
Neonate	1 week–1 month
Infant	1 month to 1 year
Toddler and preschool	2–5 years
School-age child	6–12 years
Adolescent and young adult	13–<18 years

Temperature is one of the main criteria of the pediatric SIRS definition. A core temperature greater than 38.5°C or less than 36°C may indicate serious infection. Hypothermia is more likely to occur in infants. A core temperature is the one measured by either rectal, bladder, oral, or central catheter probe. Temperatures taken via the tympanic, toe, or another auxiliary route are not sufficiently accurate. Temperature may also be documented by a reliable source at home within 4 hours of presentation to the hospital or physician's office. If environmental overheating, such as that produced by overbundling, is suspected, the child should be returned to a neutral temperature environment, unbundled, and the temperature retaken in 15 to 30 minutes.

Meeting the SIRS criteria in children requires the presence of an abnormal temperature, either hypothermia or hyperthermia, or an abnormal leukocyte count in the presence of tachypnea and tachycardia. Sepsis is defined as the proven or suspected infection in the setting of SIRS. Severe sepsis is defined as sepsis in the setting of acute respiratory distress syndrome, cardiovascular organ dysfunction, or two or more acute organ dysfunctions (respiratory, renal, hematologic, neurologic, or hepatic). The definitions of organ dysfunction have also been modified for children (Table 106-9). Carcillo et al.[16] defined pediatric septic shock (SS) as the presence of tachycardia and poor perfusion, including decreased peripheral pulses compared with central pulses; altered alertness; capillary refill greater than 2 seconds; mottled or cool extremities; or decreased urine output. This definition of pediatric SS does not include hypotension as required in adults because children will often maintain their blood pressure until they are severely ill. Shock may occur long before hypotension occurs. J.B. exhibits the majority of the criteria for pediatric SS, including lethargy, fever, tachycardia, decreased perfusion, and decreased urination.

CASE 106-4, QUESTION 2: What physiologic differences may need to be taken into account when developing a management strategy for J.B.?

Table 106-7

Definitions of Systemic Inflammatory Response Syndrome, Infection, Sepsis, Severe Sepsis, and Septic Shock in Children

SIRS	The presence of at least two of the following four criteria, one of which must be abnormal temperature or leukocyte count: ▪ Core temperature of >38°C or <36°C (must be measured by rectal, bladder, oral, or central catheter probe) ▪ Tachycardia defined as at least two standard deviations above normal for age in the absence of external stimulus, chronic drugs, or painful stimuli; or otherwise persistent elevation for a 0.5- to 4-hour time period OR for children <1 year old: bradycardia, defined as a mean heart rate <10% percentile for age in the absence external vagal stimulus, β-blocker drugs, or congenital heart disease; or otherwise unexplained depression in a half-hour period ▪ Mean respiratory rate >2 standard deviations above normal for age or mechanical ventilation for an acute process not related to underlying neuromuscular disease or receipt of general anesthesia ▪ Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced neutropenia) or >10% immature neutrophils
Infection	A suspected or proven (by positive culture, tissue stain, or polymerase chain reaction test) infection caused by any pathogen OR a clinical syndrome associated with a high probability of infection. Evidence of infection includes positive findings on clinical examination, imaging, or

	laboratory tests (e.g., white blood cells in a normally sterile body fluid, perforated viscus, chest radiograph consistent with pneumonia, petechial or purpuric rash, or purpura fulminans)
Sepsis	SIRS in the presence of or as a result of suspected or proven infection
Severe sepsis	Sepsis plus one of the following: cardiovascular organ dysfunction OR acute respiratory distress syndrome OR dysfunction of two or more other organs, as defined in Table 106-9
Septic shock	Severe sepsis with cardiovascular dysfunction, as defined in Table 106-9

SIRS, systemic inflammatory response syndrome.

There are developmental differences in the hemodynamic response to sepsis in newborns, children, and adults. Practitioners in the PICU may encounter all age ranges and thus must be familiar with the clinical differences seen between age groups because it may affect therapy. Adults and children have different adaptive responses that must be considered when selecting therapeutic management. Adolescent patients pose a unique challenge because they may present with either types of symptoms. Among adult patients, the most common hemodynamic alterations include diminished systemic vascular resistance (SVR) and elevated cardiac output (CO). SVR is diminished due to decreased vascular responsiveness to catecholamines, alterations in α-adrenergic receptor signal transduction, and the elaboration of inducible nitric oxide synthase. In general, adults with SS have myocardial dysfunction with a decreased ejection fraction; however, CO is preserved or increased through two compensatory mechanisms: tachycardia and reduced SVR.

Unlike SS in adults, pediatric SS is associated with severe hypovolemia, and children frequently respond well to aggressive fluid resuscitation. Pediatric patients demonstrate diverse hemodynamic profiles during fluid-refractory SS: 58% have low cardiac indexes responsive to inotropic medications with or without vasodilators, 20% exhibit high cardiac index and low SVR responsive to vasopressor therapy, and 22% present both vascular and cardiac dysfunctions necessitating the use of vasopressors and inotropic support.[25] Pediatric patients such as J.B. are different from adults with SS in that low CO, not low SVR, is associated with increased mortality. In fact, studies suggest that the majority of children showed some degree of cardiac dysfunction on presentation after fluid resuscitation.[13,18] Many require a change in their inotropic and vasopressor management, or the addition of another agent during the first hours of treatment, emphasizing that the hemodynamic status in children can change rapidly.[13,16–18]

Table 106-9

Organ Dysfunction Criteria

Cardiovascular Dysfunction

Despite administration of isotonic intravenous fluid bolus 40 mL/kg in 1 hour

- Decrease in BP (hypotension) <5th percentile for age or systolic BP <2 standard deviations below normal for age[a] OR
- Need for vasoactive drug to maintain BP in normal range (dopamine >5 mcg/kg/minute or dobutamine, epinephrine, or norepinephrine at any dose) OR
- Two of the following:
  - Unexplained metabolic acidosis: base deficit >5 mEq/L
  - Increased arterial lactate >2 times upper limit of normal
  - Oliguria: urine output <0.5 mL/kg/hour
  - Prolonged capillary refill: >5 seconds
  - Core to peripheral temperature gap >3°C

Respiratory[b]

- Pao$_2$/FIO$_2$ <300 in absence of cyanotic heart disease or preexisting lung disease OR
- PaCO$_2$ >65 torr or 20 mm Hg over baseline PaCO$_2$ OR
- Proven need[c] or >50% FIO$_2$ to maintain saturations >92% OR
- Need for nonelective invasive or noninvasive mechanical ventilation[d]

Neurologic

- Glasgow Coma Scale (see Table 106-12) <11 OR
- Acute change in mental status with a decrease in Glasgow Coma Scale ≥3 points from abnormal baseline

Hematologic

- Platelet count <80,000/μL or a decline of 50% in platelet count from highest value recorded in the past 3 days (for chronic hematology/oncology patients) OR

- International normalized ratio of >2

Renal

- Serum creatinine >2 times upper limit of normal for age or twofold increase in baseline creatinine

Hepatic

- Total bilirubin ≥4 mg/dL (not applicable for newborn) OR
- ALT 2 times upper limit of normal for age

[a] See Table 106-8.

[b] Acute respiratory distress syndrome must include a Pao$_2$/Fio$_2$ ratio <200 mm Hg, bilateral infiltrates, acute onset, and no evidence of left heart failure. Acute lung injury is defined identically except the Pao$_2$/Fio$_2$ ratio must be <300 mm Hg.

[c] Proven need assumes oxygen requirement was tested by decreasing flow if required.

[d] In postoperative patients, this requirement can be met if the patient has exhibited an acute inflammatory or infectious process in the lungs that prevents him or her from being extubated.

ALT alanine transaminase; BP, blood pressure.

Adapted with permission from Goldstein B et al. International pediatric sepsis consensus conference: definitions for sepsis and organ dysfunction in pediatrics. Pediatr Crit Care Med. 2005;6(1):5.

SS in the neonatal patient differs from that seen in older children. The relative ability of infants and children to augment CO through increased heart rate (HR), as seen in adults, is limited by their preexisting elevated HR, which precludes proportionate increases in HR without compromising diastolic filling time. In adults, ventricular dilation is a compensatory response used to maintain CO. However, the increased connective tissue content of the infant’s heart and diminished content of actin and myosin limits the potential for acute ventricular dilation. Neonatal SS can be further complicated by the physiologic transition from fetal to neonatal circulation. Sepsis-induced acidosis and hypoxia can increase pulmonary vascular resistance and thus arterial pressure, thereby maintaining the patency of the ductus arteriosus. This results in persistent pulmonary hypertension (PPHN) of the newborn and persistent fetal circulation. Neonatal SS with PPHN will increase the workload on the right ventricle, leading to right-ventricular failure, tricuspid regurgitation, and hepatomegaly. Therefore, therapies directed at reversing right-ventricular failure by reducing pulmonary artery pressures are commonly needed in neonates with fluid-refractory SS and PPHN.

Based on her mottled dry skin, sluggish capillary refill, and decreased urination, it is evident that J.B. has inadequate perfusion. She should receive aggressive fluid resuscitation, beginning with a fluid bolus of 400 mL (20 mL/kg) normal saline or lactated Ringer’s solution IV administered over 5 minutes. She should be reassessed immediately after the bolus to evaluate perfusion status as described previously. The 400-mL fluid bolus should be repeated until adequate perfusion has been established.

INITIAL MANAGEMENT OF PEDIATRIC SEPTIC

SHOCK

Because the landmark study by Rivers in 2001 demonstrated a 33% reduction in mortality in adult patients with sepsis when they were aggressively treated with fluid resuscitation, blood transfusion, and inotropic therapy within 6 hours of admission, goal-directed therapy has been advocated for all patients who present in SS.[15] The components of early goal-directed therapy include respiratory support along with prompt resuscitation of poor perfusion through administration of IV fluids and appropriately targeted inotropic and vasopressor therapy, early empiric antimicrobial therapy, drainage of the infection whenever possible, and continuous monitoring of the patient's hemodynamic status.[13,15–19]

CASE 106-4, QUESTION 3: J.B. has received one bolus of normal saline in the pediatric emergency department, but is still showing evidence of being hypoperfused. Her hemoglobin on admission to the PICU is 10 g/dL. Should she continue to receive traditional IV fluid replacement with normal saline or should other agents be considered to maximize perfusion and oxygenation?

There are no data to suggest a significant difference in survival rates in pediatric patients after resuscitation with colloids, including blood products, compared with crystalloid fluids.[26] The choice of fluid is less important than the volume administered. Adequate volume is necessary to sustain cardiac preload, increase stroke volume, and improve oxygen delivery. Both crystalloids and colloids, specifically packed red blood cells (PRBC), have equal effects on improving stroke volume. In addition, both restore tissue perfusion to the same degree if they are titrated to the same level of filling pressure.

Administration of blood products also differs among institutions. The optimal hemoglobin for infants and children in SS has not been established. In the early management of sepsis in adults, maintaining hemoglobin of 7 to 9 g/dL to improve oxygen carrying capacity has been documented to improve sepsis survival by improving tissue perfusion. Anemia in sepsis has been associated with increased mortality, but so has the administration of blood products.[27] Based on the limited data available, SCCM has recommended that hemoglobin concentrations in adults be maintained at 7 to 9 g/dL.[13] As pediatric data are even more limited, it is necessary to extrapolate from the adult literature suggesting maximizing tissue oxygen delivery if there is evidence of poor tissue perfusion. Once tissue hypoperfusion, acute hemorrhage, or lactic acidosis has resolved, PRBC transfusion should be considered only when the hemoglobin is less than 7 g/dL.[13,28] At this time, there is no indication for administration of blood products to J.B. Fresh frozen plasma may be infused to correct abnormal prothrombin time (PT) and partial thromboplastin time (PTT) values, but should not be rapidly infused because of the risk for acute hypotensive effects caused by vasoactive kinins and high citrate concentration. There is no literature to suggest that 5% albumin administration improves outcome in regard to sepsis mortality. Albumin administration may be considered in patients who are hypoalbuminemic, but routine use of albumin is not recommended.[29]

As described previously for the management of hypovolemic shock, patients with SS should be reassessed for signs of improved perfusion using clinical criteria such as reduction in heart rate, improvement of blood pressure, capillary refill, quality of pulses, and mental status with each fluid bolus. If the clinical signs of shock persist, another 20 mL/kg of isotonic fluid should be administered reaching, if necessary, 60 mL/kg within the first 15 to 30 minutes of treatment.[3,13,17] Some children with SS require as much as 200 mL/kg in the first hour.[17] Patients remaining in shock despite fluid resuscitation are given inotropic support to attain normal blood pressure for age and capillary refill time of less than 2 seconds. Every hour that goes by without implementing these therapies is associated with a 1.5-fold increased risk of mortality. Patients who do not respond rapidly to initial fluid boluses or those with insufficient physiologic reserve should be considered for invasive hemodynamic monitoring. Invasive monitoring of central venous pressure (CVP) is instituted to ensure that the satisfactory right-ventricular preload is present, typically using a goal of 10 to 12 mm Hg, and that oxygen carrying capacity is optimized by PRBC transfusion to correct anemia to a goal hemoglobin concentration greater than 7 g/dL.[13,17]

Up to 40% of a child's CO may be required to support the work of breathing during SS; therefore, in the presence of respiratory distress, elective intubation and mechanical ventilation can be used to allow redistribution of blood flow from respiratory muscles toward other vital organs. Intubation is not without adverse effects; it is imperative that patients receive adequate fluid resuscitation before intubation because the change from spontaneous breathing to positive-pressure ventilation will decrease the effective preload to the heart, further decreasing cardiac output. Ventilation may reduce left-ventricular afterload that may be beneficial in patients with low cardiac index and high SVR. In addition, it may provide an alternative method to alter acid base balance. If sedatives and analgesics are used for intubation, choice of agents that do not cause further vasodilation is critical.

Although laboratory studies rarely affect the management of SS in the first hour of therapy, patients should have laboratory studies sent routinely assessing for hematologic abnormalities, metabolic derangements, or electrolyte abnormalities that may contribute to morbidity. A peripheral white blood count may aid in the choice of broad-spectrum antibiotics and hemoglobin and platelet count will help in assessing the need for early blood transfusion. A type and screen should be sent to the blood bank to prepare for any necessary transfusions. Electrolyte abnormalities are common in sepsis; recognition and treatment of metabolic abnormalities such as hypoglycemia and hypocalcemia will improve outcome. A disseminated intravascular coagulation panel, including PT, PTT, and fibrinogen, will aid in assessing the severity of illness. If abnormalities exist, they may need to be corrected before performing invasive procedures. Lastly, an arterial or venous blood gas will determine the adequacy of ventilation, oxygenation, and severity of acidemia.[17]

Unfortunately, clinical response to fluid resuscitation is a relatively insensitive indicator for the completeness of restoration of microvascular blood flow. Success of adequate fluid resuscitation can be guided by additional parameters: invasive blood pressure monitoring, CVP, measurement of mixed venous oxygen saturation (Svo_2), measurement of blood lactate, and urine output. An elevated serum lactate level suggests tissue is inadequately perfused and undergoing anaerobic metabolism, even in patients who are not hypotensive. Because low CO is associated with increased O_2 extraction, Svo_2 can be used as an indirect indicator of whether CO is adequate to meet tissue metabolic demand. If tissue oxygen delivery is adequate, then Svo_2 should be greater than 70%.[17] In the goal-directed study by Rivers, maintenance of Svo_2 was greater than 70% by use of blood transfusion to a hemoglobin of 10 g/dL and inotropic support to increase CO resulted in a 40% reduction in mortality compared with patients where only mean arterial pressure and CVP were monitored.[15] de Oliveria et al.[18] reproduced this finding in children with SS, reducing mortality from 39% to 12% when directing therapy to a goal Svo_2 saturation greater than 70%.

CARDIOVASCULAR DRUG THERAPY

Pharmacologic support in children with SS must be individualized because different hemodynamic abnormalities exist in pediatric patients, and the primary hemodynamic abnormalities may change with time and progression of the patient's disease (Table 106-10). Twenty percent (20%) of children present with predominant vasodilatory shock, referred to as "warm" shock. This form of shock is associated with vasodilation and capillary leak, but normal or elevated CO. The patients have strong pulses, warm extremities, good capillary refill, and tachycardia. In warm shock, using a vasopressor such as dopamine, norepinephrine, phenylephrine, or vasopressin to promote vasoconstriction would provide the most benefit. Fifty-eight percent (58%) of children present with "cold shock" or a poor CO state. These patients have vasoconstriction, increased cardiac afterload, and a high SVR. This is clinically manifested as weak pulses, cool extremities, slow capillary refill, and hepatic and pulmonary congestion. Using an inotrope with or without a vasodilator would be most beneficial in cold shock (e.g., dobutamine, epinephrine, or milrinone). Careful assessment of clinical response is critical because a combination of warm and cold shock, with a low SVR and poor CO, occurs in approximately 22% of children.

Table 106-10

Summary of Selected Vasoactive Agents

Agent	Dose Range	Peripheral Vascular Effects			Cardiac Effects
Vasopressors					
		α	β_1	β_2	
Dobutamine	2–20 mcg/kg/minute	1+	3–4+	1–2+	Less chronotrophy and arrhythmias at lower doses; chronotropic advantage compared with dopamine may not be apparent in neonates
Dopamine	2–4 mcg/kg/minute	0	0	0	Splanchnic and renal vasodilator, increasing doses create increasing α-effect
	4–8 mcg/kg/minute	0	1–2+	1+	
	>10 mcg/kg/minute	2–4+	1–2+	2+	
Epinephrine	0.03–0.1 mcg/kg/minute	2+	2–3+	2+	β_2 effects with lower doses
	0.2–0.5 mcg/kg/minute	4+	2+	3+	
Norepinephrine	0.05–0.5 mcg/kg/minute	4+	2+	0	Increases systemic resistance, moderate inotropy
Phenylephrine	0.05–0.5 mcg/kg/minute	4+	0	0	Increases systemic resistance, moderate inotropy
Vasodilators					
Nitroprusside	0.5–8 mcg/kg/minute	Donates nitric oxide to relax smooth muscles and dilate pulmonary and systemic vessels		Indirectly increases cardiac output by decreasing afterload	Reflex tachycardia
Nitroglycerine	0.5–10 mcg/kg/minute	As a nitric oxide donor may cause pulmonary vasodilation and enhance coronary vasoreactivity after aortic cross-clamping		Decreases preload; may decrease afterload, reduces myocardial work in relation to change in wall stress	Minimal
Miscellaneous Agents					
Milrinone	50 mcg/kg load; then 0.25–1 mcg/kg/minute	Systemic and pulmonary vasodilator		Diastolic relaxation (lusitropy)	Minimal tachycardia

Vasopressin	0.003–0.002 units/kg/minute OR 18–120 milliunits/kg/hour	Potent vasoconstrictor	No direct effect	None known

CASE 106-4, QUESTION 4: Despite adequate fluid resuscitation, intubation, and mechanical ventilation, J.B.'s condition has continued to decline. During the past 30 minutes, her systolic blood pressure has ranged between 72 and 79 mm Hg (normal for age, >84 mm Hg). What would be an appropriate next step for the management of J.B.'s shock?

Vasopressors are required in shock unresponsive to initial fluid resuscitation.[3,13,17] In pediatric SS, the initial agent of choice has typically been dopamine.[13,17] Dopamine has direct and indirect effects on dopamine receptors, α-adrenergic receptors, and β-adrenergic receptors on both the heart and peripheral vasculature. One of the mechanisms of dopamine action is enhancement of endogenous catecholamine release. In severe septic states, presynaptic vacuoles may be depleted of norepinephrine, which may explain why dopamine may have diminished activity. In addition, infants younger than 6 months of age may not have developed their component of sympathetic innervations; therefore, they have reduced releasable stores of epinephrine.

Some studies have raised the concern of increased mortality with the use of dopamine. One possible explanation is the ability of dopamine to reduce the release of hormones from the anterior pituitary gland, such as prolactin, through stimulation of the dopamine D_2 receptor, thus reducing cell-mediated immunity and inhibition of thyrotropin-releasing hormone release, worsening impaired thyroid function known to occur in critical illness. Although most clinicians continue to use dopamine as their drug of choice for initiating inotropic therapy in pediatric SS, some prefer low-dose norepinephrine as a first-line agent for those children with fluid-refractory hypotensive hyperdynamic shock.[17]

J.B. should be started on dopamine at a rate of 5 mcg/kg/minute, with further titration of the dose in increments of 2.5 mcg/kg/minute every 3 to 5 minutes until the goal of improved perfusion and/or a normal blood pressure for age is achieved.[3] The maximum recommended dose of dopamine is 20 mcg/kg/minute; higher doses may contribute to increased myocardial oxygen demand without much improvement in vasopressor

---

activity. Dopamine, as well as other agents capable of producing vasoconstriction, should ideally be administered through central venous access rather than through a peripheral IV. Extravasation of these drugs from an infiltration of the IV may produce significant local tissue necrosis.

CASE 106-4, QUESTION 5: J.B.'s dopamine infusion has been steadily increased throughout the day. Her dose is currently at 20 mcg/kg/minute, but she continues to have refractory hypotension with a systolic blood pressure of 70 mm Hg. On physical examination, she is pale with cool, dry skin. Her hemoglobin remains at 10 g/dL. Central venous pressures are now being measured and range from 6 to 9 mm Hg. What alternative to dopamine should be considered for J.B.?

Dopamine-resistant shock is diagnosed after titration of dopamine to 20 mcg/kg/minute with the persistence of signs and symptoms of shock. Patients with dopamine-resistant shock should be reassessed to evaluate fluid status and hemoglobin, with additional fluids or PRBC given as needed to improve tissue oxygen. Measurement of CVP can be performed to assess intravascular volume status with the goal of achieving a CVP of 8 to 12 mm Hg, and Svo_2 can be used as a marker of cardiac output (provided that the hemoglobin is within the normal range), along with the clinical examination. Dopamine-resistant shock commonly responds to epinephrine or norepinephrine.

Epinephrine

Epinephrine is a direct agent that is naturally produced in the adrenal gland and is the principal stress hormone with widespread metabolic and hemodynamic effects. It possesses both inotropic and chronotropic effects. Epinephrine is a reasonable choice for the treatment of patients with low CO and poor peripheral perfusion because it increases HR and myocardial contractility. Depending on the dose administered, epinephrine may exert variable effects on SVR. At doses less than 0.3 mcg/kg/minute, epinephrine exerts greater β_2-adrenergic receptor activation, resulting in vasodilation in skeletal muscle and cutaneous vascular beds, shunting blood flow away from the splanchnic circulation.[17] At higher doses, α_1-adrenergic receptor activation becomes more prominent and may increase SVR and heart rate. For patients with markedly elevated SVR, epinephrine (0.05–0.3 mcg/kg/minute) may be administered simultaneously with a vasodilator. Epinephrine increases glucogenesis and glycogenolysis, resulting in elevated serum blood glucose concentrations. Children receiving epinephrine infusions should have serum glucose monitored closely.

Norepinephrine

Norepinephrine is a direct agent and is naturally produced in the adrenal gland. It is a potent vasopressor that redirects blood flow away from skeletal muscle to the splanchnic circulation even in the presence of decreased cardiac output. Norepinephrine has been used extensively to elevate SVR in septic adults and children. If the patient’s clinical state is characterized by low SVR (a wide pulse pressure with diastolic blood pressure less than one-half of the systolic blood pressure), norepinephrine (0.05–0.3 mcg/kg/minute) is recommended. Approximately

20% of children with volume-refractory SS have a low SVR. In children who are intubated and receiving sedatives or analgesics, the incidence of low SVR may be higher. The additional afterload imposed by norepinephrine may substantially compromise CO in patients with impaired contractility. In patients with both impaired or marginal CO and decreased SVR, it may be necessary to support myocardial contractility through the addition of an agent such as dobutamine.[13,17]

Vasopressin

Although not a recommendation in the 2015 Pediatric Advanced Life Support guidelines, vasopressin has been suggested as an alternative therapy for refractory cardiac arrest or hypotension due to a low SVR in children whose epinephrine infusion exceeds 1 mcg/kg/minute.[3] Vasopressin exerts its hemodynamic effects via the $V_{1\alpha}$ receptor, promoting an increase in intracellular calcium in the peripheral vasculature, thus enhancing vasoconstriction and restoring systemic vascular tone. In a preliminary case series, vasopressin at a dose of 0.3 to 2 milliunits/kg/minute (18–120 milliunits/kg/hour) improved blood pressure and urine output in patients with catecholamine-refractory vasodilatory shock and allowed weaning of catecholamines once treatment was initiated.[30] In a more recent analysis conducted by the American Heart Association, however, vasopressin use was associated with a lower rate of return to spontaneous circulation.[31] At this time, the use of vasopressin in critically ill children remains controversial.[3,13,17]

Dobutamine

Dobutamine is a nonselective β_2-adrenergic agonist, which produces improved contractility, chronotrophy, and some degree of lusitropy, or improved myocardial relaxation. The β_2 activity can lead to peripheral vasodilation, and this must be considered before its use in a patient who may already be hypotensive. If hypotension does exist, it should be used in combination with other vasopressor therapies. Dobutamine should be considered in patient who has signs and symptoms or laboratory values consistent with poor tissue perfusion, but has an adequate blood pressure to tolerate some degree of vasodilation. It should be initiated at a rate of 2.5 mcg/kg/minute and titrated in increments of 2.5 mcg/kg/minute every 3 to 5 minutes to a maximum infusion rate of 20 mcg/kg/minute.[3,17] Careful attention to the patient's blood pressure is critical. Improved perfusion, decreased lactate, and an increased Svo_2 will help determine appropriate dosing.

Vasodilators

Vasodilator medications are occasionally required in the treatment of septic pediatric patients with markedly elevated SVR and normal or decreased CO. Vasodilators decrease SVR and improve cardiac output by decreasing ventricular afterload. Nitroglycerin or nitroprusside may be used for this indication. They each have a short half-life; therefore, if hypotension occurs, it can be rapidly reversed by stopping the infusion. Both drugs can be infused at an initial rate of 0.5 mcg/kg/minute and titrated in increments of 0.5 mcg/kg/minute to a maximum infusion rate of 5 to 10 mcg/kg/minute.[3] If nitroprusside is used, it is necessary to observe for sodium thiocyanate accumulation in the setting of renal failure, and cyanide toxicity with hepatic failure or with prolonged infusions (more than 72 hours) of greater than 3 mcg/kg/minute. If a patient has tolerated short-term infusions of either of these agents, milrinone may be considered as an alternative for long-term therapy. Milrinone is a phosphodiesterase type III (PDE III) inhibitor that produces its hemodynamic effects by inhibiting the degradation of cyclic AMP in smooth muscle cells and cardiac myocytes. PDE III inhibitors work synergistically with catecholamines, which produce their hemodynamic effects by increasing the production of cyclic AMP. Milrinone, at a dose of 0.25 to 0.75 mcg/kg/minute, is useful in the treatment of infants and children with diminished CO, impaired myocardial contractility, and decreased SVR.[13,32] The primary concern with milrinone is its relatively long half-life of 2 to 6 hours, which requires several hours for the patient to reach steady state. To achieve target serum concentrations more rapidly, a loading dose of 50 mcg/kg may be administered for 10 to 30 minutes before the start of the infusion. Administration of a loading dose must be done with caution in children with sepsis and shock because it may precipitate hypotension, requiring volume infusion and/or vasopressor infusion. Administering the loading dose over several hours may avoid this adverse effect.

J.B. remains hypotensive despite adequate fluid administration and a dopamine infusion at the maximum rate. After reassessing her laboratory parameters to determine whether additional fluid or blood products are needed, J.B. should be started on epinephrine at 0.05 mcg/kg/minute. The dose may then be titrated upward in 0.05 to 0.1 mcg/kg/minute increments every 3 to 5 minutes as needed to achieve the desired clinical response or to the usual maximum of 2 mcg/kg/minute. Higher doses have been used in some pediatric cases, but may not always provide additional benefit.[3]

CORTICOSTEROID ADMINISTRATION IN

PEDIATRIC SEPTIC SHOCK

CASE 106-4, QUESTION 6: J.B. is currently receiving epinephrine at an infusion rate of 0.35 mcg/kg/minute, but she continues to have refractory hypotension with a systolic blood pressure of 70 mm Hg. Is there a role for hydrocortisone replacement in J.B.? What would be the appropriate method for assessing adrenal insufficiency and the appropriate dose for replacement?

Although adjunctive corticosteroid therapy in patients in septic shock has not made a significant difference in outcome in all studies published to date, replacement may be of benefit in some patients.[33–35] In a recent study, 77% of children with septic shock admitted to two PICUs for a 6-month period exhibited adrenal insufficiency.[35] Due to the limited evidence of their efficacy and safety in children, corticosteroids should be reserved for those with catecholamine-resistant shock, severe septic shock and purpura, children who have previously received steroid therapies for chronic illness, children with pituitary or adrenal abnormalities, and those who previously received etomidate.[5–7,13,33–35] Assessment of serum cortisol should be used to guide treatment. There are no strict definitions, but adrenal insufficiency in adults with catecholamine-resistant shock has been defined as a random cortisol level of less than 18 mcg/dL or an increase in cortisol of less than or equal to 9 mcg/dL at 30 or 60 minutes after an adrenocorticotropic hormone stimulation test.[33] Similar values have been recommended for assessment of serum cortisol in children with SS.[13]

If J.B. has a random cortisol of 10 mcg/dL in the face of catecholamine-resistant hypotension, a trial of hydrocortisone is warranted. Published guidelines for hemodynamic support of pediatric and neonatal patients in septic shock recommend 0.5 to 1 mg/kg IV every 6 hours (with a maximum dose of 50 mg).[16] Using this regimen, J.B. should be treated with 10 to 20 mg IV every 6 hours. As an alternative, some clinicians use a regimen of a single 50-mg/m^2 loading dose, followed by the same dose (50 mg/m^2) divided into four doses and given every 6 hours.[13]

ADJUNCTIVE THERAPIES

Stress-Related Mucosal Bleeding

The use of prophylaxis to prevent stress-related mucosal bleeding, although common in adult ICU patients, is not as widely used in PICUs. Studies conducted to date have provided a wide range of gastrointestinal tract bleeding rates in children, ranging from 10% to 50%, with rates of clinically significant bleeding of approximately 1% to 4%.[36,37] Several investigators have identified thrombocytopenia, coagulopathy, organ failure, and mechanical ventilation as important risk factors for gastrointestinal bleeding, similar to studies conducted in adults. A recent systematic review suggested that critically ill pediatric patients may benefit from prophylaxis; however, the results were limited by the small number of controlled studies available.[37]

Thrombosis Prophylaxis

Patients admitted to the PICU can range from newborns to young adults. Unlike adults, there are no data on the use of subcutaneous heparin or low-molecular-weight heparins as prophylaxis to prevent deep venous thrombosis (DVT) in children. However, when children reach puberty, the hormone changes that take place appear to increase their risk of thrombosis to that of adults. Although no published guidelines or consensus papers exist to guide therapy at this time, all pubescent adolescents should be considered for DVT prophylaxis. Most cases of thrombosis in infants and young children are associated with long-term use of central venous catheters. Unfortunately, a study evaluating low-dose heparin infused at 10 units/kg/hour did not prevent catheter-related thrombosis in infants after cardiac surgery.[38] It is important to note that the dose of heparin used in this study was less than the anticoagulant dose recommended for infants and children (15–25 units/kg/hour). At this time, the routine use of DVT prophylaxis in children remains controversial.

CONGENITAL HEART DISEASE

CASE 106-5

QUESTION 1: J.F. is a 3-week-old, 3.5-kg male infant who was seen by his physician with a history of poor feeding and increased work of breathing. On admission, he was mottled, and grunting, and had severe retractions. The physician referred him to the emergency department of the local children's hospital where his temperature was 40.8°C, heart rate was 200 beats/minute, respiratory rate was 80 breaths/minute, and oximetry saturation was between 60% and 70%; he had very poor peripheral perfusion. Blood gas analysis results were as follows:

pH, 6.96
PCO_2, 35 mm Hg
Base deficit, 29 mmol/L

Chest radiography showed cardiomegaly and pulmonary edema. J.F. has presented with symptoms of both respiratory failure and shock. Based on his age, the severity of his hypoxemia, and evidence of cardiomegaly, congenital heart disease (CHD) is suspected. Echocardiography reveals coarctation of the aorta. What initial therapies are needed to stabilize J.F.?

With the neonate's first breath, changes in oxygen tension and a reduction in endogenous prostaglandin E_2 production stimulate closure of the ductus arteriosus (DA), the connection between the pulmonary artery and aorta that allows shunting of blood to the aorta during fetal circulation. Functional closure of the DA typically occurs within the first 10 to 14 hours of life, but complete anatomic closure may not occur until 2 to 3 weeks of age. Prematurity, acidosis, and hypoxia prolong the time to closure. In infants with ductal-dependent CHD, closure of the DA results in inadequate delivery of oxygenated blood to the systemic circulation (Table 106-11). These infants will present just as any other patient in shock. The immediate goal in evaluating a cyanotic neonate is to differentiate between cardiac and noncardiac causes. The classic hyperoxia test is carried out by obtaining an ABG, then placing the patient on 100% oxygen for 10 minutes and then repeating the ABG. If the cause of cyanosis is pulmonary, the Pao_2 should increase by 30 mm Hg, but if the cause is cardiac, there should be minimal improvement in the Pao_2. If the patient is too unstable, one could place a pulse oximeter and place the patient on 100% Fio_2. With administration of oxygenation, there will typically be at least a 10% increase in oxygen saturation in neonates with pulmonary disease, but those with ductal-dependent CHD will have minimal or no improvement.

Table 106-11

Ductal-Dependent Congenital Heart Lesions

Lesions That Depend on Flow Via the Ductus Arteriosus to Maintain Systemic Circulation
Hypoplastic left heart syndrome (HLHS)
Coarctation of the aorta
Critical aortic stenosis
Interrupted aortic arch
Total anomalous pulmonary venous return (TAPVR) with obstruction
Lesions that Depend on Flow Via the Ductus Arteriosus to Maintain Pulmonary Circulation
Pulmonary atresia with intact ventricular septum
Critical pulmonic stenosis
Tricuspid atresia
Tetralogy of Fallot (TOF)
Epstein anomaly
Lesions that Depend on Flow Via the Ductus Arteriosus to Maintain Adequate Mixing of the Pulmonary and Systemic Circulations
Truncus arteriosus
Transposition of the great vessels (TGV)
Total anomalous pulmonary venous return (TAPVR) without obstruction

If the neonate's oxygen saturation or Pao_2 fails to improve and CHD is suspected, an infusion of alprostadil, prostaglandin E_1 (PGE_1), should be initiated at a rate of 0.05 to 0.1 mcg/kg/minute.[39] Infusion of PGE_1 maintains patency of the DA and allows blood to reach the descending aorta, bypassing the cardiac defect. Apnea is a common adverse effect of PGE_1, occurring in 10% to 20% of patients, so age-appropriate equipment for intubation and mechanical ventilation should be immediately available before starting treatment and throughout therapy.[40] Within 10 to 15 minutes after starting an alprostadil infusion, there should be an improvement in the patient's oxygen saturation. The dose may then be titrated to optimize ductal flow and minimize dose-related adverse effects. The infusion is typically continued until corrective cardiac surgery can be performed. J.F. should receive fluid boluses as needed to correct his dehydration and will require intubation. In addition, he should be started on PGE_1 at a rate of 0.05 mcg/kg/minute, with subsequent titration of the dose to open and maintain the DA until the time of surgery.

PEDIATRIC TRAUMATIC BRAIN INJURY

Among children, traumatic brain injury (TBI) is the leading cause of mortality and leads to significant morbidity among survivors. Each year more than 400,000 children in the United States suffer a TBI requiring an emergency department visit, resulting in 30,000 hospitalizations and 3,000 deaths.[41] The most common mechanisms of injury differ by patient age. Children less than 4 years old most often suffer injuries due to child abuse, falls, and motor vehicle collisions (MVC). Child abuse, or nonaccidental trauma (NAT), sadly represents up to two-thirds of severe TBI in some series. Although it is difficult to obtain accurate data, in a population-based study from North Carolina, the incidence of TBI due to NAT in the first 2 years of life was 17 per 100,000 person-years.[42] According to the National Center on Shaken Baby Syndrome, this translates to approximately 1,300 children per year in the United States who experience severe head trauma from child abuse. In school-aged children, those 5 to 12 years of age, pedestrian–motor vehicle collision and bicycle-related injuries are among the more common causes of severe injuries. For adolescents, MVC replace falls as the leading cause of all injuries, followed by assault and sports-related injuries.

CASE 106-6

QUESTION 1: K.B. is an 8-week-old, 4-kg male infant who was brought to an urgent care clinic by his 17-year-old mother. She stated that he would not wake up for his usual 7:00 PM feeding that evening. He had been in his usual state of health that morning. She fed him his usual bottle, changed his diaper, and laid him down for a nap. She left him in the care of her 19-year-old boyfriend and went to work. At the clinic, the infant was floppy and unarousable. There were no bruises or other signs of injury, but the anterior fontanel was bulging. His pupils were 3 mm and responded sluggishly to light. When prompted, the boyfriend stated that K.B. fell off the couch early in the morning but only cried for a few minutes. After some comforting, he went back to playing. He fed well the remainder of the day and was taking his evening nap when the mother returned from work. The urgent care clinic suspected NAT and transferred K.B. to the closest hospital with pediatric critical care services. What physiologic differences place K.B. at greater risk for severe TBI than an older child? What risk factors or associations for NAT can you identify in this case?

The anatomic differences of the infant’s brain render it more susceptible to certain types of injuries after head trauma.[43] Infants such as K.B. and young children have large, heavy heads. The head is unstable because of its relative size to the rest of the body. If an infant or young child falls a significant distance, is ejected during an MVC, or is thrown from a bicycle after colliding with an automobile, the head will tend to lead (i.e., the infant or child will fly head first) and severe head injuries will occur when the head ultimately strikes the ground or another object. The infant’s weak neck muscles also allow for greater movement when the head is acted on by acceleration/deceleration forces. The skull is thinner during infancy and early childhood, providing less protection for the brain and allowing forces to transfer more effectively across the shallow subarachnoid space. The base of the infant’s skull is relatively flat, which also contributes to greater brain movement in response to acceleration/deceleration forces. In addition, the infant’s brain has a higher water content (approximately 88% vs. 77% in an adult), which makes the brain softer and more prone to acceleration/deceleration injury. The water content is also inversely related to the myelination process, and the higher percentage of unmyelinated brain makes it more susceptible to sheer injuries. The infant brain is typically fully myelinated by 1 year of age. As the result of these physiologic differences, there are differences in the pathology after pediatric TBI by age group. In infants and young children, diffuse injury, such as diffuse cerebral swelling, and subdural hematomas are more common than focal injury, such as contusions, that are typically seen in older children and adults. The typical pattern of hypoxic-ischemic injury in infants and young children after NAT is rarely seen in older children and adults who are victims of abuse.

Table 106-12

Modified Glasgow Coma Scale

Eye Opening		
Score	**≥1 year**	**0–1 year**
4	Opens eyes spontaneously	Opens eyes spontaneously
3	Opens eyes to verbal command	Opens eyes to shout
2	Opens eyes in response to pain	Opens eyes in response to pain
1	No response	No response
Best Motor Response		
Score	**≥1 year**	**0–1 year**
6	Obeys command	N/A
5	Localizes pain	Localizes pain

4	Flexion withdrawal	Flexion withdrawal	
3	Flexion abnormal (decorticate)	Flexion abnormal (decorticate)	
2	Extension (decerebrate)	Extension (decerebrate)	
1	No response	No response	
Best Verbal Response			
Score	**>5 years**	**2–5 years**	**0–2 years**
5	Oriented and able to converse	Uses appropriate words	Cries appropriately
4	Disoriented and able to converse	Uses inappropriate words	Cries
3	Uses inappropriate words	Cries and/or screams	Cries and/or screams inappropriately
2	Makes incomprehensible sounds	Grunts	Grunts
1	No response	No response	No response

Source: Chung CY et al. Critical score of Glasgow Coma Scale for pediatric traumatic brain injury. Pediatr Neurol. 2006;34:379.

Goldstein et al.[44] have published risk factors for NAT based on data gathered from several earlier reports. They found that victims of inflicted head injury tended to be younger, more often from families of poorer socioeconomic backgrounds, and were more likely to have parents who were younger than 18 years of age and who had never been married. In addition, a history inconsistent with physical findings was strongly associated with the presence of inflicted head injury. Additional risk factors reported as associated with NAT are alcohol or drug abuse, previous social service intervention, or a past history of child abuse, in combination with either retinal hemorrhages or an inconsistent history or physical examination. These investigators found this combination was 100% predictive of child abuse in children admitted to a PICU. K.B. met many of these risk factors: He is young, has an unmarried parent who is younger than 18, and is from a low socioeconomic background. In addition, his injuries appear inconsistent with the history of falling from a couch. A fall of approximately 3 feet is required to cause significant head injury to an infant or child; a standard couch is 18 inches from the floor.[45]

CASE 106-6, QUESTION 2: K.B. was transferred immediately to the emergency department at a local hospital. The O_2 saturation on room air was 100%, blood pressure 90/63 mm Hg, and HR 120 beats/minute. The initial Glasgow Coma Scale (GCS) score on presentation was 7, with 2 for eye opening in response to pain, 4 for withdrawing to pain, and 1 for no verbal response. What test or assessment tools are useful for evaluating the extent of K.B.'s injuries? Which are best for predicting his outcome?

The ability to evaluate the severity of TBI is essential to appropriately direct care, predict outcomes, and compare results to evaluate and improve patient care. Initial symptoms on presentation have been found to have little or no correlation with injury severity after TBI. The GCS is a widely accepted method in initially evaluating and characterizing trauma patients with head injuries (Table 106-12). The scale is composed of visual, motor, and verbal components, with lower scores representing more serious injuries. The severity of TBI may be characterized as mild (GCS 13–

15), moderate (GCS 9–12), or severe (GCS 3–8) on presentation; however, continued evaluation of GCS scores is the best way to track the patient’s clinical progress. K.B.’s GCS of 7 on admission puts him in the category of severe TBI.

The radiologic examination of choice for immediate assessment of a child with severe TBI is a noncontrast cerebral-computed tomography (CT) scan. Most children with severe TBI undergo immediate CT imaging to delineate their injuries as soon as they have been fully assessed and sufficiently stabilized to permit safe transport to the radiology suite. If the brain injury does not need immediate surgical intervention, the patient’s care is continued in the PICU with the implementation of therapies designed to minimize secondary brain injury. In a retrospective review of 309 children presenting with TBI, Chung et al.[46] found that GCS was more useful in predicting survival among pediatric victims of TBI than CT findings and the presence of injuries to other organ systems. In addition, they identified that a GCS score of less than 5, rather than a score of less than 8 as used in adults, was the threshold at which the patient was more likely to have a poor outcome. The authors also found that head CT findings of swelling or edema and subdural and intracerebral hemorrhage were associated with worse outcomes than subarachnoid or epidural hemorrhage.

Retinal hemorrhages are frequently, although not always, observed in inflicted head injury in infants and young children. These hemorrhages are the result of sheer forces disrupting vulnerable tissue interfaces. The vitreous body is adherent to the retina in early childhood; shaking can cause retinal hemorrhaging throughout multiple tissue layers, extending to the periphery of the retina. This pattern is unique to “shaken baby syndrome.” Although useful for diagnosis, the ocular examination is often deferred initially when evaluating an infant or child for TBI, because the medications used to facilitate funduscopy will preclude the use of pupillary reactivity as a tool to monitor evolving intracranial events.

According to the American Academy of Pediatrics guidelines on imaging for NAT, a skeletal survey is strongly recommended in all cases of suspected physical abuse in children under the age of 24 months.[47] A skeletal survey consists of films of the extremities, skull, and axial skeletal images. Follow-up radiographs of the ribs to assess for healing fractures not seen in the acute phase may be helpful 2 to 3 weeks after the skeletal survey. As with the eye examination, the skeletal survey is often delayed until the child is more stable.

CASE 106-6, QUESTION 3: After assessment by the emergency room physician, K.B. was intubated using rocuronium and pentobarbital, placed on an FIO_2 of 100% and sent for a CT scan. The CT reveals a subdural hematoma and cerebral swelling. On arrival to the PICU, K.B.’s vital signs are as follows:

Blood pressure, 85/58 mm Hg

HR, 125 beats/minute
Respiratory rate on the ventilator, 20 breaths/minute
Temperature was 36.9°C. What are the next goals for stabilization of K.B.?

The initial management of a child with a head injury should focus on the basics of resuscitation: assessing and securing the airway, ensuring adequate ventilation, and supporting circulation.[48] In addition, the goals of treatment of TBI are directed toward protecting against secondary brain insults (SBI) which can exacerbate neuronal damage and brain injury. SBI are often the result of systemic hypotension, hypoxia, hypercarbia, anemia, and hyperglycemia. Aggressive treatment strategies are needed to prevent and/or treat these conditions to decrease morbidity and improve neurologic outcome after TBI in children. The criteria for tracheal intubation include hypoxemia not resolved with supplemental oxygen, apnea, hypercarbia ($Paco_2$ >45 mm Hg), a GCS score less than or equal to 8, a decrease in GCS greater than 3 compared with the initial score, cervical spine injury, loss of pharyngeal reflex, or any clinical evidence of herniation. K.B. was intubated in the emergency room based on his presenting GCS of 7. All patients should be assumed to have a full stomach and cervical spine injury, so the intubation should be carried out using a rapid sequence intubation using appropriate short-acting sedatives and muscle relaxants (Tables 106-3 and 106-4).

After intubation, K.B.'s ventilatory goals include 100% oxygen saturation, normocarbia (35–39 mm Hg), and no hyperventilation, as confirmed by ABGs, end-tidal CO_2 monitoring, and chest radiographs showing tracheal tube in good position. Unless he has signs or symptoms of herniation, prophylactic hyperventilation ($Paco_2$ <35 mm Hg) should be avoided.[48] Hyperventilation causes cerebral vasoconstriction, which decreases cerebral blood flow and subsequent blood volume. Although it will lower ICP, hyperventilation may result in ischemia. Furthermore, respiratory alkalosis caused by hyperventilation makes it more difficult to release oxygen to the brain, shifting the oxygen–hemoglobin curve to the left. Short-term use of hyperventilation, however, may be useful in preventing herniation while other medical therapies are implemented. In addition to mechanical ventilation, the head of the bed should be kept in the neutral position and jugular venous obstruction should be avoided to prevent ICP elevation. Elevation of the head of the bed to thirty degrees usually decreases ICP.

Assessment and reassessment of the patient's circulatory status, including central and peripheral pulse quality, capillary refill, heart rate, and blood pressure, is critical. Hypotension after pediatric TBI is associated with increased morbidity and mortality.[48] Initial treatment of hypotension in the head-injured child is similar to that described earlier for pediatric shock; however, the goal systolic blood pressure in the TBI patient is typically higher: equal to or greater than the 50th to 75th percentile for age, sex, and height. Systolic blood pressure less than the 75th percentile has been associated with a fourfold increase in the risk for poor outcome after severe TBI, even when values were 90 mm Hg or greater.[49] This suggests a possible benefit of a higher blood pressure target until ICP or cerebral perfusion pressure (CPP) monitoring is in place to guide therapy. As a result of the need for higher SBP, norepinephrine and phenylephrine, agents with greater vasopressor effects, are more frequently used in this patient population.[50]

The solution of choice for IV maintenance fluids in children with TBI is normal saline for children older than 1 year of age and 5% dextrose with normal saline for infants. Because hyperglycemia is known to worsen SBI, initial IV fluids for children should not contain dextrose. Infants are an exception, because their low glycogen stores make them prone to hypoglycemia, especially with poor oral intake. Hypoglycemia can also worsen neurologic outcome and should be avoided. Frequent assessment of blood glucose either by point-of-care testing or on an ABG is recommended.

Fever increases metabolic demands and is associated with worse outcomes after TBI. Treatment for K.B. should include 60 mg of acetaminophen (15 mg/kg) orally or rectally every 6 hours as needed and a cooling blanket when necessary. Ibuprofen should be avoided because it may increase the risk of bleeding. Patients who are hypothermic on arrival should only be actively rewarmed if there is hemodynamic instability or bleeding thought to be exacerbated by hypothermia. Serum electrolytes and osmolarity should be monitored regularly in K.B., along with accurate assessment of urine output. This is important to identify the development of either syndrome of inappropriate antidiuretic hormone or diabetes insipidus. Both have been reported to occur after pediatric TBI.[48]

CASE 106-6, QUESTION 4: K.B. has been intubated and placed on mechanical ventilation with an ABG showing that he is maintaining goal parameters. He is receiving fentanyl at 1 mcg/kg/hour and a midazolam infusion at 0.05 mg/kg/hour. The head of the bed is raised 30 degrees and his head is midline, supported by a head roll. K.B. has both a pulse oximeter and an end-tidal CO_2 monitor for continuous evaluation of his oxygenation and CO_2. Blood pressure is being maintained at the 75th percentile for age, height, and sex. What is the next step in monitoring head injury in K.B.?

One of the most significant consequences of TBI is the development of intracranial hypertension. The presence of an open fontanel or sutures in an infant with severe TBI does not preclude the development of intracranial hypertension or negate the utility of ICP monitoring. ICP monitoring is recommended for any child presenting with a GCS of 8 or less.[51] When possible, placement of a ventriculostomy catheter provides accurate pressure monitoring and allows for acute drainage of cerebrospinal fluid (CSF) for treatment of elevated ICP and assessment of CPP. The CPP value is calculated by subtracting the ICP from the mean arterial pressure (MAP):

$$(CPP = MAP - ICP) \quad \text{(Eq. 106-1)}$$

This value is important as an indication of blood flow and oxygen that reach the brain. Maintaining CPP requires optimization of MAP with fluid therapy, and if necessary, vasoactive drugs. In the case of ICP elevation, inotropic or vasopressor agents may be used to optimize CPP by increasing MAP, even to the point of relative systemic hypertension. In adults, a CPP of 60 to 70 mm Hg is usually targeted.

There are no data that correlate CPP in infants to outcome. There are, however, pediatric TBI studies showing that CPP values ranging from 40 to 70 mm Hg are associated with a favorable outcome and that a CPP less than 40 mm Hg is associated with poor outcomes.[51] Because infants and children normally have a lower MAP and ICP, the SCCM Pediatric Fundamental Critical Care Support course recommends the following CPP ranges: 40 to 50 mm Hg in infants, 50 to 60 mm Hg in children, and 60 to 70 mm Hg in adolescents.[52] This is more specific than the 2003 pediatric recommendations that recommend a CPP greater than 40 mm Hg and an "age-related continuum" of CPP from 40 to 65 mm Hg in infants and adolescents be maintained.[48]

CASE 106-6, QUESTION 5: The neurosurgeon has placed a ventriculostomy in K.B., and his initial ICP is 25 mm Hg. His other vitals are as follows:

Blood pressure, 83/50 mm Hg
HR, 140 beats/minute
Temperature, 38.5°C

His pulse oximeter still reads 100% and the $ETCO_2$ monitor reads 35 mm Hg. Sedative infusions are unchanged: fentanyl 1 mcg/kg/hour and midazolam 0.05 mg/kg/hour. The pediatric intensivist has placed a central line, and the CVP is 10 mm Hg. What is K.B.'s calculated CPP? What interventions are recommended to treat this ICP elevation?

Uncontrolled increased ICP is very deleterious and must be aggressively treated as soon as possible to reduce cerebral ischemia. In this setting, the goal of any therapy is to lower ICP enough to increase CPP and improve cerebral oxygenation. All initial treatments should be reassessed for efficacy, including treatment of fever, avoidance of jugular venous outflow tract obstruction, maintenance of normovolemia and normocarbia, and provision of sedation and analgesia. The latter is of considerable importance, because anxiety and pain have been shown to increase ICP. K.B. appears to be euvolemic by CVP measurement, is normocapnic, and his O_2 saturation is 100%. He is febrile; however, measures should be taken to treat the elevated temperature. Although he is receiving continuous sedation, additional bolus doses of sedatives should be given whenever needed. Because K.B. has an elevated CPP in spite of these initial therapies, the best option would be to drain CSF. This will provide an immediate, but transient, decrease in ICP. K.B. may have CSF drained until an ICP value of 15 mm Hg is reached; it should never be drained to 0 mm Hg because edema and diffuse brain swelling could cause an obstruction in the lateral ventricles. When a ventriculostomy is in place and CSF is frequently drained, it is important to replace the CSF drained with an equal amount of normal saline. Draining of large amounts of CSF without IV normal saline replacement is associated with the development of hypochloremic metabolic alkalosis. Drainage of CSF in K.B. will provide a CPP in the 40- to 50-mm Hg range. If the ICP increases again, two interventions are recommended, either the addition of a vasopressor to increase SBP or institution of hyperosmolar therapy.

Hyperosmolar therapy may be useful in preventing the ICP from exceeding 20 mm Hg and in maintaining normal CPP. Mannitol has long been the standard of care for management of elevated ICP.[48] Although extensively used since 1961 to control elevated ICP, mannitol has never been compared with placebo. Mannitol reduces ICP by reducing blood viscosity, which promotes reflex vasoconstriction of the arterioles by autoregulation, thus decreasing cerebral blood volume and ICP. This mechanism is rapid, but transient, lasting about 75 minutes and requiring an intact autoregulation. It also produces an osmotic effect by increasing serum osmolarity, causing the shift of water from the brain cell to the intravascular space. Although this effect is slower in onset (15–30 minutes), the osmotic effect lasts up to 6 hours. Mannitol is a potent osmotic diuretic; osmotic diuresis should be anticipated and fluid resuscitation is available to avoid hemodynamic compromise. A Foley catheter is recommended in these patients for accurate measurement of urine output. Mannitol is excreted unchanged in the urine; serum osmolarity should be maintained lower than 320 mOsm/L to avoid the development of mannitol-induced acute tubular necrosis.

Although mannitol has traditionally been the drug of choice for reducing elevated ICP, hypertonic saline (3% sodium chloride) is gaining favor. The main mechanism of action of hypertonic saline is an osmotic effect similar to mannitol. Hypertonic saline exhibits several other theoretic benefits such as restoration of normal cellular resting membrane potential and cell volume, inhibition of inflammation, stimulation of atrial natriuretic peptide release, and enhancement of cardiac output.[48] The theoretic advantage over mannitol is that hypertonic saline can be administered in a hemodynamically unstable patient without the risk of a subsequent osmotic diuresis. Continuous infusions of 0.1 to 1 mL/kg/hour of hypertonic saline titrated to maintain an ICP less than 20 mm Hg have been used successfully in children.[53] Bolus doses of 5-10 mL/kg of 3% sodium chloride have been administered over 20 to 30 minutes. Serum osmolarity and serum sodium increase when this regimen is used, but sustained hypernatremia and hyperosmolarity appear to be generally well tolerated. Hypertonic saline has been administered with a serum osmolarity reaching 360 mOsm/L without adverse effects in pediatric patients. Another potential concern with the use of hypertonic saline is central pontine myelinolysis that has been reported with rapid changes in serum sodium. Currently, clinical trials have shown no evidence of demyelinating disorders.

To bring his ICP values down to the normal range (<20 mm Hg), K.B. may be given mannitol at an IV dose of 2 to 4 g (0.5– 1 g/kg) administered over 20 to 30 minutes. The effects of mannitol on ICP should be evident within 15 minutes. This dose may be repeated every 4 to 6 hours as needed. If intermittent mannitol fails to bring his ICP down adequately, K.B. may be given hypertonic saline 3%, beginning at 0.1 mL/kg/hour or as a bolus dose of 5-10 mL/kg administered over 20 minutes. Dosing of either agent should be guided by regular assessment of serum electrolytes and osmolarity.

CASE 106-6, QUESTION 6: K.B. has been in the PICU for 24 hours. Initial treatment allowed K.B. to maintain a CPP of 50 mm Hg and an ICP less than 20 mm Hg the majority of the day.

He is receiving 3% sodium chloride combined with maintenance IV fluids, giving him a serum sodium of 166 mEq/L. Intermittent ICP spikes have responded to intermittent 4 g doses of mannitol; however, the most recent serum osmolarity is 330 mOs/L. What options remain to treat increased ICP in K.B.?

Two nonsurgical options are included in the TBI guideline: barbiturate coma and therapeutic hypothermia.[48] Barbiturates exert neuroprotective effects by reducing cerebral metabolism, lowering oxygen extraction and demand, and alternating vascular tone. Barbiturate serum levels poorly correlate with clinical efficacy; therefore, monitoring of electroencephalographic (EEG) patterns for burst suppression is recommended. Burst suppression also represents near-maximum reduction in cerebral metabolism and cerebral blood flow. A pentobarbital loading dose of 10 mg/kg/dose may be administered over 30 minutes, followed by a continuous infusion of 1 mg/kg/hour. Additional loading doses, in 5 mg/kg/dose increments, may be necessary to achieve burst suppression. The primary disadvantage of barbiturate coma is the risk for myocardial depression and hypotension. In addition, the long-term effect on neurologic outcome is unknown. The TBI guideline states that high-dose barbiturate therapy may be considered in hemodynamically stable patients with salvageable severe head injury and refractory intracranial hypertension.[48]

Post-traumatic hyperthermia is defined as a core body temperature greater than 38.5°C, and hypothermia is defined as a temperature of less than 35°C. Although most clinicians agree that hyperthermia should be avoided in children with TBI, the role of hypothermia is unclear. Potential complications associated with hypothermia are increased bleeding risk, arrhythmias, and increased susceptibility to infection. A multicenter, international study of children with severe TBI randomly assigned to hypothermia therapy initiated within 8 hours after injury (32.5°C for 24 hours) or to normothermia (37°C) was recently published.[52] The study reported a worsening trend with hypothermia therapy: 31% of the patients in the hypothermia group had an unfavorable outcome, compared with 22% of the normothermia group. There were several methodological problems with this study. Although the investigators screened patients within 8 hours, the mean time to initiation of cooling was 6.3 hours, with a range of 1.6 to 19.7 hours. In addition, the protocol included a rapid rewarming of

0.5°C every 2 hours so that the patients were normothermic by a mean of 19 or 48 hours postinjury. They found that the ICP was significantly lower in the hypothermia group during the cooling period, but that it was significantly higher than the normothermic group during rewarming. Another trial conducted in Australia and New Zealand evaluated strict normothermia (temperature 36°C–37°C) versus therapeutic hypothermia (temperature 32°C–33°C).[54] Patients were enrolled within 6 hours of injury and therapeutic hypothermia or strict normothermia was maintained for 72 hours. The rewarming rate was at a maximum of 0.5°C every 3 hours or slower if needed to maintain normal CPP or ICP <20 mmHg. Rewarming took a median of 21.5 hours (16–35 hours) and was without complications. However, there was no difference in pediatric cerebral performance category (PCPC) scores between the 2 groups at 12 months.[54] It is unclear whether therapeutic hypothermia is not efficacious because patients are not cooled soon enough (median time to target temperature = 9.3 hours) or due to the heterogeneous nature of TBI. The pediatric TBI guideline states that despite the lack of clinical data, hypothermia may be considered in the setting of refractory hypertension.[48]

Decompressive craniectomy, removal of a section of skull to allow room for brain swelling without herniation, is another option for managing pediatric TBI patients who fail to respond to standard therapies. A randomized trial of early decompressive craniectomy in children with TBI and sustained intracranial hypertension revealed that 54% of the surgically treated patients had a favorable outcome compared with only 14% of the medically treated group.[55] Additional case series have confirmed that patients who receive a decompressive craniectomy have improved survival and neurologic outcomes compared with those undergoing medical management alone.[56] As with barbiturate coma and therapeutic hypothermia, decompressive craniectomy is not without risk. A recent study reported an increased risk of post-traumatic hydrocephalus, wound complications, and epilepsy in children with severe TBI.[57] Further studies are needed to establish the timing, efficacy, and safety of this management strategy. The pediatric TBI guideline states that decompressive craniectomy should be considered in pediatric patients with severe TBI, diffuse cerebral swelling, and intracranial hypertension refractory to intensive medical management.

CASE 106-7

QUESTION 1: L.B. is an 18-kg, 6-year-old child hit by a car while riding her bicycle. When emergency medical services arrived, they witnessed a 2-minute tonic-clonic seizure. GCS at the scene was 11. Should L.B. receive anticonvulsant medication after her TBI?

Post-traumatic seizures (PTS) are classified as early (occurring within 7 days after injury) or late (occurring after 7 days). In the immediate period after severe TBI, seizures increase the brain metabolic demands, increase ICP, and are associated with TBI. Therefore, it would be prudent to prevent PTS in the period when the patient is at highest risk of SBI. Infants and children are reported to have a greater risk of early

PTS compared with adults. Children younger than 2 years of age have almost a threefold greater risk of early PTS after TBI than children between 2 and 12 years of age. In addition to age, a low GCS (8–11) has been linked to an increased risk of early PTS. The pediatric TBI guideline states that prophylactic antiseizure therapy may be considered as a treatment to prevent early PTS. No prophylactic anticonvulsant therapy is recommended to prevent late PTS.[48]

The majority of the published studies in children have used phenytoin for PTS prophylaxis. Both phenytoin and carbamazepine have been reported to reduce the incidence of PTS in adults. A large (n = 813) prospective multicenter trial evaluated the effectiveness of levetiracetam for seizure prophylaxis in severe TBI in adults.[58] Although the trial demonstrated that levetiracetam was equally effective to phenytoin in preventing PTS after TBI, the authors concluded that the significant cost difference between the 2 treatments makes phenytoin the preferred therapy. There are currently no studies of levetiracetam for PTS prophylaxis in children. Due to the seizure witnessed at the scene, her young age, and her initial GSC score of 11, L.B. meets the criteria for prophylaxis. An appropriate regimen for L.B. would be phenytoin 45 mg given orally 3 times daily (7.5 mg/kg/day) for 7 days.

107

Geriatric Drug Use

Suzanne Dinsmore, Mary Kathleen Grams, and Kristin M. Zimmerman

CORE PRINCIPLES

AGE-RELATED PHYSIOLOGIC, PHARMACOKINETIC, AND PHARMACODYNAMIC CHANGES

	CORE PRINCIPLES	CHAPTER CASES
1	Age-associated physiologic changes are associated with pharmacokinetic and pharmacodynamic alterations of drugs in older adults. Decline in drug metabolism and excretion and exaggerated response to drugs are important considerations in drug therapy of the elderly.	**Case 107-1 (Questions 1–4)**
2	Adverse drug events are one of the most important problems associated with drug use in older adults.	**Case 107-2 (Question 1)**

DISEASE-SPECIFIC GERIATRIC DRUG THERAPY

	CORE PRINCIPLES	CHAPTER CASES
1	Elderly patients have multiple chronic conditions and take numerous medications. Disease state education, awareness of potential adverse effects and drug interactions, consultation with healthcare providers, and behavioral modification are important steps to ensure medication safety.	**Case 107-3 (Questions 1, 2)**
2	Pharmacologic treatments of heart failure in the elderly include a diuretic, β-blocker, an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB), with or without digoxin and spironolactone. Benefits should be weighed against risks based on the patient's concurrent conditions.	**Case 107-3 (Questions 3–6)**
3	Statins are the drug of choice for treating hyperlipidemia in the elderly. Combination with other agents is considered only if necessary and is based on concurrent disease states, potential adverse effects, and drug interactions.	**Case 107-3 (Questions 7, 8)**
4	First-line therapy for prevention of coronary artery disease (CAD) includes acetylsalicylic acid (ASA) and β-blockers. Other agents are considered based on concomitant diseases and relative indications.	**Case 107-3 (Question 9)**
5	Hypertension should be treated in the elderly according to the guidelines, and monitoring is essential to prevent excessively low blood pressure,	**Case 107-3 (Question 10)**

bradycardia, and orthostatic hypotension.	
⑥ The glycosylated hemoglobin (Hgb A_{1c}) goal may be higher for elderly patients who have hypoglycemia. Pharmacologic therapies for diabetes are recommended based on level of hyperglycemia and relative contraindications.	**Case 107-3 (Question 11)**
⑦ Depression is the most common psychiatric disorder in the elderly, often presenting with atypical symptoms. Selective serotonin reuptake inhibitors are generally better tolerated than other agents and are considered first-line therapy for older adults.	**Case 107-4 (Questions 1, 2)**
⑧ Asthma is a significant source of morbidity in the elderly. The management of asthma in older adults does not differ significantly from that for younger individuals. However, coexisting chronic medical conditions, exaggerated systemic adverse drug reactions, and dexterity concerns must be considered when managing drug therapy for asthma in the elderly.	**Case 107-5 (Questions 1, 2)**

---

⑨ Pneumonia is the leading infectious cause of mortality in the elderly, who typically present with atypical symptoms of lower respiratory infection. Influenza and pneumococcal vaccinations are beneficial in the prevention of pneumonia in the older population.	**Case 107-5 (Questions 3–5)**
⑩ Urinary tract infection is the most common bacterial infection in the elderly. Oral antibiotics are appropriate for most older patients with symptomatic infection.	**Case 107-6 (Question 1, 2)**
⑪ Arthritis is the most common cause of disability in the elderly, and there are several analgesic agents available for the management of osteoarthritis. Safe and appropriate use of these analgesic medications is important because older adults are at increased risk of adverse drug reactions.	**Case 107-7 (Questions 1, 2)**

LONG-TERM CARE FACILITIES

① Federally mandated responsibilities of pharmacists in long-term care facilities include monthly medication regimen review for appropriateness of drug therapy. Provision of pharmaceutical care in long-term care facilities helps to minimize medication errors, adverse drug reactions, and inappropriate prescribing.	**Case 107-8 (Questions 1, 2)**

DEMOGRAPHIC AND ECONOMIC CONSIDERATIONS

Demographic changes and medical progress in the United States (U.S.) over the last half of the 20th century have created the need for imperatives to improve our knowledge about the health care and drug therapy of older adults. The Federal Interagency Forum on Aging-Related Statistics, is made up of multiple Federal agencies which came together in 1996 to provide information on the health, finances, and well-being of older Americans in the United States.[1] The latest report compiles information from over 16 national data sources and separates data into 41 indicators in the areas of population, economics, health status, health risks and behaviors, and health care and environment, of the older population. The U.S. Department of Health & Human Services published "A Profile in Older Americans", updated in 2016.[2] Both reports include valuable information that describe the older population (Table 107-1).

The oldest-old category (i.e. those older than 85 years of age) will have the greatest impact on the healthcare system because the number of people in this group has increased faster than any other age category. This group will triple its size by 2040.[2]

Older adults often have multiple chronic conditions, higher prescription drug costs, and higher out of pocket healthcare expenditures, and account for more overnight hospital stays than younger adults. Many older adults live at home and may receive personal assistances with one or more activities of daily living (ADLs) including bathing, eating, and dressing; or instrumental activities of daily living (IADLs), which include preparing meals, washing clothes, shopping, paying bills, and taking medication. Often, informal care from children and other relatives is a large reason disabled older adults can continue to live in the community. Thus, it is important to include the caregiver in the counseling and monitoring of daily activities when feasible. An increase in this informal assistance and the reliance on others to perform ADLs and IADLs leads to a loss of independence and the inability of older adults to remain living at home or alone in the community. Approximately 1.2 million U.S. residents 65 years of age or older reside in long-term care facilities (LTCFs). The percentage of those living in nursing homes increases greatly with age (1% age 65–74; 3% age 75–84; 9% age 85 and greater).

Health care for older adults in an institutional setting is largely based on a prospective reimbursement system, where payment for services is based on a fixed amount. Managed-care practices aim to minimize high-cost hospitalizations by shifting care to lower-cost alternatives, such as home health care, assisted living, and hospice care. The escalating costs and affordability of medications are a national concern, especially in the Medicare population. The Medicare Prescription Drug Improvement and Modernization Act of 2003 provided voluntary prescription drug insurance benefits, known as Medicare Part D, to improve older adults' access to prescription drugs. Medicare Part D implementation is associated with up to a 13% increase in drug use in older adults and up to an 18% decrease in patient out-of-pocket costs.[3]

Table 107-1

Profile of Older Americans

Current Facts About Older Americans[1,2]

- The older population, persons aged 65 years and older, numbered 47.8 million in 2015, representing 14.9% of the U.S. population. This is a 30% increase from 2005.
- Approximately 1 in every 7 of the U.S. population is considered an older American.
- The older population is predominantly female. There are 126.5 women for every 100 men aged 65 and older, and this increases to 189.2 women to 100 men at age 85 and older.
- The older population is getting even older. The 85 and older age group grew from just over 100,000 in 1900 to 0.3 million in 2015.
- The average life expectancy for someone born in 2015 is 78.8 years, an increase by about 30 years as compared to 1900.
- The centenarian population or those aged 100 and greater accounted for 0.2% of the age 65 and older population in 2015.
- The most common and costly health conditions among all persons aged 65 and older are heart disease, heart disease, stroke, cancer, diabetes and arthritis.
- Among all persons aged 65 and older, the leading causes of death are heart disease, cancer, chronic lower respiratory diseases, stroke, Alzheimer's disease, diabetes, unintentional injuries, and influenza and pneumonia.

Future Expected Growth

- A rapid increase in the older population is expected between the baby boomer generation reaches age 65.
- The population of those age 65 and older is expected to double to 98 million by 2060.
- The very old, those age 85 and greater are expected to double from 6.3 million in 2015 to 14.6 million in 2040.

Adapted from Federal Interagency Forum on Aging-Related Statistics. Federal Interagency Forum on Aging-Related Statistics. Older Americans 2016 and Department of Health & Human Services USA. A Profile of Older Americans: 2016.

AGE-RELATED PHYSIOLOGIC, PHARMACOKINETIC, AND PHARMACODYNAMIC CHANGES

Physiologic changes that are seen with aging are progressive and occur gradually over a lifetime, rather than abruptly at any given age.[4] These changes may lead to decreases in the function of tissues and organs and the ability for each organ system to maintain homeostasis: a phenomenon often called "homeostenosis."[5,6] The impaired ability to recover from drug-induced insults may increase the risk of drug-related problems in older adults. Homeostatic mechanisms in the cardiovascular and nervous systems are less efficient, drug metabolism and excretion decrease, and body tissue composition and drug volume of distribution change and drug receptor sensitivity may be altered. Age-related physiologic changes may result in pharmacokinetic and pharmacodynamic changes and should be considered when selecting and evaluating drug therapy.

Absorption

The absorption of some drugs administered by the extravascular route may be altered by age-related physiologic changes, unlike drugs administered by the intravascular route which are considered to have 100% bioavailability.[7] In the gastrointestinal (GI) tract, a decrease in intestinal blood flow, increase in gastric pH, delayed gastric emptying, and decreased gastrointestinal motility occur with aging. Increased gastric pH due to aging alone is thought to have a minimal effect on absorption and be rarely clinically significant.[8] However, the use of H2-receptor antagonists and proton pump inhibitors combined with gastric pH changes may affect drugs that require an acidic environment for absorption such as iron and ketoconazole.[9] In general, the rate of absorption is slower or unaltered in older patients, and the extent of absorption by the oral route is similar as compared to young adults.

The transdermal administration of drugs is becoming increasingly common and used for several medications prescribed to older adults. Changes in skin seen with aging such as decreased elasticity, thinning of the epidermis, dryness, and decreased sebaceous gland activity may affect drug absorption.[10]

Lipophilic drugs (e.g., estradiol) appear to be less affected by aging skin and are easily dissolved, whereas hydrophilic compounds may not dissolve as readily on aging skin.

CASE 107-1

QUESTION 1: M.G. is a 75-year-old female, 5′4″, 120 pounds, with a serum creatinine concentration of 1.9 mg/dL. She has an acute exacerbation of heart failure (HF). She is given furosemide 40 mg orally, but this produces little increase in urine output or resolution of her symptoms.

What would explain M.G's lack of response to furosemide and how might the desired response to furosemide be achieved?

The extent of furosemide absorption is not changed in older patients, but the rate of absorption is slowed. This results in a diminished efficacy of the drug because active secretion into the urine (rate of entry) must reach the steep portion of the sigmoid dose–response curve for maximal effect of the drug.[11]

M.G. should be given a 40 mg dose of furosemide intravenously to bypass the problem of decreased rate of absorption. High sodium intake or concurrent use of nonsteroidal anti-inflammatory drugs (NSAIDs) may also decrease the effectiveness of furosemide. Further increases in dose of furosemide may be necessary, with consideration of a continuous infusion in patients with severe chronic renal insufficiency (see Chapter 28, Chronic Kidney Disease).

Distribution

There are a number of age-related changes that may affect the distribution of drugs in the body.[12] Total body water and lean body mass both decline with age by 10% to 15%, and total fat content increases by 20% to 40%. Thus, the volume of distribution (Vd) of drugs that are distributed primarily in body water or lean body mass (e.g., lithium, digoxin) is decreased in older adults, and unadjusted dosing may result in higher blood levels. Conversely, the Vd of highly lipid-soluble drugs, such as long-acting benzodiazepines (e.g., diazepam), may be increased, thereby delaying maximal effects or leading to accumulation with continued use.

Serum albumin concentrations were found to progressively decrease for each decade beyond 40 years of age, reaching a mean of 3.58 g/dL in those older than 80 years of age, and this may reduce protein binding.[13] Changes in protein binding due to aging alone are thought to be only clinically significant with highly extracted drugs, drugs that are highly protein bound, that have a narrow therapeutic index, those with a small volume of distribution, and those given intravenously.[7,9,14] Other factors in older patients that may also affect binding include protein concentration, disease states, coadministration of other drugs, and nutritional status.

Altered Protein Binding

CASE 107-1, QUESTION 2: M.G. is brought to the emergency department (ED) for evaluation of a “shaking spell”. In the ED, another “spell” is observed, starting with shaking of the left arm and progressing into a generalized tonic–clonic seizure. A loading dose of phenytoin 1,000 mg is given intravenously (IV) over 30 minutes. M.G. is admitted to the neurology unit for further evaluation and given phenytoin 300 mg by mouth (PO) at bedtime. Is the phenytoin regimen appropriate for M.G.? What laboratory tests should be ordered, and how often should these be monitored?

M.G. received a phenytoin loading dose of 17 mg/kg (adult dose 15–20 mg/kg) and is receiving the usual oral daily maintenance dose.[15] Monitoring parameters include a serum sodium concentration to rule out a hyponatremia-induced seizure. Because phenytoin is 90% protein bound, a serum albumin concentration should be drawn. In patients with hypoalbuminemia or renal impairment, free (unbound) phenytoin levels should be monitored. A serum phenytoin concentration at discharge to determine whether the desired therapeutic serum concentration has been achieved is also recommended. A follow-up, steady state serum phenytoin concentration should be obtained in 10 to 14 days to evaluate the current dose and to determine whether dose adjustments are needed. The serum phenytoin concentration should be monitored periodically thereafter and whenever an adverse drug reaction or seizure occurs.

CASE 107-1, QUESTION 3: M.G. returns for a follow-up appointment 2 weeks later after having labs drawn. Serum albumin concentration is 2.2 g/dL, sodium 140 mEq/L, and serum phenytoin 15 mcg/mL. M.G. complains of drowsiness and has a wide-based, unsteady gait. What is the most likely cause of her symptoms?

Although the serum phenytoin is within the therapeutic range (10–20 mcg/mL), phenytoin is highly protein bound, and in the presence of low albumin, free phenytoin concentrations could be higher. A corrected phenytoin level can be calculated using an equation:

$$\text{Total Phenytoin Concentration} = \text{Total Phenytoin measured}/[(0.2 \times \text{serum albumin g/dL}) + 0.1] \qquad \text{(Eq. 107-1)}$$

This would produce an equivalent phenytoin concentration of 27 mcg/mL, explaining M.G.'s symptoms (assuming her serum phenytoin concentration is at steady state). In M.G.'s case, free phenytoin (unbound phenytoin) concentration monitoring would be appropriate, if available, and her dosage should be adjusted accordingly.[15,16]

Metabolism

M.G.'s phenytoin metabolism may be affected by factors known to influence hepatic drug metabolism, which include disease states, concurrent drug use, nutritional status, environmental compounds, genetic differences, sex, liver mass, and blood flow. Liver mass decreases by approximately 20% to 30% with age, and hepatic blood flow decreases by approximately 20% to 50%.[7,12] Compounds undergoing phase I metabolism (reduction, oxidation, hydroxylation, demethylation) have a decreased or unchanged clearance, whereas compounds metabolized by phase II processes (conjugation, acetylation, sulfonation, glucuronidation) have no change in clearance with age.[7] Drugs with high hepatic-extraction ratios, such as the nitrates, barbiturates, lidocaine, and propranolol, may have reduced hepatic metabolism in older adults.[17]

Excretion

In older adults, changes in aging kidneys include a decrease in renal mass by 20% to 30%, decrease in renal blood flow, and decrease in tubular secretion.[18] Increases in sclerotic glomeruli and decreases in functioning glomeruli may contribute to a decline in glomerular filtration rate (GFR).[18] After age 30, GFR is estimated to decline 8 mL/minute every 10 years, although not all older adults have decreased renal function.[12]

The plasma half-life is prolonged for a number of renally excreted drugs in "healthy" older adults, and the highest-risk drugs are those that depend entirely on the kidney for elimination. Examples of these are listed in Table 107-2.

GFR is the most prevalent measurement that is used to evaluate overall renal function and to diagnose kidney disease, using markers that are renally excreted such as creatinine.[19] These markers are measured by collecting urine over a 6- to 24-hour period and drawing blood before or after. Because timed urine and serum collections may not always be possible or accurate in older adults due to inconvenience, or incomplete collection in those with incontinence, several equations are used to estimate creatinine clearance.[20] Whereas GFR is used to diagnose and stage kidney disease, equations that estimate creatinine clearance are used to guide practitioners in drug dosing. The Cockcroft–Gault equation is commonly used for most drug dosing; however, controversies exist with regard to using actual or ideal weight, and using correction factors in the calculation. The use of lean body weight in the equation may reflect serum creatinine (SCr) production more accurately because creatinine is produced in muscle mass, which is decreased in older patients. The Cockcroft–Gault equation depends on SCr concentration and tubular secretion of creatinine, which may result in an overestimation of renal function in obese patients.

CASE 107-1, QUESTION 4: For renally cleared drugs that require dosage adjustment for M.G., is the Cockroft–Gault equation an appropriate tool to estimate renal function?

Cockroft and Gault

$$\text{eCrCl} = (140\text{-age}) \times \text{weight in kg} / (72 \times \text{SCr}) \times 0.85 \text{ in females} \qquad \text{Eq. 107-2)}$$

M.G. is 75 years old, weighs 120 lbs or 54.43 kg, and her serum creatinine is 1.9 mg/dL. Using the Cockcroft–Gault equation, her estimated CrCl is 22 mL/minute. The equation was derived from a predominantly male veteran population who had a single measured 24-hour creatinine clearance, and a correction factor of 0.85 is used in female patients.[21]

Table 107-2

Drugs Highly Dependent on Renal Function for Elimination[18,20,a]

Acetazolamide	Duloxetine	Nizatidine
Acyclovir	Edoxaban	Penicillins (most)
Allopurinol	Enalapril	Phenazopyridine
Amantadine	Enoxaparin	Pregabalin
Amiloride	Famotidine	Probenecid
Aminoglycosides	Fluconazole	Procainamide
Amphotericin B	Fluroquinolones (most)	Pyridostigmine

Apixaban	Fondaparinux	Ranitidine
Atenolol	Furosemide	Rivaroxaban
Aztreonam	Gabapentin	Spironolactone
Captopril	Imipenem	Sulfamethoxazole
Cephalosporins (most)	Levetiracetam	Thiazides
Clonidine	Lisinopril	Tramadol
Cimetidine	Lithium	Trimethoprim
Colchicine	Methotrexate	Triamterene
Dabigatran	Metoclopramide	Vancomycin
Digoxin	Nadolol	

[a]This list does not include all drugs highly dependent on renal function for elimination.

Adapted from American Geriatrics Society 2015 Updated Beers Criteria for Potentially Inappropriate Medication Use in Older Adults. J Am Geriatr Soc. 2015;63:2227–2246 and Arnoff GR et al., eds. Drug Prescribing in Renal Failure: Dosing Guidelines for Adults. 5th ed. Philadelphia, PA: American College of Physicians; 2007.

M.G. is not underweight or obese, so the Cockroft-Gault equation is an appropriate tool to estimate creatinine clearance for drug dosing and remains the most common method to determine dosing of renally cleared drugs. Other assessments of renal function, including urine output, should be considered when assessing drug dosage adjustments in older individuals such as M.G., along with close monitoring for adverse drug reactions.

Table 107-3 provides a composite picture of the age-related physiologic changes, disease states, and pharmacologic factors that affect pharmacokinetic processes in older adults.

PHARMACODYNAMIC CHANGES

Pharmacodynamics refers to the effect of a medication at its receptor site, or site of action, and is largely determined by drug concentration and its ability to bind at the receptor site.[22] Aging can affect the number of receptors available and their affinity to medications. Together, comorbidities, pharmacokinetic changes, and pharmacodynamic changes make an individual drug response in an older adult largely unpredictable. Because older persons can be sensitive to the effects of medication, care should be taken to avoid unwanted adverse effects when starting or stopping medications.

The ability to preserve homeostasis decreases with aging, which results in a decrease in functional reserve and a decreased ability to respond in times of physiologic stress.[23] Cardiovascular changes during aging along with an impaired baroreceptor response increase the prevalence of orthostatic hypotension in the elderly population.[23,24] Prevalence ranges from 6% in middle age to 30% or greater in patients 70 years of age or older.[25] Orthostatic hypotension is often aggravated by drugs with sympatholytic activity (e.g., α-adrenergic blocking agents, phenothiazines, tricyclic antidepressants [TCAs]), volume-depleting drugs (e.g., diuretics), and vasodilating agents (e.g., nitrates, alcohol).[24,26] In a study of 100 geriatric psychiatric outpatients, almost 40% complained of dizziness and falling, which were attributed to psychotropic medications.[27] Patients with impaired cardiac output and taking concurrent diuretic therapy are especially vulnerable.[24] Changes in gait and balance are common in the older adult population.[28]

p. 2220

Table 107-3

Changes Affecting Pharmacokinetic Parameters

Parameter	Physiologic Changes	Disease States	Pharmacologic Factors
Absorption (bioavailability, first-pass metabolism)	Gastric pH Absorptive surface Splanchnic blood flow GI motility Gastric emptying rate	Achlorhydria, diarrhea, gastrectomy, malabsorptive syndromes, pancreatitis	Drug interactions, antacids, anticholinergics, cholestyramine, food
Distribution	Cardiac output TBW Lean body mass Serum albumin α_1-Acid glycoprotein Body fat Altered relative tissue perfusion	HF, dehydration, edema, ascites, hepatic, failure, malnutrition, renal failure	Drug interactions, protein-binding displacement
Metabolism	Hepatic mass Enzyme activity Hepatic blood flow	HF, fever, hepatic failure, malignancy, malnutrition, thyroid disease, viral, infection or immunization	Dietary makeup, drug interactions, insecticides, alcohol, smoking, induction of metabolism, inhibition of metabolism
Excretion	Renal blood flow GFR Tubular secretion Renal mass	Hypovolemia, renal insufficiency	Drug interactions

GFR, glomerular filtration rate; GI, gastrointestinal; HF, heart failure; TBW, total body water.

Table 107-4

Adverse Drug Reactions That May Affect Mobility of the Older Patient

Medication Class	Adverse Drug Reaction
Tricyclic antidepressants (TCAs)	Orthostatic hypotension, tremor, cardiac arrhythmias, sedation
Benzodiazepines and sedative hypnotics	Sedation, weakness, coordination, confusion

Opiate analgesics	Sedation, coordination, confusion
Antipsychotics	Orthostatic hypotension, sedation, extrapyramidal effects
Antihypertensives	Orthostatic hypotension
β-Adrenergic blockers	Ability to respond to workload (dose needed may increase risk)

Certain medications or classes of medications, such as antiarrhythmics, diuretics, digoxin, narcotics, anticonvulsants, psychotropics, and antidepressants, can lead to gait disturbances and contribute to drug-induced falls in older adults. Table 107-4 reviews the therapeutic agents commonly associated with adverse drug reactions that may affect the mobility of older patients.

Blood–Brain Barrier

The function and integrity of the interface between the brain and the body, the blood–brain barrier, may decline as a result of aging, disease, or ischemic injury.[29] An exaggerated response and increased sensitivity to some drugs that effect the central nervous system (CNS) may be seen as a result of changes in permeability of the blood–brain barrier and changes in receptor sensitivity in older adults.[30] Normal aging involves a reduction in cerebral blood flow and oxygen consumption, and increased cerebrovascular resistance. Drugs with anticholinergic properties are associated with memory loss, confusion, cognitive impairments, and functional decline in older patients.[31] Several examples of therapeutic classes with anticholinergic properties are listed in Table 107-5.

Both central responsiveness and peripheral responsiveness of adrenergic receptors decline with aging.[32] Monoamine-oxidase activity increases with normal aging, and this is reflected by a decline in norepinephrine and dopamine levels in aging brains.[33] The decline in CNS dopamine synthesis is associated with increased sensitivity to dopamine blocking agents (e.g., antipsychotics). However, β-receptor sensitivity to both β-agonists and β-antagonists decreases, even if the number of β-receptors does not decrease in older patients.[34,35] Because these neurologic and biochemical reserves are reduced as a normal consequence of aging, iatrogenic behavioral disorders are relatively common in older adults, and drugs are one of the most common causes of sudden, unexplained mental impairment in the older adult.

PROBLEMS ASSOCIATED WITH DRUG USE IN OLDER ADULTS

Polypharmacy

Over half of all older adults carry three or more chronic diseases. This multimorbidity is associated with increased morbidity, mortality, functional decline, health resource use, and multiple medication use.[36]

Table 107-5

Categories of Anticholinergic Drugs That May Induce Confusion in Older Patients[5,19]

Therapeutic Class	Example
Antimuscarinics	Darifenacin Fesoterodine Flavoxate Oxybutynin Solifenacin Tolterodine Trospium
Antispasmodic	Atropine[a] Clidinium-chlordiazepoxide Dicyclomine Homatropine[a] Propantheline Scopolamine[a]
Antiparkinson	Benztropine Trihexyphenidyl
Antihistamine	Brompheniramine Chlorpheniramine Clemastine Dimenhydrinate Diphenhydramine Doxylamine Hydroxyzine HCL Meclizine
Antidepressant	Amitriptyline Clomipramine Desipramine Doxepin (>6 mg) Imipramine Nortriptyline Paroxetine Trimipramine
Antiarrhythmic	Disopyramide Quinidine
Antipsychotic	Clozapine Olanzapine Quetiapine
Hypnotic	Hydroxyzine Pamoate

Skeletal Muscle Relaxant	Cyclobenzaprine Orphenadrine

This chart does not include all anticholinergic drugs that may cause confusion in older adults.

[a] Does not include ophthalmic.

Adapted from American Geriatrics Society 2015 Updated Beers Criteria for Potentially Inappropriate Medication Use in Older Adults. J Am Geriatr Soc. 2015;63:2227–2246.

Multiple medication use is associated with increased healthcare costs and increased drug-related adverse events in the older population.[37] Polypharmacy exists due to multiple chronic diseases, which often need to be treated with multiple medications. For these reasons, monitoring drug therapy in these patients is not only challenging but imperative. Duplicative prescribing within the same drug class may occur, and unrecognized drug side effects may be treated with additional drugs. Careful medication regimen review is essential to identify potentially unnecessary or inappropriate medications and to systematically taper and discontinue these agents, with attentive monitoring to older adults.[38]

Adverse Drug Events

An adverse drug event includes preventable and nonpreventable events and accounts for errors related to prescribing and administration. The combining of several medications can also increase the risk of clinically significant drug–drug interactions and subsequent adverse drug events in the elderly. Nearly one in 25 community-dwelling older adults is potentially at risk for a major drug–drug interaction.[39] Adverse drug events in general are expected to increase due to the increase in medication use for prevention, medication use for chronic conditions, aging and better access to prescription coverage.[40]

The use of high-risk medications such as anticholinergics, antipsychotics, opiate analgesics, and hypnotics, along with polypharmacy, increases the risk of adverse drug events.[38]

Up to 31% of hospitalizations of older persons involve adverse drug events.[41] Adverse drug events may be underreported and be difficult to detect in older patients because they often present atypically and with nonspecific symptoms, such as lethargy, confusion, lightheadedness, or falls. Nevertheless, most adverse reactions represent extensions of a drug’s pharmacologic effect, have identifiable predictors, and are potentially preventable.[42]

ADVERSE DRUG REACTIONS IN OLDER PATIENTS

CASE 107-2

QUESTION 1: S.E. is an 85-year-old woman and resident of a long-term care facility (LTCF). She is 5′2″ and 102 pounds, with a serum creatinine of 1.6 mg/dL. She is admitted to the hospital for chest pain and shortness of breath, and to rule out myocardial infarction (MI). Her physician is concerned about oversedation with narcotics and prescribes ketorolac 30 mg IV every 6 hours. She has a history of severe HF and angina for which she takes lisinopril 10 mg daily, furosemide 40 mg daily, aspirin 81 mg daily, and isosorbide mononitrate 30 mg daily. The lisinopril dosage is increased to 20 mg daily, and the furosemide dosage is increased to 40 mg twice daily. Her blood pressure (BP) is 110/66 mm Hg, and her urine output has been from 20 to 30 mL/hour for 4 hours since ketorolac was initiated. What risk factors are present in S.E. for drug-induced renal problems?

S.E. has a number of risk factors for the development of drug-induced acute renal failure. Angiotensin-converting enzyme (ACE) inhibitors are indicated for HF management and improve renal function by increasing cardiac output. However, they can diminish efferent arteriole glomerular capillary filtration pressure and precipitate acute renal failure in predisposed patients. The use of ketorolac is another risk factor. A 13% incidence of azotemia has been reported in LTCF residents started on a short course of NSAID treatment.[43] A low serum sodium concentration, high-dose diuretics, diabetes, severe HF (i.e., New York Heart Association [NYHA] class IV), use of a long-acting ACE inhibitor, and concurrent NSAID use are all risk factors for drug-induced acute renal failure (see Chapter 28, Acute Kidney Injury). Elderly patients may be particular susceptible, owing to the renal changes of aging described earlier. Patients with these risk factors should be monitored closely when an ACE inhibitor is initiated and when the dosage of an ACE inhibitor is increased (see Chapter 14, Heart Failure). Renal prostaglandins (PGE_2, PGI_2) increase or help maintain renal blood flow when renal function is compromised by intrinsic renal disease, HF, liver disease with ascites, or hypertension; therefore, the use of a prostaglandin inhibitor such as ketorolac places S.E. at an increased risk for acute renal failure.

The ketorolac dose is excessive for S.E. based on the maximum recommended dose of 60 mg/day for elderly patients.[44]

APPROACH TO APPROPRIATE PRESCRIBING

As a result of high rates of multimorbidity and polypharmacy in older adults, in 2012, the American Geriatrics Society convened an Expert Panel on the Care of Older Adults with Multimorbidity to design a set of Guiding Principles for the Care of Older Adults with Multimorbidity.[36] The five steps include the following: eliciting and incorporating patient preferences and goals of care, recognizing the applicability and limitations of available evidence, framing clinical decisions in terms of prognosis, considering treatment complexity and feasibility, and continually optimizing treatment plans. Effective implementation of these principles is likely to require the input of interprofessional team members and high-quality-care coordination. Pharmacists have an integral role in applying these guiding principles.

DISEASE-SPECIFIC GERIATRIC DRUG THERAPY

Cardiovascular Disease in the Ambulatory Older Patient

CASE 107-3

QUESTION 1: T.M. is a 73-year-old woman who comes to a “brown bag” session at the local senior center. She reports recently feeling “sluggish” and dizzy. She lives at home alone on a modest, fixed retirement income. T.M.’s chronic medical problems include coronary artery disease (CAD), HF, hypertension, diabetes, and hyperlipidemia. She states that different specialists prescribe her “a lot of medications,” but she does not know their names. She admits to skipping her medications periodically when she does not feel well. T.M. usually maintains an active social life, visiting her friends and attending the local seniors’ luncheons. She is interested in natural medicines, and self-medicates with nonprescription medications and herbal remedies that her friends also take. Because of the recent weakness, however, she has not gone out as much. Review of her brown bag reveals the following items: glyburide 2.5 mg twice daily, hydrochlorothiazide 25 mg daily, atenolol 50 mg daily, niacin 500 mg 3 times a day, ASA 325 mg as needed, digoxin 0.25 mg daily, isosorbide dinitrate (ISDN) 20 mg 4 times a day, nitroglycerin (NTG) 0.4 mg sublingual (SL) as needed, captopril 25 mg 3 times a day, furosemide 40 mg twice daily, acetaminophen 500 mg as needed, verapamil 60 mg 4 times a day, multivitamins with minerals, calcium carbonate 500 mg 3 times a day, ibuprofen 200 mg as needed, and pioglitazone 30 mg daily. She also drinks a glass of red wine with dinner. What initial steps are necessary for safe and effective management of T.M.’s drug therapy?

Like many ambulatory older patients who are being treated for multiple chronic medical conditions, T.M. is at high risk for drug-induced problems secondary to nonadherence, medication errors, prescribing from multiple providers, self-medicating, and polypharmacy. She is representative of more than nine million older adults who live at home alone. The isolated community-dwelling older patient is typically female 75 years of age or older, has multiple medical issues, and takes multiple medications.[1] With rising life expectancy, the increased complexity of managing multiple medical conditions has put nonhospitalized elderly individuals at higher risk of experiencing adverse drug reactions and for adverse drug-related admissions.[42,45] Another group of older individuals at higher risk of having adverse drug reactions is those who are recently discharged from the hospital. The postdischarge period is often a time of confusion, and elderly patients may have difficulty coping and sorting out new versus replacement or duplicate drugs. A summary of the various factors contributing to nonadherence in the older patient is presented in Table 107-6.[46]

Table 107-6

Factors Influencing the Inability to Adhere to a Medication Regimen

Low health literacy (understanding of medication instructions and importance)
Medication cost
Significant cognitive or physical impairment (e.g., memory, hearing, vision)
Inconsistent filling or refilling of prescriptions

Adverse effects
Lack of clinical evidence of effectiveness

Adapted From Bosworth HB et al. Medication adherence: a call for action. Am Heart J. 2011;162(3):412–424. doi:10.1016/j.ahj.2011.06.007.

CASE 107-3, QUESTION 2: T.M. presents to the multidisciplinary geriatric care team on the advice of pharmacists at the brown bag session. During the intake interview, she admits to selective adherence with many medications based on how they make her feel and their costs. Her wine intake with dinner is 8 to 12 ounces most days of the week. She also has not taken her furosemide and potassium supplement because she feels that they are contributing to her sluggishness and dizziness. T.M.'s medical history and physical examination are as follows: 73-year-old white woman, 5′6″, 189 pounds; vital signs are as follows: BP, 168/82 mm Hg; heart rate (HR), 54 beats/minute; temperature, 98.7°F; and respiratory rate, 18 breaths/minute. Pertinent laboratory values are as follows:

Serum creatinine, 1.5 mg/dL
Blood urea nitrogen, 35 mg/dL
Sodium, 153 mEq/L
Potassium, 3.1 mEq/L
Magnesium, 1.5 mEq/L
Glucose, 250 mg/dL
Glycosylated hemoglobin (Hgb A_{1c}), 9.5%
Total cholesterol, 259 mg/dL
Low-density lipoprotein, 140 mg/dL
High-density lipoprotein, 40 mg/dL
Triglycerides, 200 mg/dL
Urine dipstick 2+ protein
Digoxin level, 1.5 ng/mL

Electrocardiogram showed sinus bradycardia with an old anterior MI. Echocardiogram showed an ejection fraction (EF) of 25%. Her problem list includes new-onset sluggishness and fainting, chest pain and shortness of breath (SOB) on exertion, 3(+) pitting edema bilaterally, NYHA class II–III HF, hypertension, type 2 diabetes, obesity, excessive alcohol intake, CAD, and hyperlipidemia. What factors may be contributing to T.M.'s feeling of sluggishness and dizziness?

T.M. needs a primary-care provider to coordinate her medical care and to evaluate the new-onset sluggishness and dizziness. She should also be advised to establish a client–patient relationship at a specific pharmacy for all her medications to be on one profile for continuous assessment. Furthermore, T.M. should be counseled to discontinue alcohol, which can interact with several of her current medications and worsen her conditions. Finally, assessment of the risk for medication-related problems (MRPs) is highly recommended.[47]

T.M.'s sluggishness and dizziness are most likely caused by her low heart rate, somewhat dehydrated state, and multiple

medications that have the potential for producing weakness. Specifically, digoxin 0.25 mg daily is considered a high dose; patients over age 70 should be limited to

0.125 mg daily as initial therapy to limit the development of toxicities from reduced renal clearance. A level of 1.5 ng/mL is excessive because the therapeutic range is from 0.5 to 0.9 ng/mL for HF; therefore, the digoxin dose should be lowered to 0.125 mg daily.[48]

If HF is controlled, one can try discontinuing digoxin to evaluate the continued necessity of this agent. Finally, atenolol and verapamil can both lower the heart rate and contribute further to the sluggishness. Switching atenolol to an extended-release β-blocker indicated for heart failure may help. Verapamil can be discontinued because it may not have benefits for T.M. other than for hypertension and may contribute to a worsening of her HF.

HEART FAILURE

CASE 107-3, QUESTION 3: What is appropriate management for T.M.'s stage of HF?

On the basis of T.M.'s history of an old MI evidencing structural heart disease, her low EF, and the presence of fluid-retention symptoms, T.M. is in stage C HF based upon the American College of Cardiology/American Heart Association classification scheme (see Chapter 14, Heart Failure). Heart failure is a common cause of morbidity and mortality in older patients. The standard therapy for HF with reduced ejection fraction typically consists of ACE inhibitors or ARBs, and β-blockers. In symptomatic patients, diuretics may be used for symptomatic relief, and an aldosterone antagonist for its morbidity and mortality benefits. In selected patients, digoxin or hydralazine/isosorbide may also be appropriate to reduce morbidity and mortality, as well as to prevent hospitalizations. The recommended therapy for T.M. includes an ACE inhibitor, or ARB, a β-blocker, aldosterone antagonist, and diuretic for symptomatic relief. Routine use of multiple medications in the treatment of HF with coexisting medical conditions makes close monitoring of drug therapy essential. Concurrent behavior modification with weight loss and salt restriction will also allow better control of HF.[49]

DIURETICS

CASE 107-3, QUESTION 4: Is the combination of furosemide and hydrochlorothiazide the most appropriate diuretic regimen for T.M.?

Loop diuretics are generally more effective than thiazides in providing symptomatic relief; furosemide is also preferred in T.M. because hydrochlorothiazide is less effective in moderate-to-severe renal compromise (creatinine clearance <30 mL/minute).[50] Furthermore, the combination of furosemide and hydrochlorothiazide (HCTZ) is duplicative in diuretic action and may be excessive. Discontinuing the HCTZ will likely help with T.M.'s hypokalemia and slightly dehydrated state. Regular monitoring of serum creatinine, urea nitrogen, sodium, and potassium is essential while on diuretics. The need for potassium supplementation will depend on the resultant level after T.M. adheres to furosemide while being maintained on an ACE inhibitor. Elderly patients often dislike taking diuretics because of the frequent need to urinate. T.M. may be advised to take furosemide later during the day after she returns from her social engagements.

ACE INHIBITORS AND ANGIOTENSIN RECEPTOR BLOCKERS

CASE 107-3, QUESTION 5: T.M. has been taking captopril 25 mg 3 times a day. Is this an appropriate choice of ACE inhibitor for T.M.?

Blockade of the renin–angiotensin–aldosterone system is essential in the management of HF. However, 3 times daily dosing of captopril is inconvenient and may contribute to poor adherence. Although captopril, enalapril, and lisinopril have all proven efficacious for HF in clinical trials, lisinopril is the only agent of these that may be dosed daily. Alternatively, fosinopril may also be desirable based on its 50% hepatic and 50% renal elimination profile.[51] An ARB may also be appropriate if therapy with an ACEI is not tolerated. Although previous studies have supported the addition of an ARB to ACE inhibitor therapy based on a lower mortality and hospitalization rate compared with an ACE inhibitor alone,[52] more recent data present concerns about the use of combination therapy, particularly in the elderly, owing to higher risk of hyperkalemia and worsening renal function.[53]

β-BLOCKERS

CASE 107-3, QUESTION 6: T.M. is being treated with atenolol 50 mg daily. Is this an appropriate choice of β-blocker for T.M.?

The β-blockers carvedilol, metoprolol, and bisoprolol have been proven to reduce morbidity and mortality in patients with HF.[54–56] In T.M.'s case, atenolol is not clinically indicated for HF and should be discontinued. Additionally, it is renally cleared and may contribute to excessive sluggishness in an elderly patient with compromised kidney function. Although any of the proven agents would be appropriate, extended-release versions of carvedilol or metoprolol may reduce T.M.'s medication burden.

CARDIOVASCULAR DISEASE AND HYPERLIPIDEMIA

CASE 107-3, QUESTION 7: T.M. does not take her niacin because she experienced unbearable facial flushing. Despite her history of MI, she does not believe that cholesterol and "heart disease" are major health concerns for a woman. Are women older than age 65 at different risk of death owing to coronary heart disease (CHD) compared with their male counterparts, and is it important to manage cholesterol in an elderly woman with CHD?

More than 60% of cardiovascular disease (CVD) deaths occur in people aged 75 or older. Approximately 70% of older adults aged 60 to 79 have CVD.[57] For those over age 80, 83.0% of men and 87.1% of women have CVD.[57] Although male sex is an independent risk factor for CVD, more women than men die from heart attacks because these events occur in women at an older age. The significantly higher rate of hypercholesterolemia in women seems also to predict a higher CVD risk than for men later in life. Therefore, it is important to treat dyslipidemia in most patients with clinical ASCVD, in those aged 40 to 75 with diabetes who have LDL-C levels of 70 to 189 mg/dL, and in those without diabetes and an estimated 10-year ASCVD risk >/=7.5%.[58]

CASE 107-3, QUESTION 8: What is an optimal therapeutic plan for management of T.M.'s hyperlipidemia?

T.M. is a 73-year-old female with history of diabetes, elevated cholesterol and blood pressure conferring a 10-year ASCVD risk greater than 7.5%.[58] T.M.'s treatment plan should begin with lifestyle and dietary modifications. Based on her high ASCVD risk level and concomitant diabetes, a high intensity statin should be started to lower LDL by at least 50%. However, the relative benefits of statin therapy should be weighed against the potential risk of adverse reactions. Liver transaminases should be monitored on a regular basis. Although rare, elderly patients, particularly the frail elderly with low body mass, may be at increased risk for muscle-related side effects. The hydrophilic statins pravastatin,

---

rosuvastatin, and pitavastatin are not metabolized significantly by the cytochrome P-450 system and may present fewer side effects and lower potential of drug interactions.[59] Both atorvastatin and rosuvastatin may be given at any time of day, owing to their longer half-lives. Additionally, atorvastatin is less effected by renal impairment and may be preferred in T.M.[60]

Clinical guidance for the care of adults over age 74 with hyperlipidemia is limited by lack of clinical trial data. Current guidelines recommend for the continuation of currently tolerated statins as patients age.[58] If new statin initiation is required after age 74, a careful assessment of risk versus benefit is warranted, and guidelines recommend for consideration of moderate-intensity statins in patients who would otherwise be candidates for high-intensity therapy. Medical conditions, such as presence of high cardiovascular risk or vascular dementia, functional status, and overall prognosis, may be helpful determinants in these cases.

At this time, there are insufficient data for guidelines to support combination therapy. If combination therapy is indicated, ezetimibe can be added to further reduce the levels of LDL and reduce cardiovascular outcomes without escalating the dose and potential side effects of a statin as shown in the IMPROVE-IT trial.[61] Combination of a statin with niacin is less preferred. Results from the AIM-HIGH trial found no added clinical benefit despite improvements in lipid profile and a possible increase in stroke risk and adverse drug events.[62] Additionally, intolerable side effects of flushing and risk for myopathy and hyperglycemia may limit use. The addition of fibrates to statins has become controversial in patients with diabetes, as shown recently in the ACCORD lipid trial. The addition of fenofibrate to simvastatin in patients with diabetes did not reduce the rate of fatal CHD events, nonfatal MI, or nonfatal stroke compared with those who received only simvastatin.[63] Finally, because alcohol can increase triglycerides as much as 50%, abstinence is strongly recommended.[64]

CASE 107-3, QUESTION 9: What other interventions should be implemented to optimize management of T.M.'s CAD?

Any strategy to optimize T.M.'s CAD management should take into consideration the patient's functional status, comorbidities, and risks versus benefits. T.M. is still experiencing anginal pain on her current regimen, possibly caused by more advanced disease or inability to adhere to the 4-times-daily regimen of ISDN. She should be evaluated for coronary vessel disease and appropriate antiplatelet therapy initiated if necessary. A once-daily long-acting nitrate preparation (isosorbide mononitrate [ISMN]) may be better suited for her, with sublingual NTG available as needed. T.M. should be maintained on first-line CAD therapy of aspirin and β-blockers because aspirin is indicated for MI prevention and β-blockers may also be beneficial for HF. To prevent further endothelial injury from the atherosclerosis that leads to plaque rupture, statins are indicated as described previously. ACE inhibitors have been shown to reduce mortality and to provide secondary prevention in CAD, particularly among those 65 years or older. These agents should be part of the regimen because ACE inhibitors also have benefits for T.M.'s HF and HTN, as well as diabetic nephropathy.[65] Although calcium-channel blockers are indicated in CAD, they have not been proven beneficial for HF; therefore, verapamil may be held at this time whereas the other agents are being optimized.

HYPERTENSION

CASE 107-3, QUESTION 10: T.M. has uncontrolled hypertension. How should this be managed in light of her advanced age?

Despite her advancing age, T.M.'s blood pressure is well above the goal of less than 140/90 mm Hg for diabetic patients as set forth by the American Diabetes Association (ADA) and the 2014 Evidence-Based Guideline for the Management of High Blood Pressure in Adults: Report From the Panel Members Appointed to the Eighth Joint National Committee (JNC 8).[65,66] (see Chapter 9, Essential Hypertension.) Hypertension is present in more than two-thirds of individuals older than 65 years of age. Despite having the highest prevalence of hypertension, only a small percentage of this population is controlled or adequately treated for their blood pressure.[67] In patients greater than 60 years of age without diabetes or CKD, a blood pressure goal of <150/90 is appropriate. The HYVET study has shown that a mean reduction of blood pressure from a baseline of 173/91 mm Hg by 15/6 mm Hg in patients 80 years or older resulted in a 30% reduction in stroke, a 39% reduction in rate of death from stroke, a 23% reduction in the rate of death from cardiovascular causes, and a 64% reduction in the rate of heart failure.[68]

Although adequate dosing and combination therapy may be essential in achieving blood pressure control in the elderly population, close monitoring is also necessary to avoid systolic blood pressure (SBP) less than 120 mm Hg based on the recent findings from the ACCORD BP trial. Intensive target of SBP less than 120 mm Hg did not reduce fatal and nonfatal major cardiovascular events but increased the incidence of adverse effects.[69] Serious side effects of aggressive BP lowering include hypotension, bradycardia, hypokalemia, and elevated SCr, and these effects must be diligently monitored. For T.M., it is recommended that adequate doses of furosemide and an ACE inhibitor or ARB with close monitoring be the main therapeutic approach for her HTN. Extended- or controlled-release formulations of metoprolol or carvedilol should be considered as it has for HF management. Though beneficial for CAD and HTN, verapamil in sustained-release formulation should not be used based on T.M.'s unstable HF.[49]

Diabetes in the Elderly

CASE 107-3, QUESTION 11: T.M. reports that she frequently feels lightheaded and shaky after she takes the glyburide. She admits to not taking glyburide regularly because it also causes rapid heartbeats. What is an optimal therapeutic plan for the management of T.M.'s diabetes?

Comprehensive diabetes education needs to be initiated, stressing the importance of weight loss, self-monitoring of blood glucose, alcohol abstinence, and medication adherence. A 5% to 10% weight loss will improve T.M.'s glucose control and cardiovascular status.[66] T.M.'s alcohol consumption and self-reported erratic meal schedule may be contributing to the hypoglycemia (in addition to the glyburide), as well as to the worsening of her hypertension and HF. The daily recommended allowance of alcohol is no more than two drinks (24 ounces of beer, 10 ounces of wine, or 3 ounces of 80-proof liquor) for men and no more than one drink for women.[70] Glyburide is also a long-acting sulfonylurea and is associated with severe hypoglycemia more commonly than other sulfonylureas because of its active metabolites and highly renal elimination. In general, the elderly are more susceptible, even at low doses, to hypoglycemia and may have difficulty recognizing the symptoms of hypoglycemia. Among the second-generation sulfonylureas, glipizide or glimepiride is preferred in renal impairment. Meglitinides, such as repaglinide or nateglinide, may be preferred over the sulfonylureas in the elderly population because they do not require dose adjustment in renal compromise and also allow for a more flexible meal pattern. These agents, however, require multiple daily dosing and may still contribute to hypoglycemic risk. Any new diabetes medication should be initiated in low doses and gradually titrated upward to avoid hypoglycemic episodes and to achieve glycemic goals in accordance with ADA guidelines.[66]

The current treatment algorithm for diabetes states that metformin with lifestyle modification is the initial management approach.[71] Per FDA labeling, metformin is contraindicated in T.M. because of a serum creatinine greater than 1.4 mg/dL; however, the American Diabetes Association and European Association for the Study of Diabetes reports that metformin seems safe unless eGFR falls to <30 mL/minute. As such, consideration of dosage reductions when renal function begins to decline below 45 mL/minute may be appropriate.[72] When metformin is contraindicated or inadequate, the effective and affordable sulfonylureas or pioglitazone may be added; caution for risks of side effects such as hypoglycemia should be exercised. Pioglitazone should be avoided in T.M. owing to her history of HF. Injections such as GLP-1 analogs are often reserved unless a patient's Hgb A_{1c} remains above 8% while adhering to an appropriately titrated oral combination regimen. Basal insulin can be added if A_{1c} is significantly elevated at baseline, or if patients fail to achieve glycemic goals. More expensive and less effective A_{1c}-lowering alternatives may include dipeptidyl peptidase-4 (DPP4) inhibitors and sodium glucose cotransport 2 (SGLT2) inhibitors. DPP4 inhibitors do not promote hypoglycemia and may be considered early on during the disease state. Their dosages, however, need to be adjusted if the creatinine clearance is less than 50 mL/minutes.[73] In general, the priority of diabetes management in the elderly population should be on reduction of cardiovascular risks with strict control of blood pressure and lipids in addition to avoidance of hypoglycemic events. Hgb A_{1c} goals in older adults should generally be 7.5% to 8%. In the presence of few comorbidities and good functional status, an Hgb A_{1c} goal between 7% and 7.5% may be appropriate if it can be safely achieved. Higher Hgb A_{1c} targets may be appropriate for some elderly patients who are functionally impaired, cognitively impaired, have complex multimorbidity, end-stage illness, or are prone to hypoglycemia or falls.[66,74] It is recommended that glyburide and pioglitazone be discontinued, and either glipizide or repaglinide in combination with sitagliptin, or basal insulin such as glargine, be initiated for T.M.'s diabetes. Finally, comprehensive screening of diabetic complications should be done routinely to decrease morbidity and mortality.[66]

Depression and the Older Patient

Significant depression is the most common mental illness among adults older than 65 years of age, occurring in about 15%; it is a source of significant morbidity and mortality in this population.[75] Unfortunately, depression remains under-recognized and undertreated, even though it is a major risk factor for suicide in the elderly, who have a suicide death rate that is higher than the national average.[76,77] Older patients may be at increased risk for depression because of the high prevalence of comorbid medical conditions (i.e., stroke, cancer, MI, rheumatoid arthritis, dementia, Parkinson's disease, DM).[78] Refer to Chapter 86: Depression for further discussion of risk factors for depression and potential drug-induced causes.

CASE 107-4

QUESTION 1: J.W. is a married, 5′8″, 110-pound, 79-year-old woman who presents for a psychiatric evaluation. Her husband says she just has not been herself lately. The changes in J.W. began on a family vacation 6 months earlier when she got lost on the cruise ship. Since that incident, she has become increasingly anxious and has developed insomnia. Although she does not feel sad or "depressed," she generally does not feel well. J.W.'s normally positive attitude toward life has become pessimistic. Her husband confirms that she has become more forgetful and no longer enjoys eating. In fact, she has lost 18 pounds during the past 2 months. J.W. no longer does her volunteer work at the local children's center. She says she wants to die because she is no longer the person she used to be, but she denies having any specific suicidal thoughts. Her medical history is significant for diabetes and hypertension, which are both well controlled on glipizide 5 mg every morning and hydrochlorothiazide 25 mg daily. Her medical evaluation and physical examination are unremarkable. Laboratory results and head-computed tomography scan are within normal limits. J.W. is diagnosed as having a major depressive episode. What symptoms of depression are present in J.W.?

J.W.'s presenting symptoms are typical of major depression in an older patient, which is commonly quite different from that of younger depressed patients. Criteria set forth in the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, for diagnosing depression were developed using younger subjects and may not be applicable to the older depressed patient.[79] Older patients are less likely to report suicidal thoughts, but are more likely to experience weight loss as a symptom of depression. Anxiety, irritability, somatic complaints, or a withdrawal from normal activities, as exhibited by J.W., may be more significant features in late-life depression than depressed mood. Memory problems, such as J.W.'s forgetfulness, may be attributable to a lack of concentration or effort stemming from her depression. This is distinct from dementia, which manifests itself predominantly with impairment in short- and long-term memory (see Chapter 108, Geriatric Neurocognitive Disorders). Therefore, depressed mood cannot be relied on for determining whether an older patient has a depressive disorder.[76] Table 107-7 lists atypical depressive symptoms that may be found in older adults. The presence of any one of these symptoms should be considered a red flag and should prompt further evaluation for major depression.

CASE 107-4, QUESTION 2: J.W.'s physician decides to prescribe an antidepressant. Which antidepressants are preferred for use in older adults?

Selection of an antidepressant drug for elderly patients must take into consideration age-related changes in pharmacokinetic, pharmacodynamic, and physiologic parameters that make this population more vulnerable to adverse effects. Although the available antidepressants are equally effective, selective serotonin reuptake inhibitors (SSRIs) are better tolerated than older agents, such as the tricyclic antidepressants. Therefore, low-dose SSRIs should be considered first-line therapy for older patients. Of course, this does not preclude the use of sound clinical judgment that incorporates the patient's history of response, comorbidities, and the drug's side effect profile. J.W. should start taking a low-dose SSRI, such as citalopram 10 mg daily, with gradual dose titration to achieve control of her depressive symptoms. Doses of citalopram should not exceed 20 mg per day in adults over age 60 due to risk of QTc prolongation. Table 107-8 lists recommended starting doses for antidepressants in older patients. Full antidepressant response may take twice as long in older patients compared with younger patients; it may take 8 to 12 weeks before assessment of J.W.'s full response can be made.[80]

Table 107-7

Atypical Depressive Symptoms in the Older Adult

Agitation, anxiety, or worrying
Reduced initiative and problem-solving capacities
Alcohol or substance abuse
Paranoia
Obsessions and compulsions
Irritability
Somatic complaints
Excessive guilt
Marital discord
Social withdrawal
Cognitive impairment
Deterioration in self-care

Source: Sable JA et al. Late-life depression: how to identify its symptoms and provide effective treatment. Geriatrics. 2002;57:18.

Table 107-8

Antidepressant Dosing in Older Adults

	Initial Dosage	Maximum Dosage
Citalopram	10 mg every day	20 mg every day
Escitalopram	5 mg every day	10 mg every day

Fluoxetine	5 mg every day	40 mg every day
Fluvoxamine	25 mg at bedtime	200 mg at bedtime
Paroxetine	10 mg every day	40 mg every day
Sertraline	25 mg every day	150 mg every day
Mirtazapine	7.5 mg at bedtime	45 mg at bedtime
Bupropion	37.5 mg twice a day	75 mg twice a day
Duloxetine	20 mg every day	40 mg every day
Venlafaxine	25 mg twice a day	225 mg every day
Desvenlafaxine	50 mg every day	400 mg every day

Asthma and Chronic Obstructive Pulmonary Disease in the Elderly

Epidemiologic studies estimate the prevalence of asthma in the elderly to be approximately 4.5% to 12.7%.[81,82] Although 25% of asthmatics with 65 and older have a history of childhood asthma diagnosed before the age of 20, 27% are diagnosed with asthma after the age of 60.[83] Rates of asthma-related hospitalization and mortality are highest amongst adults over age 65, possibly because of underdiagnosis and undertreatment of the disease.[83] Symptoms of asthma, including wheezing, cough, chest tightness, and dyspnea, are similar in both older and younger patients (see Chapter 18, Asthma). However, because the elderly are more likely to have coexisting medical conditions (e.g., HF, angina, COPD, gastroesophageal reflux disease [GERD]) with symptoms that mimic asthma, accurate diagnosis and assessment of severity is often more difficult.[83]

Chronic obstructive pulmonary disease is largely a disease of older patients with a prevalence of as high as 10% in those 75 and older.[84] This chronic condition is a major cause of morbidity and mortality in the older population, accounting for approximately one-fifth of all U.S. hospitalizations in those over age 65.[85] It is often undiagnosed as it may be mistaken as a “normal” part of the aging process, and may be confounded by physical deconditioning or comorbidities such as HF.[85] Drug therapy for COPD in the elderly does not differ significantly from standard management regimens (see Chapter 19, Chronic Obstructive Pulmonary Disease). However, older patients with pulmonary disease and coexisting medical problems may be more sensitive to the adverse effects of pharmacologic agents.

CASE 107-5

QUESTION 1: J.C., a 67-year-old woman, 5′6″, 145 pounds, presents to the ED complaining of shortness of breath for the past 2 days. She was in her usual state of health until 4 days ago when she exhibited flulike symptoms consisting of fever, cough, and mild wheezing. J.C. has a history of asthma, diabetes, hypertension, headache, and GERD. Her current medications include glipizide 5 mg daily, lisinopril 10 mg daily, metoprolol 50 mg twice daily, lansoprazole 30 mg daily, ibuprofen 200 mg every 6 hours as needed for headache, albuterol metered-dose inhaler (MDI) 2 puffs 4 times a day as needed for SOB, and fluticasone HFA (44 mcg) MDI 2 puffs twice daily. Her drug regimen has been unchanged for the past 2 years, and she reports taking all medications as prescribed. The only recent change has been the need for albuterol every 3 to 4 hours for coughing and wheezing during the past few days. What factors (including medications) may have contributed to her acute asthma exacerbation?

Management of acute asthma exacerbations in previously stable elderly asthmatics should begin with a review of the medication history for asthma-inducing agents. Aspirin and other NSAIDs are known to induce acute bronchoconstriction in adult asthmatics.[86] J.C. should be queried about her previous (especially recent) use of ibuprofen in relation to her asthma symptoms, and these agents should be avoided if associated. An alternative agent for pain control is acetaminophen.[87] Nonselective β-blockers, including topical ophthalmic formulations, can precipitate acute bronchoconstriction and should be avoided in patients with reactive airway disease. Although cardioselective β-blockers are generally considered safe for use in patients with asthma, it is important to recognize that cardioselectivity may be lost with higher dosages. Because J.C. has been taking low-dose metoprolol (a cardioselective agent) for years without problem, this medication is unlikely to be contributing to her current asthma exacerbation. One of the most important triggers for asthma exacerbations is respiratory infection (particularly viral). J.C. reports the recent onset of symptoms consistent with influenza, and this is likely precipitating her current pulmonary symptoms. As a future prophylactic measure, J.C. should be counseled to receive the influenza vaccine annually. J.C. does not recall every receiving the pneumococcal vaccine. In adults aged 65 and older who have never received the pneumococcal vaccine or who are unsure like J.C., they should receive a one-time dose of pneumococcal conjugate vaccine (PCV13), and 12 months later they should receive the pneumococcal polysaccharide vaccine (PPSV23).[88]

CASE 107-5, QUESTION 2: Are the medication regimens used to treat asthma in elderly patients different from those used in children and younger adults? Should J.C.'s maintenance asthma regimen be changed?

Medications used in the management of persistent asthma in the elderly are similar to those used in younger patients and consist of bronchodilators in combination with anti-inflammatory agents (see Chapter 23, Asthma). Drug selection and monitoring may be more complicated in the elderly because of the greater likelihood of coexisting medical conditions and increased potential for drug–disease and drug–drug interactions.

Inhaled β_2-agonists are an important class of drugs used to treat asthma in all age groups. The low incidence of drug interactions and reduced side effect profile make inhaled β_2-agonists ideal for use in the older asthmatics. However, these agents can cause dose-dependent systemic side effects, such as tremor, tachycardia, hypokalemia, and arrhythmias, which are of particular concern in patients with cardiac conditions.[82] Inhaled corticosteroids are the preferred treatment for all forms of persistent asthma yet they may be underused in the elderly. Though generally well tolerated, elderly patients receiving high-dose therapy are at an increased risk for osteoporosis, cataracts, skin thinning, and bruising.[89] In addition to the well-known complications associated with systemic corticosteroid use (see Chapter 44, Rheumatoid Arthritis), these agents can acutely cause confusion, agitation, and hyperglycemia.

J.C. is currently maintained on low doses of an inhaled corticosteroid (fluticasone) in combination with a short-acting β_2-agonist (albuterol), and this is an appropriate regimen for a patient with mild-persistent asthma. Following resolution of her viral infection, J.C.'s asthma control should be re-evaluated within the next 3 months for a step-up or down in therapy. Because J.C. is postmenopausal, she is at risk for osteoporosis; calcium and vitamin D supplementation should be initiated (see Chapter 110, Osteoporosis).

Appropriate use of MDIs is difficult for most patients, but may be particularly problematic in the elderly population because of decreased hand strength or arthritis, difficulty timing actuation to inhalation, or impaired mental function. The use of spacer or holding chamber devices can minimize the coordination necessary for proper use of an MDI and may reduce the incidence of systemic and local (cough, hoarseness, thrush) side effects associated with inhaled corticosteroids. J.C. should be discharged with a spacer device to use with her albuterol and fluticasone MDIs. Even though J.C. previously used an MDI, she should be asked to demonstrate her MDI technique and reinstructed, if necessary, to ensure she is using the inhaler and spacer correctly. If J.C. is unable to correctly use her MDIs with a spacer, use of nebulized solutions, breath-activated inhalers, or dry-powdered delivery devices should be considered.

Infectious Diseases in the Elderly

Infections are among the most common problems in the elderly and are a significant cause of morbidity and mortality. Infections are also one of the most frequent reasons for hospitalization of older ambulatory persons.[90] Antibiotic therapy for an infection in the elderly may be delayed because they may present with atypical signs and symptoms. The older population is also more likely to have polymicrobial infections than younger people, and changes in renal function should be taken into account when selecting, dosing, and monitoring antibiotic therapy.

PNEUMONIA

CASE 107-5, QUESTION 3: J.C. was admitted to the hospital and given intravenous methylprednisolone for 4 days. She was then discharged home with a new prescription for prednisone 40 mg daily for 7 days. Three days after J.C. is discharged from the hospital, she presents again to the ED. This time, she is accompanied by a neighbor who noted that J.C. suddenly became forgetful and confused, and continues to have difficulty breathing. Her neighbor reports that J.C. has been staying in bed for the past 2 days and has not eaten much. J.C. has a low-grade fever, and chest examination reveals faint breath sounds with light crackling rales over her right lung base. A chest radiograph confirms the diagnosis of pneumonia. How is J.C.'s clinical presentation consistent with community-acquired pneumonia in the elderly?

Community-acquired pneumonia is one of the most prevalent causes of hospitalization and death due to infection in adults in the United States.[91] In a large population-based study of community-acquired pneumonia, adults aged 65 to 79 years were found to have an incidence of pneumonia requiring hospitalization that was 9 times as high as those aged 18 to 49, and 25 times as high in those aged 85 and older.

Risk factors for CAP in all adults include age greater than 65, COPD, smoking, alcoholism, aspiration, and chronic medical conditions such as heart, renal, and liver disease.[92,93] Streptococcus pneumoniae is the most common cause of CAP in the elderly.[91]

Respiratory symptoms and fever are often subtle or absent in older patients with pneumonia[93]; instead, like J.C., they may present only with altered mental status (delirium, acute confusion, memory problems) or a decline in functional status. Delirium or acute confusion is a common presentation in elderly patients who may have new-onset lower respiratory infection.

CASE 107-5, QUESTION 4: How should J.C. be treated for her respiratory infection?

In many cases, management of pneumonia in the elderly requires hospitalization because they are at greater risk for mortality and complications. Early empiric antibacterial therapy is particularly important for older patients with pneumonia (see Chapter 67, Respiratory Tract Infections). J.C. should be hospitalized again and treated aggressively for pneumonia with broad-spectrum IV antibiotics. The Infectious Diseases Society of America/American Thoracic Society Consensus Guidelines on the Management of Community-Acquired Pneumonia in Adults recommends treatment of most hospitalized nonintensive care unit (ICU) patients with a respiratory fluoroquinolone (moxifloxacin, gemifloxacin, levofloxacin) or β-lactam plus macrolide, and for ICU patients the recommendation is for a β-lactam plus either azithromycin or a respiratory fluroquinolone.[93]

PREVENTION

CASE 107-5, QUESTION 5: After 7 days of hospitalization, J.C. is discharged home with an oral antibiotic to finish the 14-day course of therapy. What preventative measures are available to J.C. after she is discharged?

Once patients are stable and ready to be discharged home, they should be switched to oral antibiotics to complete their therapy at home.

Both influenza and pneumococcal vaccinations are beneficial and recommended in the prevention of community acquired-pneumonia.[93–95]

The CDC now recommends pneumococcal conjugate vaccine (PCV13) for all adults aged 65 and older who have not previously received it, followed by the pneumococcal polysaccharide vaccine (PPSV23) 12 months later.[96] If the PPSV23 has already been received, the dose of PCV13 should be given at least 1 year after (see Chapter 64, Vaccinations).

J.C.'s immunization status should be confirmed, and as a preventative measure, J.C. should be offered both influenza and pneumococcal vaccines after she is discharged from the hospital.

URINARY TRACT INFECTION

CASE 107-6

QUESTION 1: A.H. is a 72-year-old Hispanic woman who is currently wheelchair-bound because of pain in her right hip. Her granddaughter brings A.H. to the geriatric clinic because she has recently developed urinary incontinence. Her granddaughter reports that A.H. has been feeling weak for the past 2 days and fell while getting out of the wheelchair. A urinalysis indicates the presence of a urinary tract infection (UTI).

Are A.H.'s symptoms typical of urinary tract infections?

Urinary tract infections are common in older patients, and clinical symptoms often vary from patient to patient.[97,98]

Common signs and symptoms may include dysuria, hematuria, urinary frequency, urinary incontinence, pyuria and fever.[98] Bacteriuria is estimated to be asymptomatic in more than 15% of women over age 70 who live in the community, and even greater in men and women who reside in long-term care.[99] Asymptomatic bacteriuria may not always require antibiotic treatment.[97] Impaired voiding with residual urine in older women and obstructive uropathy from prostatic disease in older men predispose them to bacteriuria.[100] The severity of UTI in the older population ranges from mild cystitis to life-threatening urosepsis; both are more difficult to treat because of resistant organisms and age-related decreases in host defenses. The majority of UTIs in the older population do not present typically; instead, there are often nonspecific manifestations such as decline in functional status, cognitive impairment, weakness, falls, and urinary incontinence.[101]

A.H.'s presentation (weakness, urinary incontinence, and a recent fall) is consistent with this pattern. As with most UTIs, those in the elderly are caused primarily by Escherichia coli. However, other species of bacteria such as Klebsiella species, Proteus species, and Enterococcus species are also frequently involved (see Chapter 71, Urinary Tract Infections).

CASE 107-6, QUESTION 2: A.H. is prescribed a 7-day course of ciprofloxacin 250 mg PO twice daily. Is this drug therapy appropriate?

Oral antibiotics, such as nitrofurantoin and sulfamethoxazole-trimethoprim, are appropriate for most patients with symptomatic UTI, reserving fluoroquinolones as alternatives.[102] An important consideration of antibiotic therapy for older adults with UTI is impaired renal function.[103] Nitrofurantoin should not be used in those patients with significantly impaired renal function due to the potential risk of peripheral neuropathy and pulmonary toxicity.

Ciprofloxacin is a reasonable choice for A.H. because E. coli is the most likely causative agent. Fluoroquinolones carry a black box warning due to an increased risk of tendonitis and tendon rupture. Along with renal function, monitoring should include symptoms of tendon inflammation or pain.

Osteoarthritis Pain

Arthritis is the leading cause of functional decline and morbidity in older patients, with prevalence rates up to 30%.[104,105] This immobility may place older patients at risk of confinement to their bed or home. Osteoarthritis, also called degenerative joint disease, is the most common type of joint disease in the older population. Nonpharmacologic management of osteoarthritis, such as physical and occupational therapy, has been shown to decrease pain and improve function in patients with osteoarthritis, both alone or in combination with appropriate analgesics.[106]

CASE 107-7

QUESTION 1: C.W., a 71-year-old retired schoolteacher, has been suffering from osteoarthritis of his hands for 5 years. He is an active older adult who enjoys volunteer work at the local hospital. He presents to the geriatric clinic with increased arthritis pain, which is uncontrolled by his current pain medication. He also complains of increased heartburn and gastric reflux symptoms. His past medical history is significant for diabetes, hypertension, hypercholesterolemia, and GERD. C.W.'s current medications include glipizide 10 mg daily, verapamil sustained-released 240 mg daily, atorvastatin 10 mg daily, famotidine 20 mg twice daily, docusate sodium 100 mg twice daily, and ibuprofen 200 mg 4 times a day as needed. What modifications can be made to his drug regimen to better control his arthritis pain and minimize side effects from his pain medication?

Acetaminophen is the drug of choice for mild-to-moderate arthritis pain (see Chapter 43, Osteoarthritis). Though pain control may be inferior to NSAIDs, its reduced gastrointestinal and renal toxicity provides an advantage in older patients who may be more susceptible to the adverse effects of NSAIDs.[104] Doses greater than 3,000 mg per day should be avoided in the elderly and more conservative dosing utilized for those with a history of alcohol abuse or hepatic impairment.[104,107] If C.W. has not tried acetaminophen in the past for his arthritis pain, acetaminophen 1,000 mg 3 times a day should be initiated. Older patients with osteoarthritis pain often find relief from NSAIDs, which should be used with caution because of their potential GI complications, renal toxicity, and cardiovascular risks. Though not as common as GI toxicity, advanced age is a major risk factor for NSAID-associated renal toxicity, such as sodium and water retention as well as risk for hypertension.[108] Thus, ibuprofen may be contributing to C.W.'s increased GERD symptoms and to his hypertension. Nonacetylated salicylates, such as salsalate, can be used if acetaminophen does not provide adequate pain relief. Compared with NSAIDs, nonacetylated salicylates have less renal and GI toxicity, but cardiovascular risks are unknown. The currently available selective COX-2 inhibitor celecoxib is less likely to cause GI complications than nonselective agents; however, the risk of adverse renal and cardiovascular events persists.[108] A COX-2 inhibitor or the addition of a more potent gastroprotective agent such as a proton-pump inhibitor to ibuprofen is the option for C.W., who may experience reduced GI symptoms with equally effective pain relief. The topical analgesics often require multiple daily applications, assessment of skin integrity, and application technique.[104] The use of glucosamine and chondroitin has been shown to decrease osteoarthritis pain and delay progression of the disease in some studies; however, their place in therapy is controversial.[109] Glucosamine may increase insulin resistance in diabetic patients, and C.W. should be counseled to monitor his blood glucose more closely if initiating this agent.

CASE 107-7, QUESTION 2: C.W. reveals that he has tried acetaminophen without much relief of his pain. He is prescribed celecoxib and tries it for several months, but his pain continues and he is still experiencing GI distress. What other pain medication options does C.W. have?

For moderate-to-severe chronic pain caused by osteoarthritis, a low-dose opiate may provide relief from pain with minimal adverse drug effects (see Chapter 55, Pain Management). Of particular concern in elderly patients are the risks of falls, delirium, and constipation with opioid medication use. Codeine and tramadol are "weak" opioids that have ceiling effects, generally do not provide adequate analgesia, and may carry dangerous side effects in the elderly. Meperidine should also be avoided in older adults because of its high potential for CNS side effects, especially in those with reduced renal function. C.W. is a candidate for opioid therapy. He should be started on the lowest dose of a short-acting formulation on a scheduled regimen and counseled on the adverse drug reactions. Constipation may be a particular problem because he is also taking verapamil, which can also cause significant constipation. The elderly are also at increased risk for constipation as a result of age-related reduced bowel motility. To prevent opioid-associated constipation in C.W., prophylactic laxatives and stool softeners should be started at the initiation of opioid therapy.

LONG-TERM CARE FACILITIES

The LTCF environment is governed in part by the Omnibus Budget Reconciliation Act (OBRA), as well as by numerous other laws and regulations, which are contained in the federal Centers for Medicare and Medicaid Services (CMS) publication, States Operations Manual (SOM).[110] The federal mandates include monthly review of each resident's medication regimen to help ensure each resident's regimen is free from unnecessary drugs and that their medication regimen helps to support their mental, physical, and psychosocial well-being. Medication regimens are reviewed to determine the following:

1. Is each drug clearly indicated?
2. Have therapeutic goals been established for chronic drug therapies?
3. If indicated, is it being dosed and administered appropriately?
4. Are any real or potential problems with drug side effects or interactions present?
5. If antipsychotics are being prescribed, have nonpharmacologic approaches been used first, has their use been justified, and is the therapy being monitored?
6. What specific recommendations can be made to optimize the resident's drug therapy?
7. Are the laboratory results and vital signs being monitored appropriately, and are they available for adequate evaluation of therapy?

The findings of the medication regimen review, including medication discrepancies, errors, and adverse drug reactions, must be documented and reported to the patient's physician who must respond to any recommendations in a timely manner. The American Society of Consultant Pharmacists publishes detailed information concerning standards of practice in the LTCF environment.[111]

CASE 107-8

QUESTION 1: As a new consultant pharmacist to a 60-bed, skilled nursing facility, several multiple-drug-use problems become apparent during initial chart reviews. A typical case is D.M., an 82-year-old man who has resided there for the past month. D.M.'s past medical history is significant for hypertension, depression, constipation, long-standing mild cognitive impairment that is now worsening, and dizziness. In the nurses' notes, it is documented that D.M. had a fall when getting out of bed last week.

At admission, D.M.'s weight was 165 pounds; BP 100/60 mm Hg; pulse 85 beats/minute; and temperature 98.6°F. Subsequent vital signs are not recorded systematically into his medical record. Sporadic documentation in the nurses' notes indicates little change from admission values. No laboratory information is available at this time. D.M. has no known allergies.

Current medications include amlodipine 10 mg daily, diltiazem CD 240 mg daily, hydrochlorothiazide 25 mg daily, quetiapine 300 mg daily, lorazepam 0.5 mg every 8 hours as needed for anxiety, docusate sodium 100 mg twice daily, milk of magnesia 30 mL daily, temazepam 15 mg at bedtime, and acetaminophen one to two 325-mg tablets every 4 to 6 hours as needed for pain. D.M. follows a 2-g sodium diet.

D.M. is ambulatory and takes his meals in the facility's dining room. He is not in any acute distress, but the nurses' notes indicate that D.M. is often confused and complains of dizziness when ambulating. His weight has decreased 4 pounds since being admitted. What should be expected of this LTCF with respect to medication monitoring?

Under the CMS-mandated regulations, the establishment of goals of antihypertensive therapy and monitoring for these goals are required. D.M.'s blood pressure should be measured and documented in his medical record with a signature and date on a regular basis. D.M.'s dizziness, a symptom of orthostatic hypotension, may be caused by overtreatment of his hypertension as evidenced by his low admission blood pressure. Orthostatic hypotension occurs in 10% to 30% of older adults and is most common when patients first arise, indicating that this may have been the cause of D.M.'s recent fall.[25] D.M. is being treated with two calcium-channel blockers. Discontinuation of one of them should reduce his dizziness and help prevent future falls. Because D.M. is being treated with a diuretic, monitoring should include a chemistry panel for electrolyte abnormalities.

CASE 107-8, QUESTION 2: What changes should be made to D.M.'s medication regimen?

In the admission workup, D.M. was described as having a long-standing history of mild cognitive impairment, but subsequent nursing notes suggest that his symptoms of disorientation and confusion worsened quickly after admission. Chronic dementia is not normally characterized by rapid deterioration of mental acuity (see Chapter 108, Geriatric Neurocognitive Disorders). This should raise the suspicion that a reversible factor could be responsible for D.M.'s mental decline. Potentially inappropriate drug use in older adults living in the community and in long-term care is well documented.[112–114] The cognitive impairment of chronic degenerative dementia can be greatly exaggerated by D.M.'s treatment with lorazepam, temazepam, and quetiapine, especially with higher than recommended dosages.[115] Benzodiazepines may also increase the risk of falls and bone fractures in the geriatric population.[116] Antipsychotics are some of the most commonly prescribed drugs in nursing home residents. It is only appropriate to use these agents if the patient's behavior is considered to be a danger to themselves or others (including staff), impairing the patient's daily functioning, interfering with the staff's ability to care for them, or causing distress to the patient (i.e., frightening hallucinations).[110] Antipsychotics may be unnecessarily prescribed for anxiety, insomnia, confusion, or failure to conform to the institution's standards for behavior. Antipsychotic use in older adults with dementia has been shown to be associated with a 1.7-fold increased risk of all-cause mortality compared with nonusers.[117] Primary reasons for death were heart failure, sudden cardiac death, or pneumonia. Federal regulations require that these drugs be used for a specified condition, at the lowest possible dosage, and for the shortest possible duration. Regulations also mandate tapering of doses and careful documentation of all clinical assessments that justify the ongoing need for antipsychotics.[109]

In light of the atypical deterioration of D.M.'s cognitive function, the doses of all psychotropic medications should be gradually tapered down to the lowest effective dose and/or discontinued if appropriate. It may not be appropriate to make multiple changes all at once; however, a plan should be developed to target the medications that are likely responsible for D.M.'s decline in mental status. A baseline assessment of D.M.'s cognitive function and psychiatric status should be performed by a geriatrician, psychiatrist, or clinical psychologist to establish the presence or absence of psychotic behavioral disturbances or depression. If any of these disorders are present, then each should be managed with appropriate nonpharmacologic interventions and drug therapy that includes appropriate therapeutic doses and duration of treatment.

The American Geriatrics Society (AGS) updated the Beers Criteria for Potentially Inappropriate Medication Use in Older Adults in 2015.[118] This evidence-based review outlines medications that may lead to adverse events in older adults. Other helpful tools available include the Screening Tool of Older Persons' potentially inappropriate Prescriptions (STOPP) and Screening Tool to Alert Doctors to Right Treatment (START) criteria.[118] The combined use of these tools along with clinical judgment is meant to guide clinicians in drug selection, to help decrease exposure to medications that may increase the risk of adverse drug events, and to support the safe medication therapy of older adults.

Geriatric Neurocognitive Disorders

Nicole J. Brandt and Bradley R. Williams

CORE PRINCIPLES	CHAPTER CASES
NEUROCOGNITIVE DISORDERS (NCD)	
1 NCD is a syndrome that exhibits multiple cognitive deficits that compromise normal social or occupational function. There are numerous etiologies such as Alzheimer's disease (AD), dementia with Lewy bodies (DLB), and vascular disease, which require a comprehensive evaluation to define a potential diagnosis.	**Case 108-1 (Question 1)**
NCD DUE TO ALZHEIMER'S DISEASE	
1 AD is a chronic, progressive, neurodegenerative disorder that results from neuropathological findings, such as neurofibrillary tangles and β-amyloid plaques that interfere with cholinergic transmission, as well as other neurochemical changes in the brain.	**Case 108-1 (Questions 1–3)**
2 AD has multiple risk factors such as age, family history, Down syndrome, head trauma, hypertension, and mild cognitive impairment, yet the exact etiology is still unknown.	**Case 108-1 (Question 2)**
3 Treatment for AD currently is symptomatic management, not disease altering, and focuses on neurotransmission (e.g., cholinergic system).	**Case 108-1 (Question 4)**
4 Cholinesterase inhibitors may be used as monotherapy or in combination with an N-methyl-D-aspartate antagonist for patients in the moderate to severe stage of AD.	**Case 108-1 (Questions 4–6)**
5 Monitoring for treatment efficacy should focus on cognition, function, and possibly behaviors, whereas treatment toxicity should look for common adverse effects such as gastrointestinal complaints with cholinesterase inhibitors.	**Case 108-1 (Question 5)**
NCD DUE TO LEWY BODY DISEASE	
1 Has similar neuropathology noted with α-synuclein aggregates found in Lewy bodies and neuritis (α-synucleinopathies), which typically present with parkinsonian findings as well as associated symptoms such as falls and visual hallucinations.	**Case 108-2 (Question 1)**
2 Cholinesterase inhibitors have demonstrated symptomatic benefit in patients with Lewy body dementias, yet monitoring for worsening of	**Case 108-2 (Question 2)**

motor symptoms such as tremor is needed.	

VASCULAR NCD

① Vascular dementia is a broad classification of cognitive disorders caused by vascular disease, and notable multiple risk factors include advancing age, diabetes mellitus, small vessel cerebrovascular disease, hypertension, heart disease, hyperlipidemia, cigarette smoking, and alcohol use.	**Case 108-3 (Questions 1, 2)**
② Treatment for vascular dementia strives to control the underlying modifiable risk factors owing to limited efficacy and controversial evidence with cholinesterase inhibitors.	**Case 108-3 (Question 3)**

BEHAVIORAL DISTURBANCES IN DEMENTIA

① When evaluating a dementia patient with behavior disturbances, the first step is to ensure that the problem is not caused by an unrecognized medical problem or adverse effect of a medication.	**Case 108-4 (Question 1),** **Case 108-5 (Question 1)**
② Nonpharmacologic strategies are effective for managing many behavior disturbances and should be attempted before using medications to manage behavior.	**Case 108-4 (Questions 1–4)**
③ Delusions and hallucinations are common behaviors in dementia patients, yet the use of antipsychotics for these symptoms is not approved by the US Food and Drug Administration and has been associated with the increased risk of stroke and mortality in this patient population.	**Case 108-4 (Question 2)**
④ Wandering is a safety concern that often does not respond to pharmacologic intervention; instead, other strategies such as environmental modifications are used.	**Case 108-4 (Question 3)**
⑤ Antidepressants such as selective serotonin reuptake inhibitors have shown promise in addressing depressive symptoms, as well as screaming and irritability.	**Case 108-4 (Question 4)**
⑥ Caregiver support is essential to maintaining a dementia patient safely in his or her home as long as possible.	**Case 108-1 (Questions 3, 5),** **Case 108-4 (Question 5)**

Neurocognitive disorders span a wide range of conditions that exhibit a global decline in cognition. Among the disorders included are delirium, dementia, and several other disorders with various etiologies (e.g., head trauma, HIV, Huntington disease).[1] Among older adults, the dementias are the most commonly encountered diseases and are the focus of this chapter.

GERIATRIC DEMENTIAS

With the continuing growth in the elderly population, the incidence and prevalence of neurocognitive disorders continues to rise.[1,2] Alzheimer’s disease (AD) is the most common cause, and accounts for more than half of all diagnosed cases.[4–6] Vascular dementia (VaD), dementia with Lewy bodies (DLB), and Parkinson’s disease with dementia (PDD) are the next most common dementias, with frontotemporal dementia, pseudodementia, and other forms occurring less often.[5,7] AD is currently the fifth leading cause of death for people age 65 years and older and the sixth leading cause of death for all people in the United States.[3,8]

Incidence and Prevalence

It is estimated that 5.3 million Americans have AD, including approximately 11% of people age 65 years and older and 32% of people age 85 years and older. Of these, more than 3.2 million are women. Prevalence is greater among both African Americans and Hispanics compared with whites.[3] The annual incidence of AD in the United States rises from 53 per 1,000 among people age 65 to 74 years to 170 per 1,000 for those age 75 to 84 years, and to 231 per 1,000 for those at least 85 years of age.[9] Worldwide prevalence has been estimated to be as high as 24.3 million, with 8.4 million new cases annually.[2,10] Projections into the mid-century include a worldwide prevalence of more than 81 million, with cases in undeveloped countries occurring at about three times the rate as in developed countries.[10] In the United States, AD accounts for nearly 70% of cases; VaD accounts for 17.4%, with the remaining 12.6% attributable to DLB, frontotemporal dementia, and other forms.[6] Life expectancy after a diagnosis of AD is reduced by as much as 69% for those diagnosed before age 70 years and by 39% for those diagnosed after age 90 years.[11]

The cost of dementia is staggering. Annual costs for Medicare recipients with dementia average $21,585, compared with $8,191 for those without dementia. For Medicaid recipients with dementia, the annual costs are $11,021, compared with $574 for those without dementia. The annual direct costs, in 2014 dollars, of treating a dementia patient are $47,752 annually, compared with $15,115 for an older adult without dementia. This translates to an estimated annual direct cost for dementia care of $226 billion for the year 2015.[3]

Clinical Diagnosis

Dementia is a neurocognitive disorder that exhibits impaired short- and long-term memory as its most prominent feature. Multiple cognitive deficits that compromise normal social or occupational function must be present before dementia can be diagnosed (Table 108-1).[1] Commonly, forgetfulness is the primary complaint of patients or the first symptom noted by the family.[12] Family members or others may note several symptoms that should prompt a medical evaluation (Table 108-2).[12,13] Memory loss often accompanies several diseases or disorders in elderly individuals. Therefore, a medical history, physical examination, and medication history are essential in excluding systemic illness or medication toxicity as causes of the memory loss (Table 108-3).[13–16] Laboratory and other tests to assist in differentiating dementia from other disorders are listed (Table 108-4). In patients with AD, test results will generally be normal; evidence of cerebrovascular disease is present in patients with VaD.

Brain imaging, such as a computed tomography (CT) scan or magnetic resonance imaging (MRI), can be useful in establishing the presence of a dementia, but neither is diagnostic. A CT scan is useful when a space-occupying lesion, such as a tumor, is suspected as a possible cause. An MRI scan is capable of identifying small infarcts, such as those found in some forms of VaD, and atrophy of subcortical structures such as the brainstem.[15]

Several simple tests, including the Mini-Cognitive Assessment Instrument (Mini-Cog), the Montreal Cognitive Assessment (MoCA), and the St. Louis University Mental Status (SLUMS) exam are appropriate for initial screening of people with suspected cognitive impairment.[17–19] The Folstein Mini-Mental State Exam (MMSE) also can be used; however, it is less sensitive than others for dementia and now is proprietary.[20] These tests rapidly assess multiple domains, typically including orientation, registration, attention and calculation, recall, and language. Patients with dementia exhibit deficits in multiple areas. Those who score below the normal range on the MMSE or other screens, or who exhibit symptoms characteristic of dementia receive further testing. A somewhat more detailed screen, the Cognitive Abilities Screening Instrument (CASI), provides quantitative assessment on attention, concentration, orientation, short-term memory, long-term memory, language abilities, visual construction, list-generating fluency, abstraction, and judgment.[21] All screening tests are subject to limitations. Therefore, additional psychometric testing is often ordered to further establish the presence and type of dementia.[2,22]

Dementias may be classified as cortical or subcortical, according to the areas of the brain preferentially affected by the disorder. AD, a typical cortical dementia, disrupts the cerebral cortex. Patients with cortical dementias display impaired language rather than impaired speech, a learning deficit (amnesia), reduced higher cortical functions (e.g., inability to perform calculations, poor judgment), and an unconcerned or disinhibited affect. Subcortical dementias such as PDD primarily affect the basal ganglia, thalamus, and brainstem. Deficits include abnormal motor function, disrupted speech patterns rather than language difficulties, forgetfulness (impaired recall), slowed cognitive function, and an apathetic or depressed affect.[16]

Table 108-1

Differentiating Neurocognitive Disorders

Mild (formerly Mild Cognitive Impairment)	**Major (formerly Dementia)**
Neurocognitive Disorder (NCD)	
Modest cognitive decline from previous (baseline) performance in at least one cognitive domain, including: ■ Learning and memory ■ Complex attention ■ Executive function ■ Language ■ Perception and motor ■ Social cognition The deficits do not impair the capacity to be independent in everyday activities The cognitive symptoms do not occur exclusively during a period of delirium The cognitive deficits are not better explained by depression, schizophrenia or other mental disorders	Significant cognitive decline from previous (baseline) performance in at least one cognitive domain, including: ■ Learning and memory ■ Complex attention ■ Executive function ■ Language ■ Perception and motor ■ Social cognition The deficits impair the capacity to be independent in everyday activities The cognitive symptoms do not occur exclusively during a period of delirium The cognitive deficits are not better explained by depression, schizophrenia or other mental disorders
NCD due to Alzheimer’s Disease	

Criteria for either mild or major NCD are met
Insidious onset and gradual progression of impairment
■ Mild: impairment in one cognitive domain
■ Major: impairment in at least two cognitive domains
Probable Alzheimer’s disease (either of the following must be present)
■ Alzheimer’s disease genetic mutation based on family history or genetic testing
■ All of the following are present:
  ■ Decline in memory and learning plus one other cognitive domain
  ■ Steady and gradual cognitive decline
  ■ No evidence of another condition that is likely to cause cognitive decline
Possible Alzheimer’s disease
■ Lack of an Alzheimer’s disease genetic mutation
■ All of the following are present:
  ■ Decline in memory and learning
  ■ Steady and gradual cognitive decline
  ■ No evidence of another condition that is likely to cause cognitive decline
Cognitive decline is not better explained by cerebrovascular disease or another condition associated with cognitive decline or neurodegeneration	

Vascular NCD

Criteria for either mild or major NCD are met

Clinical presentation is consistent with a vascular cause (either of the following is present)

- Onset of cognitive impairment follows a cerebrovascular event or multiple events
- Prominent decline in complex attention and executive function

History, physical exam and/or neuroimaging indicates cerebrovascular disease as the most likely cause of the cognitive decline

Probable vascular NCD (at least one of the following is present)

- Neuroimaging supports cerebrovascular disease as the cause of the clinical presentation
- The neurocognitive deficit follows at least one cerebrovascular event
- Presence of both clinical and genetic evidence of cerebrovascular disease

Possible vascular NCD

- Clinical criteria are met
- Neuroimaging is not available
- Temporal relationship between the cerebrovascular event(s) and the onset of neurocognitive decline is not established

A systemic disorder or other brain disease do not adequately explain the symptoms

NCD with Lewy Bodies

Criteria for either mild or major NCD are met

The onset is insidious, with gradual progression

A combination of the following core and suggestive diagnostic features are present

- Core features
    - Fluctuating cognition accompanied by variable attentiveness and alertness
    - Recurrent, well-formed and detailed visual hallucinations
    - Onset of Parkinsonian features that are exhibited after the onset of cognitive decline
- Suggestive features
    - Criteria for rapid eye movement (REM) sleep behavior disorder are met
    - Severe sensitivity to neuroleptic agents

Probable NCD with Lewy Bodies (either of the following is present)

- At least two core features
- One or more core features and one suggestive feature

Possible NCD with Lewy Bodies (either of the following is present)

- One core feature
- One or more suggestive features

Cognitive decline is not better explained by cerebrovascular disease or another condition associated with cognitive decline or neurodegeneration

Table 108-2

Symptoms Suggesting Dementia

Symptom	Evidence
Difficulty learning or retaining new information	Repeats questions; difficulty remembering recent conversations, events, etc.; loses items
Unable to handle complex tasks	Cannot complete tasks that require multiple steps (e.g., difficulty following a shopping list)
Impaired reasoning	Difficulty solving everyday problems; inappropriate social behavior
Impaired spatial orientation and abilities	Gets lost in familiar places; difficulty with driving
Language deficits	Problems finding appropriate words (e.g., difficulty with naming common objects)
Behavior changes	Changes in personality; suspiciousness

Adapted from Costa P et al. Recognition and initial assessment of Alzheimer's disease and related dementias. Clinical Practice Guideline No. 19. Rockville, MD: U.S. Department of Health and Human Services, Public Health Service, Agency for Health Care Policy and Research. AHCPR Publication No. 97-0702. November 1996.

Table 108-3

Causes of Dementia Symptoms

Central Nervous System Disorders	Systemic Illness	Medications
Adjustment disorder (e.g., inability to adjust to retirement)	Cardiovascular disease Arrhythmia Heart failure	Anticholinergic agents Anticonvulsants Antidepressants Antihistamines
Amnestic syndrome (e.g., isolated memory impairment) Delirium	Vascular occlusion Deficiency states Vitamin B_{12} Folate Iron	Anti-infectives Antineoplastic agents Antipsychotic agents Cardiovascular agents Antiarrhythmics
Depression Intracranial causes Brain abscess Normal pressure Hydrocephalus Stroke Subdural hematoma Tumor	Infections Metabolic disorders Adrenal Glucose Renal failure Thyroid	Antihypertensives Corticosteroids H_2-receptor antagonists Immunosuppressants Narcotic analgesics Nonsteroidal anti-inflammatory agents Sedative hypnotics and anxiolytics Skeletal muscle relaxants

Table 108-4

Dementia Screening Tests

Test	Rationale for Testing
Complete blood count with sedimentation rate	Anemic anoxia, infection, neoplasms
Metabolic screen	
Serum electrolytes	Hypernatremia, hyponatremia; renal function
Blood urea nitrogen, creatinine	Renal function
Bilirubin	Hepatic dysfunction (e.g., portal systemic encephalopathy, hepatocerebral degeneration)
Thyroid function	Hypothyroidism, hyperthyroidism
Iron, vitamin B_{12}, folate, vitamin D	Deficiency states (vitamin B_{12}, folate neuropathies, vitamin D deficiency), anemias
Stool occult blood	Blood loss, anemia
HIV and RPR	Infection
Urinalysis	Infection, proteinuria
Chest roentgenogram	Neoplasms, infection, airway disease (anoxia)
Electrocardiogram	Cardiac disease (stagnant anoxia)
Brain scan	Cerebral tumors, cerebrovascular disease
Mental status testing	General cognitive screen
Depression testing	Depression, pseudodementia

ALZHEIMER'S DISEASE

Etiology

A definitive cause for AD has yet to be determined. Several risk factors, however, have been identified. Advancing age is the primary risk factor for AD; other risks include family history, head trauma, metabolic syndrome, diabetes, hypertension and cardiovascular disease.[3,23-27] Genetics plays a significant role in the development of Alzheimer's disease. The high familial occurrence of AD has been linked to autosomal-dominant traits on chromosomes 21, 14, and 1.[28,29] A gene that encodes for amyloid precursor protein (APP), a normal protein, is located on chromosome 21. A defect on chromosome 14 has been identified as the locus for the presenilin-1 gene, which codes for an inherited form of AD. The presenilin-2 gene, located on chromosome 1, also codes for an inherited form. Despite a strong genetic link in some pedigrees, the great majority of AD cases are sporadic.[29,30] The more common sporadic form appears to be linked to a susceptibility gene, apolipoprotein E, which occurs in three isoforms.[29] APP, a normal protein found throughout the body, maps on chromosome 21 and plays a pivotal role in AD neuropathology. Because of overproduction or transcription errors, an abnormal subunit (i.e., β-amyloid) is produced.[29] Mutations on chromosomes 14 (presenilin-1 gene) and 1 (presenilin-2 gene) and the presence of apolipoprotein E4 allele code for alterations in the processing of APP. The abnormal cleavage of APP produces a 42–amino acid form of β-amyloid (Aβ) that demonstrates a higher toxicity than other amyloid forms.[29]

Apolipoprotein E (ApoE), a protein that is involved in cholesterol and phospholipid metabolism, plays a role in the development of sporadic, late-onset AD. The ApoE gene possesses three alleles: E2, E3, and E4. The E3 allele is most common, the E2 allele appears to be protective against AD, and the E4 allele increases the risk for AD.[29] The presence of ApoE-4, the protein coded for by the E4 allele, appears to increase the deposition of Aβ and promote its change to a more pathological configuration.[29] The presence of one or two copies of ApoE4 increases the risk of developing AD twofold or fivefold, respectively.[30] Aβ, which differs from amyloid protein found in other regions of the body, appears to contribute to neuronal death through a combination of apoptosis, a direct toxic effect, and an increased risk for damage owing to oxidative and metabolic stresses.[29,31]

Neuropathology

Although brain atrophy is the most obvious finding among patients with Alzheimer-type dementia, it is not diagnostic for AD or other dementias because some degree of atrophy accompanies normal aging. Atrophic changes induced by AD are found primarily in the temporal, parietal, and frontal areas of the brain; the occipital region, primary motor cortex, and somatosensory areas are generally unaffected (Fig. 108-1).[5,31]

Neuronal changes in the cerebral cortex associated with AD include neurofibrillary tangles, neuritic plaques, amyloid angiopathy, and granulovacuolar degeneration. These changes lead to loss of neurons and synapses (Fig. 108-2).[28] Neurofibrillary tangles (NFTs) are found primarily in the pyramidal regions of the neocortex, hippocampus, and amygdala, but they are also noted in areas of the brainstem and locus coeruleus.[5,31] NFTs are composed of paired helical filaments, combinations of fibrils with a characteristic width and contour, containing a tau protein with an abnormal pattern of phosphate deposition. They are highly immunoreactive and are most likely to form in large pyramidal neurons.

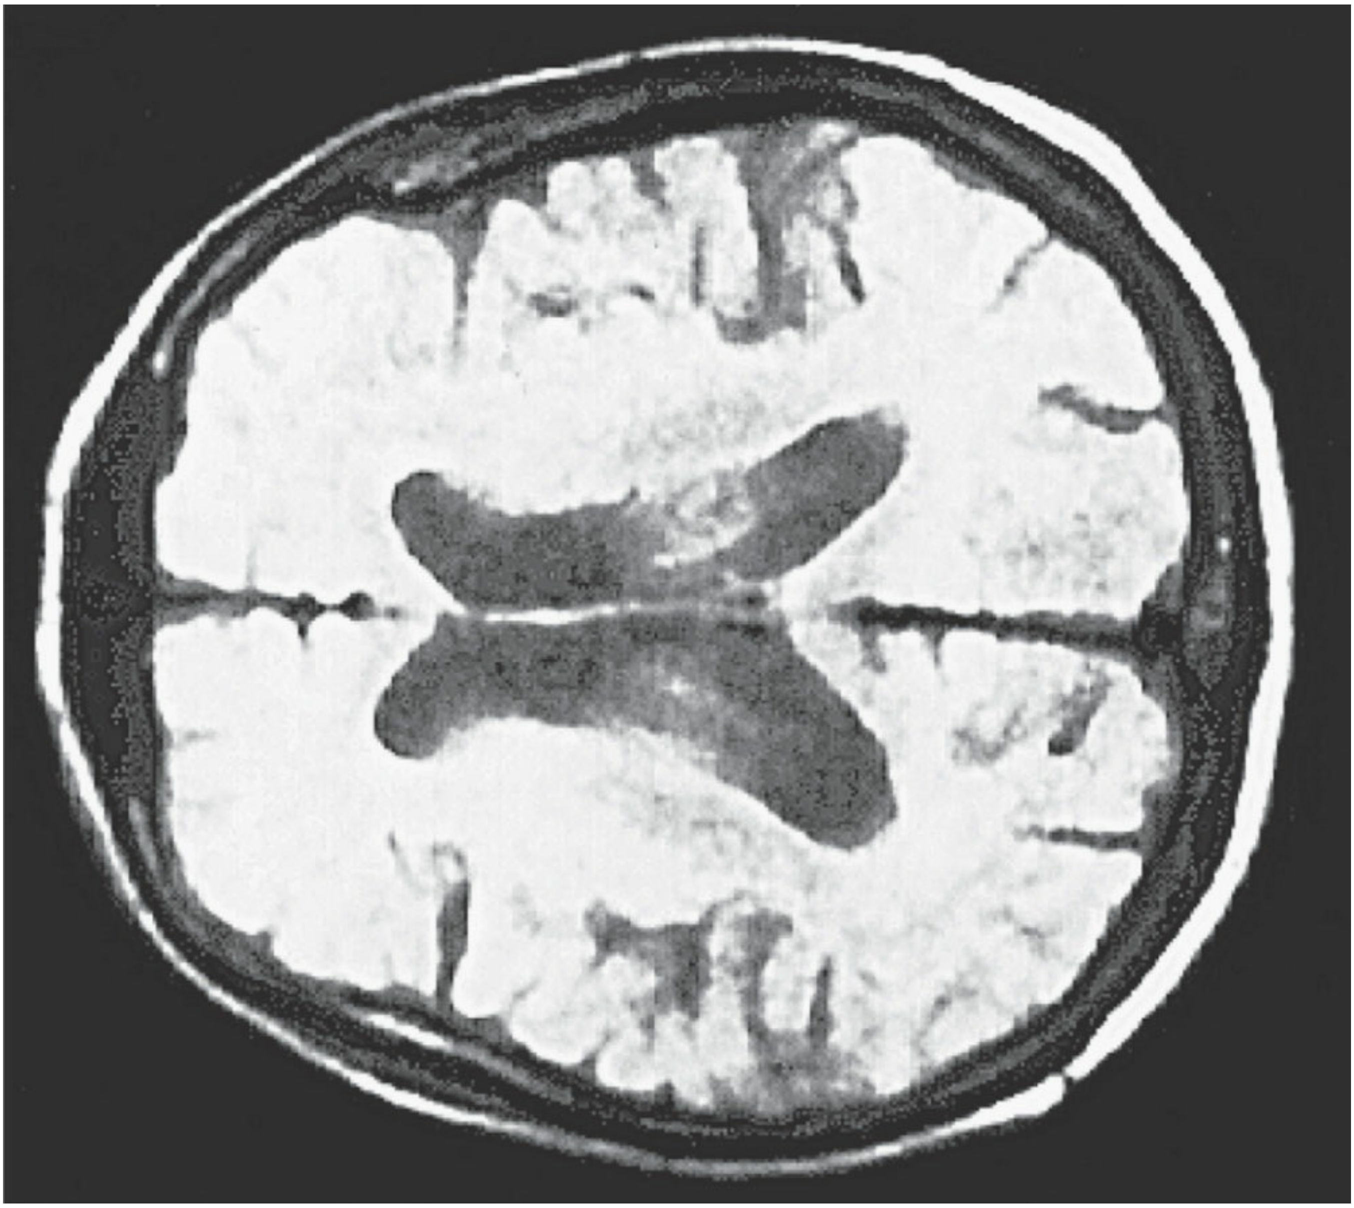

Figure 108-1 Alzheimer disease: magnetic resonance imaging scan. Ventricles are enlarged, and there is generalized atrophy, with greater atrophy present near the temporal areas.

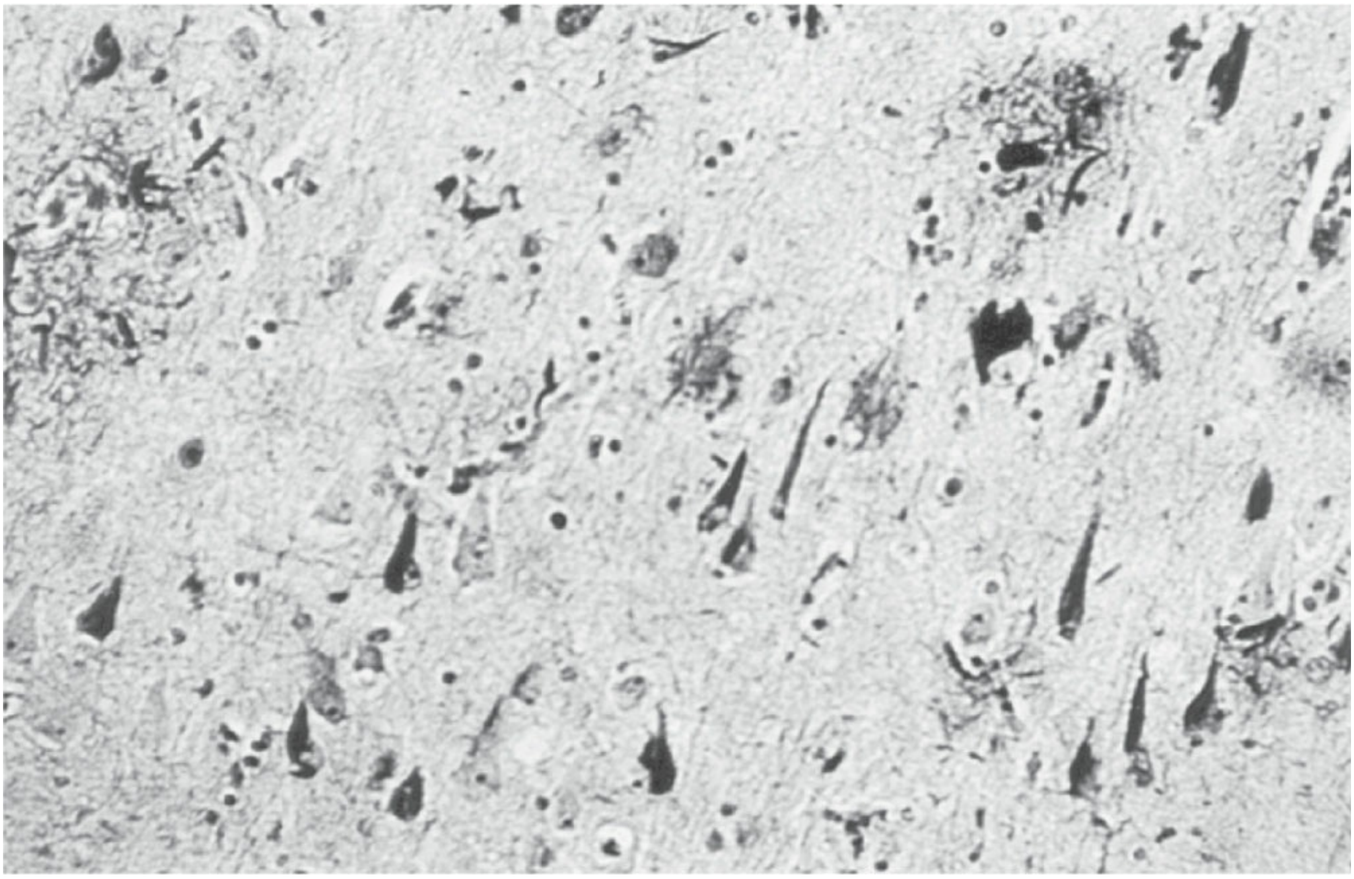

Figure 108-2 Numerous plaques (large, round bodies) and tangles (tear-shaped bodies) are found throughout the cortex in Alzheimer-type dementia.

Neuritic plaques are spherical bodies of tissue composed of granular deposits and remnants of neuronal processes.[5] The typical neuritic plaques of AD are spherical structures that exhibit a three-tiered structure: a central amyloid core, a middle region of swollen axons and dendrites, and an outer zone containing degenerating neuritic processes.[28] Plaques contain APP, which can be cleaved by a defective metabolic process to form Aβ.[29] In addition to Aβ, plaques also contain protein, ApoE, and acute-phase inflammatory proteins such as α_1-chymotrypsin and α_2-macroglobulin.[28] The deposition of amyloid in neuritic plaques correlates with the severity of AD, and the density of cortical plaques is associated with decreased choline acetyltransferase and the severity of cognitive impairment.[5] Aβ has been identified in plaques associated with Down syndrome and in both familial and sporadic forms of dementia of the Alzheimer type.[29] The pathological process of AD development may begin as early as 20 to 30 years before any disease symptoms appear.[5,29,32]

Granulovacuolar degeneration is the other major histologic finding in AD. It consists of clusters of intracytoplasmic vacuoles that contain tiny granules. The vacuoles appear to be specifically located in the pyramidal neurons of the hippocampus.[5,16,28] The loss of cortical neurons that originate in the nucleus basalis and project into the cerebral cortex is the most significant histopathological consequence of AD.[31] Cell loss, granulovacuolar degeneration, and neurons with NFTs are concentrated in this area.[16,28]

Accompanying these changes are decreased concentrations of several neurotransmitters and enzymes. Choline acetyltransferase levels are reduced 60% to 90% in the cortical and hippocampal regions.[28] Acetylcholine and acetylcholinesterase (AChE) are also decreased, whereas muscarinic receptors in the cortex and hippocampus remain at normal levels or are moderately decreased. Nicotinic receptor proteins are also reduced in patients with Alzheimer-type dementia when compared with age-matched controls. Decreased choline acetyltransferase activity has been correlated with plaque density and disease severity. Cortical synapse loss, especially in the midfrontal region, is associated with disease severity.[5,29-31]

Changes affecting AChE have significant implications for the management of AD symptoms. Many isoforms of AChE have been identified; they possess identical amino acid sequences, but display different posttranslational modifications, predominate at diverse anatomical and microanatomical locations, and function in different ways. The predominant form of AChE in the cortical and hippocampal regions of humans is G4, a tetrameric form that is membrane bound. The monomeric form, G1, is found in a much lower concentration. There is a selective loss of the G4 form in patients with AD, allowing the G1 form to assume greater importance.[33] Although cholinergic activity is most significantly affected by Alzheimer-type dementia, other neurochemical systems are also altered. Norepinephrine, serotonin, and γ-aminobutyric acid receptors are affected.[28,29]

Clinical Presentation and Diagnosis

CASE 108-1

QUESTION 1: T.D. is a 72 year old man who is accompanied by his wife for a memory assessment. During the interview, the patient notes that memory issues started about 6 to 12 months ago but recently worsened after he was hospitalized for a fall. The wife notes that he retired at age 70 because he was slowing down and admits that he may have been having some memory issues back then due to his inability to manage the finances even though he was an accountant. Since the fall, which occurred when he was doing work on the house and fell off the ladder and broke his leg, the wife admits he is not quite the same.

T.D.'s medical history is significant for osteoarthritis benign prostatic hyperplasia (BPH) and hypertension. He is currently taking tamsulosin 0.4 mg in the evening for BPH and amlodipine 10 mg daily for HTN, His family history is negative for stroke and positive for heart disease and his father died of a myocardial infarction at age 84. The wife admits that his mother had AD and was diagnosed in her early 70s as well. She died at the age of 76 due to complications with her AD in a nursing home and her husband witnessed her dramatic decline from the AD, which worries him.

Physical examination reveals a pleasant, well-groomed man who is in good health oriented to person and place but not time. His blood pressure (BP) is 120/66 mm Hg supine and 132/72 mm Hg standing, with pulse rates of 56 beats/minute and 62 beats/minute, respectively.

The Folstein MMSE score was 22/30, with errors in orientation, attention, calculation (inability to spell "world" backward), recall, and language (difficulty with word finding). The rest of the physical examination was within normal limits.

What additional evaluation steps should be considered for T.D.?

Before any conclusions can be reached, potentially reversible causes for T.D.'s impaired cognition must be evaluated. Although he displays several trigger symptoms associated with dementia (Table 108-2), including difficulty with managing finances (change especially noted in light that he was an accountant) and word finding issues coupled with memory impairment impacting day to day function.

Several systemic diseases and other disorders can cause cognitive impairment, as shown in Table 108-3. T.D. should undergo a battery of laboratory tests to rule out anemia, cardiac and renal disease, thyroid abnormalities, and tumors. In addition, he should receive thorough neuropsychological testing, including depression screening and more in-depth assessment of his cognitive function. The testing should be conducted by clinicians who are skilled in cognitive assessment, as educational and cultural factors can influence an individual's performance on these tests.[34]

CASE 108-1, QUESTION 2: T.D. is referred by his physician for additional testing. Laboratory tests performed include renal and liver chemistries, thyroid function tests, vitamin B_{12} and folate levels, syphilis and HIV tests, complete blood cell count with sedimentation rate, and urinalysis. All results were normal with the exception of a low B12 level (147 ng/L). Chest radiograph and electrocardiogram were normal. Neurologic examination revealed no deficits. Depression testing revealed a mildly anxious individual who was not depressed just worried about his future.

What is the most probable diagnosis for T.D.?

T.D.'s score of 22/30 on the Folstein MMSE is consistent with mild cognitive impairment or early dementia as evidenced by errors in orientation, calculation, recall, and language.[20] Secondary medical causes of cognitive impairment can be eliminated by T.D.'s generally normal physical examination and laboratory test results. MRI or CT scanning may be useful in many cases to help eliminate brain pathology, such as stroke.[34] A positron emission tomography (PET) scan or a single photon emission computed tomography (SPECT) scan may be useful to help locate specific areas of pathology and assist with a differential diagnosis, but are not required.[35] Secondary psychiatric causes for T.D.'s decline can also be discounted. Although he is sad and anxious, the absence of alterations in appetite or sleep patterns, absence of suicidal thoughts, and the results of psychologic testing indicate T.D. is not depressed. He is fully conscious, alert, and oriented to place and person. He exhibits no psychotic behavior and no evidence of delirium.

T.D.'s slowly progressive decline and its impact on his social and occupational function (forgetting appointments, failing to pay bills), normal physical examination and laboratory findings, and family history meet the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-V) criteria for dementia (Table 108-1). His history and course to date satisfy the criteria for AD and do not indicate a likely alternative explanation for his condition. Thus, T.D. can be classified as probable AD.[36]

CASE 108-1, QUESTION 3: T.D. 's children are very concerned about the family history for dementia. They ask whether there are any tests they should receive at this time to determine their risk. What should they be told?

Although there is a strong genetic association with AD, such instances account for a small minority of cases.[29] There is no apparent family history of Down syndrome. Mutations in the presenilin-1 and presenilin-2 genes are associated with only a small fraction of AD cases.[29] Although several potential biomarkers have been identified, they have not been sufficiently validated to be considered reliable predictors for the development of AD.[3,36,35]

Prognosis

CASE 108-1, QUESTION 4: What is the likely prognosis for T.D.?

AD follows a predictable course that may progress over the course of 10 years or more.[2,10] Two common rating scales for dementia are the Global Deterioration Scale and the Clinical Dementia Rating Scale. According to the Global Deterioration Scale (Table 108-5), T.D.'s impaired social functioning, anxiety, and objective cognitive decline as well as his continued ability to concentrate and perform some complex skills, combined with his preserved affect and social interaction, are consistent with the features of stage three dementia of the Alzheimer type. This stage of AD is generally associated with a period of mild cognitive decline.[38] The more general Clinical Dementia Rating Scale also places T.D. in the category of mild dementia.[39] Clinical diagnoses of AD using clinically appropriate criteria and assessment methods for probable AD have a sensitivity of up to 90% when compared with autopsy-confirmed cases.[1,34,37]

Because of technologic advances, it is possible to diagnose dementia earlier and to keep patients alive into the final stages of the disease.[40] The early diagnosis of AD in T.D. will allow his condition to be followed closely. To ensure the most favorable outcome, T.D. should receive a thorough assessment beyond his dementia. This should include evaluation of his daily function (i.e., ability for self-care), comorbid medical conditions, medications, living arrangements, safety, and potential for abuse and neglect. Attention also should be given to T.D.'s caregivers and support system.[41,42] He should be reassessed every 6 months to both document disease progression and ensure that he is receiving the most appropriate care. At some point, care at home may become unrealistic. At that time, T.D. should be moved into a sheltered environment (e.g., residential-care facility or nursing home) before suffering an injury caused by his poor judgment (e.g., failing to dress properly for the weather, falling). In the later stages, interventions ranging from tube feedings to life support may prolong life, yet prove to be controversial.[43] Death in the late stage of AD is commonly associated with the development of infections such as pneumonia, urinary tract infections, or decubitus ulcers.

Table 108-5

Stages of Dementia of the Alzheimer Type

Stage of Cognitive Decline	Features
No cognitive decline	Normal cognitive state
Very mild cognitive decline	Forgetfulness, subjective complaints only; no objective decline
Mild cognitive decline	Objective decline through psychiatric testing; work and social impairment; mild anxiety and denial
Moderate cognitive decline	Concentration, complex skills decline; flat affect and withdrawal
Moderately severe cognitive decline	Early dementia; difficulty in interactions; unable to recall or recognize people or places
Severe cognitive decline	Requires assistance with bathing, toileting; behavioral symptoms present (agitation, delusions, aggressive behavior)
Very severe cognitive decline	Loss of psychomotor skills and verbal abilities; incontinence; total dependence

Adapted from Reisberg B et al. The global deterioration scale for assessment of primary degenerative dementia. Am J Psychiatry. 1982;139:1136.

Treatment

Maintaining independence as long as possible is an important goal in treating a patient with dementia. Keeping patients in familiar surroundings allows them to function without the added burden of having to attempt to adapt to a strange environment. Concurrent diseases and many medications can reduce function and increase cognitive impairment in patients with dementia.

CASE 108-1, QUESTION 5: What is an appropriate initial treatment strategy for T.D.?

T.D.'s family needs to be educated about what to expect as his dementia progresses. They should be referred to the Alzheimer's Association (www.alz.org) and to the Family Caregiver Alliance (www.caregiver.org). Both organizations provide a wealth of information and community resources, including caregiver support groups. They also should be encouraged to enroll in the MedicAlert + Alzheimer's Association Safe Return program, which provides 24-hour nationwide emergency response for people with dementia who wander or suffer a medical emergency. T.D.'s family should include him in any advance planning, seek legal advice regarding advance directives and durable power of attorney for health care and finance, and conduct estate planning to avoid having to perform these tasks when T.D. is no longer competent to participate.[41]

Currently, there are two classes of medications that are used in the treatment of Alzheimer's disease, cholinesterase inhibitors (ChEIs) and N-methyl-D-aspartate (NMDA) receptor antagonist.[44] They are pharmacologically distinct and can be prescribed concurrently in patients in the moderate to severe stages of the illness. ChEIs act on inhibiting acetylcholinesterase, an enzyme directly involved in the destruction of acetylcholine leading to increasing its concentration in the nucleus basalis of Meynert in the brain and hence ameliorating the cognitive and functional aspects of AD. Cholinesterase inhibitors have been shown to improve cognition and function, and delay symptom progression in people with dementia, however benefits are limited Cholinergic-related effects, particularly in the gastrointestinal (GI) tract, are the most common adverse effects cause by all of the agents.[45]

DONEPEZIL

Donepezil is a piperidine derivative that is somewhat selective for central AChE. It reversibly inhibits cholinesterase activity. Donepezil is highly bioavailable and exhibits a long half-life, allowing it to be given as a single daily dose. It is highly protein bound, primarily to albumin.[46]

Donepezil may improve cognition, global function, and behavioral symptoms across all stages (mild, moderate, and severe) of AD. In a multicenter, double-blind, placebo-controlled trial, subjects with mild to moderately severe AD improved during a 12-week treatment period.[47] Subjects taking 10 mg of donepezil at bedtime improved their cognitive function as measured by the Alzheimer's Disease Assessment Scale-Cognitive Subscale (ADAS-Cog), and their overall function as measured by the Clinician's Interview-Based Impression of Change with caregiver input (CIBIC-Plus).[48,49] A 24-week multicenter, placebo-controlled trial using dosages of 5 mg/day and 10 mg/day demonstrated similar results. Both 5- and 10-mg doses were superior to placebo; adverse effects were less common with the 5-mg dose.[50] A long-term, open-label follow-up study to these trials demonstrated that donepezil effects may persist for almost 3 years.[51] Interruption or discontinuation of donepezil treatment was followed by a return of cognition and function to baseline or below.

Donepezil is indicated also for the severe stage of AD. A 6-month, double-blind, parallel group, placebo-controlled study in patients with severe AD (MMSE 1–10) demonstrated an improvement in the Severe Impairment Battery[52] and Modified Alzheimer's Disease Cooperative Study activities of daily living inventory for severe AD. The domains that showed a significant improvement versus placebo were language, praxis, visuospatial, bowel/bladder function, and ability to get dressed. There were no differences noted in the neuropsychiatric inventory for behavioral issues associated with dementia.[53] A 23-mg dose of donepezil was approved for patients in the moderate to severe stages of AD. Small improvements were seen in the Severe Impairment Battery, and there was no improvement in the CIBIC-Plus when compared with the 10-mg dose. More than 30% of the high-dose group and nearly 18% of the low-dose group failed to complete the 24-week trial.[54]

The most common adverse effects of donepezil are associated with cholinergic activity. They tend to be mild to moderate in nature and resolve with stabilization of the dose.[47,50] In a 144-week extension trial of donepezil, the most frequently encountered adverse effects were nausea, diarrhea, and headache.[51] In clinical trials, however, adverse effects were the primary reason for withdrawal from studies, with an overall dropout rate of 29% in the treatment groups.[45]

RIVASTIGMINE

Rivastigmine is a carbamate derivative that inhibits both AChE and butyrylcholinesterase (BChE) activity. BChE provides an alternative pathway for acetylcholine metabolism. Rivastigmine inhibits the activity of both cholinesterases, primarily in the central nervous system.[55] Its AChE inhibition is greater for the G1 as compared with the G4 form.[33] The drug binds to the esteratic sites of the AChE and BChE molecules and slowly dissociates. Because of this, it is often referred to as a "pseudoirreversible" inhibitor.[56] Rivastigmine's biological half-life is approximately 1 hour, but because its slow dissociation extends its activity for at least 10 hours, it can be dosed twice daily. Rivastigmine is bound approximately 40% to serum proteins and is metabolized via hydrolysis to renally excreted inactive compounds.[55] Rivastigmine absorption is nearly complete, but because it undergoes a significant first-pass effect, the resultant bioavailability is approximately 36%.

In two large clinical trials conducted in patients with mild to moderately severe AD, rivastigmine improved cognition, the ability to perform daily activities, and global function over the course of 24 weeks.[56,57] In each multicenter, double-blind, placebo-controlled trial, subjects were randomly assigned to receive placebo or low-dose (1–4 mg/day) or high-dose (6–12 mg/day) rivastigmine in two divided doses during a 26-week period. In one study, subjects in both dosage groups demonstrated statistically significant improvement after 26 weeks on the ADAS-Cog and CIBIC-Plus scales.[56] In the other trial, only those subjects taking 6 to 12 mg/day improved on the same scales.[57] An open-label extension study that included subjects from both previous studies found that subjects taking 6 to 12 mg/day of rivastigmine had significantly better cognitive function after 1 year than did subjects who had originally received placebo.[58]

Adverse effects typically include nausea, vomiting, diarrhea, and other cholinergic mediated GI effects.[55] They are most common when rivastigmine is taken on an empty stomach or when the dose escalation is too rapid. Headache, dizziness, and fatigue are also common adverse effects. Increasing the dose by 1.5 mg twice daily at 4-week intervals increases drug tolerability and reduces the frequency and severity of GI side effects. Adverse effect severity appears to be less problematic with a transdermal formulation that delivers 4.6 or 9.5 mg/24 hours, which correspond to 6- and 12-mg daily doses of the oral formulation.[59] The maintenance dose is generally 9.5 to 13.3/day. In patients with moderate to severe AD, the maintenance dose is 13.3

mg/day. If treatment is interrupted for at least 3 days, the lowest dosing should be restarted.

GALANTAMINE

Like other agents used to treat AD, galantamine enhances cholinergic activity by inhibiting AChE. However, it also stimulates nicotinic receptors (α 7-nicotinic receptor agonist) at a site distinct from that stimulated by acetylcholine, an action that does not rely on the presence of acetylcholine. This action is referred to as allosteric modulation.[33] Galantamine is rapidly and completely absorbed, reaches peak serum levels in less than 2 hours, and has a half-life of approximately 5 hours. It exhibits low protein binding and has a large volume of distribution. Galantamine is metabolized primarily by cytochrome P-450 (CYP) isoenzymes CYP2D6 and CYP3A4, and is eliminated in the urine.[60]

Clinical trials have shown galantamine to be effective for the symptomatic treatment of mild to moderate AD. Doses of 16 and 24 mg/day produced clinically meaningful improvement in ADAS-Cog and CIBIC-Plus scores during a 5-month, randomized, placebo-controlled trial.[61] A similar trial conducted in Europe and Canada that evaluated patients for 6 months used doses of 24 and 32 mg/day. Both doses were more effective than placebo, but patients in the 32-mg/day group exhibited more adverse effects.[62] A 6-month, open-label extension trial showed that patients treated with galantamine 24 mg/day maintained ADAS-Cog scores throughout the entire 12 months of the study.[62]

As with the other ChEIs, cholinergic effects in the GI tract are the most commonly encountered adverse effects. Nausea, diarrhea, vomiting, and anorexia were the most frequent events encountered during clinical trials.[33,45] They were typically present during the dose escalation phases of the studies. A dose titration interval of 4 weeks reduces the severity of adverse effects and increases tolerability.

CASE 108-1, QUESTION 6: Should treatment with a cholinesterase inhibitor be instituted in T.D., and if so how should therapy be monitored?

T.D. is in the mild stage of the disease, so a ChEI is an appropriate choice.[42] It is unlikely that a ChEI will produce a dramatic or long-lasting improvement in T.D.'s cognitive abilities. Systematic reviews of ChEI therapy have consistently concluded that these agents provide modest benefits, at best, in the majority of patients.[45,63] Treatment, however, may slow his cognitive decline, help maintain his ability to care for himself for 1 year or more, and reduce the risk for nursing facility placement for as much as 2 years.[60] Beneficial effects may occur for as long as 3 years, and patients who start therapy earlier may experience greater benefit than those who delay treatment.[61,62] The choice of drug is based on the agent most likely to produce a positive response with the fewest adverse effects. Ease of adherence must also be considered. All agents exhibit similar adverse effect profiles. Rivastigmine may be less prone to drug interactions because of its metabolic pathway.[55] It is also available as a transdermal patch that is applied daily. Whereas the oral formulation of rivastigmine requires an initial, nontherapeutic titration dose to reduce the severity of adverse effects, the initial transdermal dosage is therapeutic.[59] Donepezil and galantamine extended-release can be given as a single daily dose and are available as generic equivalents. They can be given at bedtime, which may make cholinergic side effects less troublesome.

Donepezil may be an appropriate agent for T.D.. He should receive donepezil 5 mg at bedtime. He should be monitored for cholinergic side effects (particularly nausea and diarrhea), insomnia, headache, and dizziness, the adverse effects most commonly reported in clinical trials.[47,50] Additionally, he should be monitored for bradycardia due to his pre-existing low heart rate. Patients who received moderate to high doses of donepezil showed an increased incidence and greater risk of bradycardia especially those with risk factors (e.g. cardiovascular disease, concomitant use of beta blockers, calcium channel blockers, antiarrhythmics).[64] His family and physician should look for improvements in his memory, orientation, and ability to concentrate on complex tasks, such as managing finances. He may also become less irritable.

CASE 108-1, QUESTION 7: T.D. was unable to tolerate the donepezil and his family was wondering what other options could be employed to address the progression of the dementia?

After 1 month, his physician should assess him for adverse effects.[42] If he has not improved noticeably after 4 to 6 weeks, the dose of donepezil may be increased to 10 mg at bedtime. If his condition does not respond to donepezil after a 6-month trial, or he is unable to tolerate the donepezil, it is reasonable to switch T.D. to another ChEI. Both rivastigmine and galantamine have additional mechanisms of action that might prove beneficial. Rivastigmine is started at a dose of 1.5 mg twice daily with meals to slow absorption and improve tolerability. The dose may be increased at 4 week intervals by 1.5 mg twice daily, up to the maximal dose of 6 mg twice daily; however, the transdermal formulation is better tolerated and may be preferable by avoiding a titration phase. Galantamine can be started at 4 mg twice daily or 8 mg daily (extended-release) and increased every 4 weeks by 8 mg, up to a maximal dose of 24 mg daily. As with oral rivastigmine, the initial dose is not therapeutic.[60] Taking galantamine with meals may improve tolerability of GI effects. If a trial of a second agent does not improve or stabilize a patient's condition, there is no value in attempting a third agent. T.D. should have routine reassessment of his daily function, cognition, and behavior at 6-month intervals.[65-67] Close attention also must be paid to his other medical conditions, and his family should be provided ongoing support, such as through an AD caregiver support group.

MEMANTINE

As T.D.'s AD progresses, there are two treatment options that can be tried. One option is to further titrate up the donepezil dose to 23 mg a day as mentioned above with some limited clinical efficacy.[51] Another option is to use an N-methyl-D-aspartate (NMDA) antagonist, which has been shown to reduce the release of glutamate in the central nervous system that can lead to excitotoxic reactions and cell death in AD and other neurodegenerative disorders.[68] Memantine is a noncompetitive NMDA receptor antagonist with moderate affinity and voltage-dependent binding. It is completely absorbed after oral administration, reaches peak serum concentrations in 3 to 8 hours, and is moderately protein bound.

Multiple clinical trials have evaluated memantine in subjects with moderate to severe AD. A dose of 10 mg/day for 12 weeks increased functional ability (e.g., dressing, toileting, participating in group activities) and reduced care dependence compared with placebo.[68] A 28-week trial using a dose of 20 mg/day improved CIBIC-Plus scores, activities of daily living, and global function compared with placebo.[69] Overall, the benefits of memantine are modest.[70] The combined use of memantine and a ChEI has been shown to be superior to a ChEI alone by improving daily function in individuals with moderate to severe dementia.[71-73] Common adverse effects include diarrhea, insomnia, dizziness, headache, and hallucinations.[68] Memantine has also been studied in patients with mild to moderate AD with 2,000 IU/d of alpha tocopherol compared with placebo.[74] The alpha tocopherol resulted in slower functional decline, while there were no significant differences in the groups receiving memantine alone or memantine plus alpha tocopherol. T.D. should be started on memantine 5 mg daily, with the dosage increased in weekly intervals by 5 mg/day, up to a dose of 10 mg twice daily.[68] As an alternative, he can be started on the extended-release formulation given in weekly escalating doses of 7, 14, 21, and 28 mg daily.

LEWY BODY DEMENTIAS

Etiology

Lewy bodies are hyaline-containing inclusion bodies typically found in people with Parkinson's disease. Recently, attention has been given to distinguish DLB and PDD to help further research.[75] It is known that up to 25% of patients with dementia have Lewy bodies in the brainstem and cortex (particularly in the limbic and paralimbic cortices and frontal and temporal lobes).[5,76] Concentrations are found in the substantia nigra, locus coeruleus, hypothalamus, basal nucleus of Meynert, and neocortex. There is decreased dopamine in the basal ganglia and a loss of choline acetyltransferase (and thus, acetylcholine) in the basal nucleus of Meynert.[5] Many of these patients display extrapyramidal signs without the classic presentation of Parkinson's disease.[7] The role of α-synuclein is a common biological theme in both DLB and PDD, with α-synuclein aggregates found in Lewy bodies and neurites.

Clinical Presentation

CASE 108-2

QUESTION 1: J.F. is a 72-year-old woman who was diagnosed with mild cognitive impairment 6 months ago. She had been increasingly forgetful and confused for about 1 year before the diagnosis. Approximately 3 months ago, J.F. and her family decided that J.F. should move in with them so she would not be left alone. Since moving in with the family, her son has noted that she seems "spaced out" at times. Some days, she appears to be very clear and not confused; other days she is very forgetful and requires assistance with daily tasks. Her daughter-in-law reported that J.F. has been unsteady on her feet at times and has fallen twice. She notes at times she moves very slowly and has difficulty initiating movement. Recently, J.F. reported seeing people coming out of the painting on the wall (a European street scene), stating that "they were walking all through the house trying to steal anything that can be hidden in a coat pocket."

At the physician visit, J.F. was found to be medically stable. Vital signs, serum chemistries, and complete blood cell count were within normal limits. Her MMSE score was 21/30. During the review of systems, J.F.'s daughter-in-law had to answer some questions because J.F. appeared either not to hear them or to ignore them. On physical examination, she demonstrated mild cog-wheeling rigidity bilaterally, bradykinesia, and masked facies; she did not display a resting tremor. What is the most likely explanation for J.F.'s presentation?

Given her physical health, inability to live alone because of impaired cognition, and MMSE score, J.F. meets the criteria for dementia. Her rigidity, bradykinesia, and masked facies are consistent with early Parkinson's disease (see Chapter 59 Parkinson's Disease and Other Movement Disorders). There have been revised criteria for the clinical diagnosis of DLB (Table 108-1).[77] J.F. exhibits all the central features, two core features, and the supportive feature of repeated falls. Her presentation is consistent with probable DLB versus PDD because of her temporal sequence and lack of well-established diagnosis of Parkinson's disease.

Treatment

CASE 108-2, QUESTION 2: What is an appropriate treatment for J.F.?

To date, ChEIs are the only treatment strategy for the cognitive symptoms of both PDD and DLB. All ChEIs have demonstrated symptomatic benefit in patients with DLB.[78,79] The largest randomized, placebo-controlled trials have used rivastigmine (up to 12 mg/day) in subjects with mild to moderate disease, and this medication has received US Food and Drug Administration (FDA) indication for PDD. Rivastigmine was reported to worsen tremor in 10% of the patients with PDD, yet overall there was not a statistically significant difference between groups.[75] Rivastigmine treatment has demonstrated improvements in apathy, anxiety, delusions, and hallucinations when titrated appropriately to doses of 6 to 12 mg daily.[80] Dose initiation, titration, and monitoring are conducted in the same manner as when ChEIs are used for the treatment of AD.

J.F.'s symptoms of Parkinson's disease should be fully evaluated, and appropriate treatment, such as levodopa/carbidopa, should be started (see Chapter 59, Parkinson's Disease and Other Movement Disorders). Because several medications for parkinsonism can have psychiatric effects, it is important to monitor for adverse effects such as worsening psychosis and cognition. Typical antipsychotics, such as haloperidol, may worsen her extrapyramidal symptoms (EPS) and should be avoided. Novel atypicals, namely, quetiapine and clozapine, may be less likely to exacerbate the parkinsonism but should be instituted after a trial of a ChEI or if more acute symptom control of behaviors is required.[75,77]

VASCULAR DEMENTIA (VAD)

Etiology

VaD is a broad classification of cognitive disorders caused by vascular disease. The most common cause of VaD is occlusion of cerebral blood vessels by a thrombus or embolus, leading to ischemic brain injury.[81,82] In the majority of cases, the dementia syndrome is the result of multiple individual cerebral infarcts, a single infarct in an area related to cognitive function, or diffuse white matter lesions in the subcortex.[16] A number of diseases, including atherosclerosis, arteriosclerosis, and vasculitis, lead to the production of emboli and thrombi that potentially occlude brain vessels. Hemorrhagic phenomena and disorders such as hypertension or cardiac disease can produce episodes of cerebral ischemia or hypoxia and are responsible for some cases of VaD.[81-83] Specific risk factors for VaDs include advancing age, diabetes mellitus, small vessel cerebrovascular disease, hypertension, heart disease, hyperlipidemia, cigarette smoking, and alcohol use.[82-84]

Neuropathology

VaDs are typically subcortical. Most patients with VaD have blockage of multiple blood vessels and infarction of the cerebral tissue supplied by those vessels.[83,84] When the distribution of a large artery or medium-size arteriole is blocked, focal neurologic deficits can result (see Chapter 61, Ischemic and Hemorrhagic Stroke). Depending on the area affected, there may be significant cognitive impairment. More often, however, a patient may have experienced transient ischemic attacks (TIAs) or multiple microinfarcts that have remained unrecognized.[83,84] Patients with subcortical VaDs often exhibit small, deep ischemic infarcts in arterioles of the basal ganglia, thalamus, and internal capsule.[83,84] A history of atherosclerosis, diabetes mellitus, or hypertension is often present without a history of stroke.[83,84] MRI scans can be very useful in diagnosing VaDs because areas of cerebral infarction are easier to visualize than they are with CT scanning (Fig. 108-3).[16,22] Lesions in white matter may occur in as many as 85% of patients with VaD. Deep white matter lesions known as leukoaraiosis often include demyelination and may represent early changes in dementia.[83] Because of the etiologic factors involved, VaD typically has an earlier onset than AD, and affects more men than women.

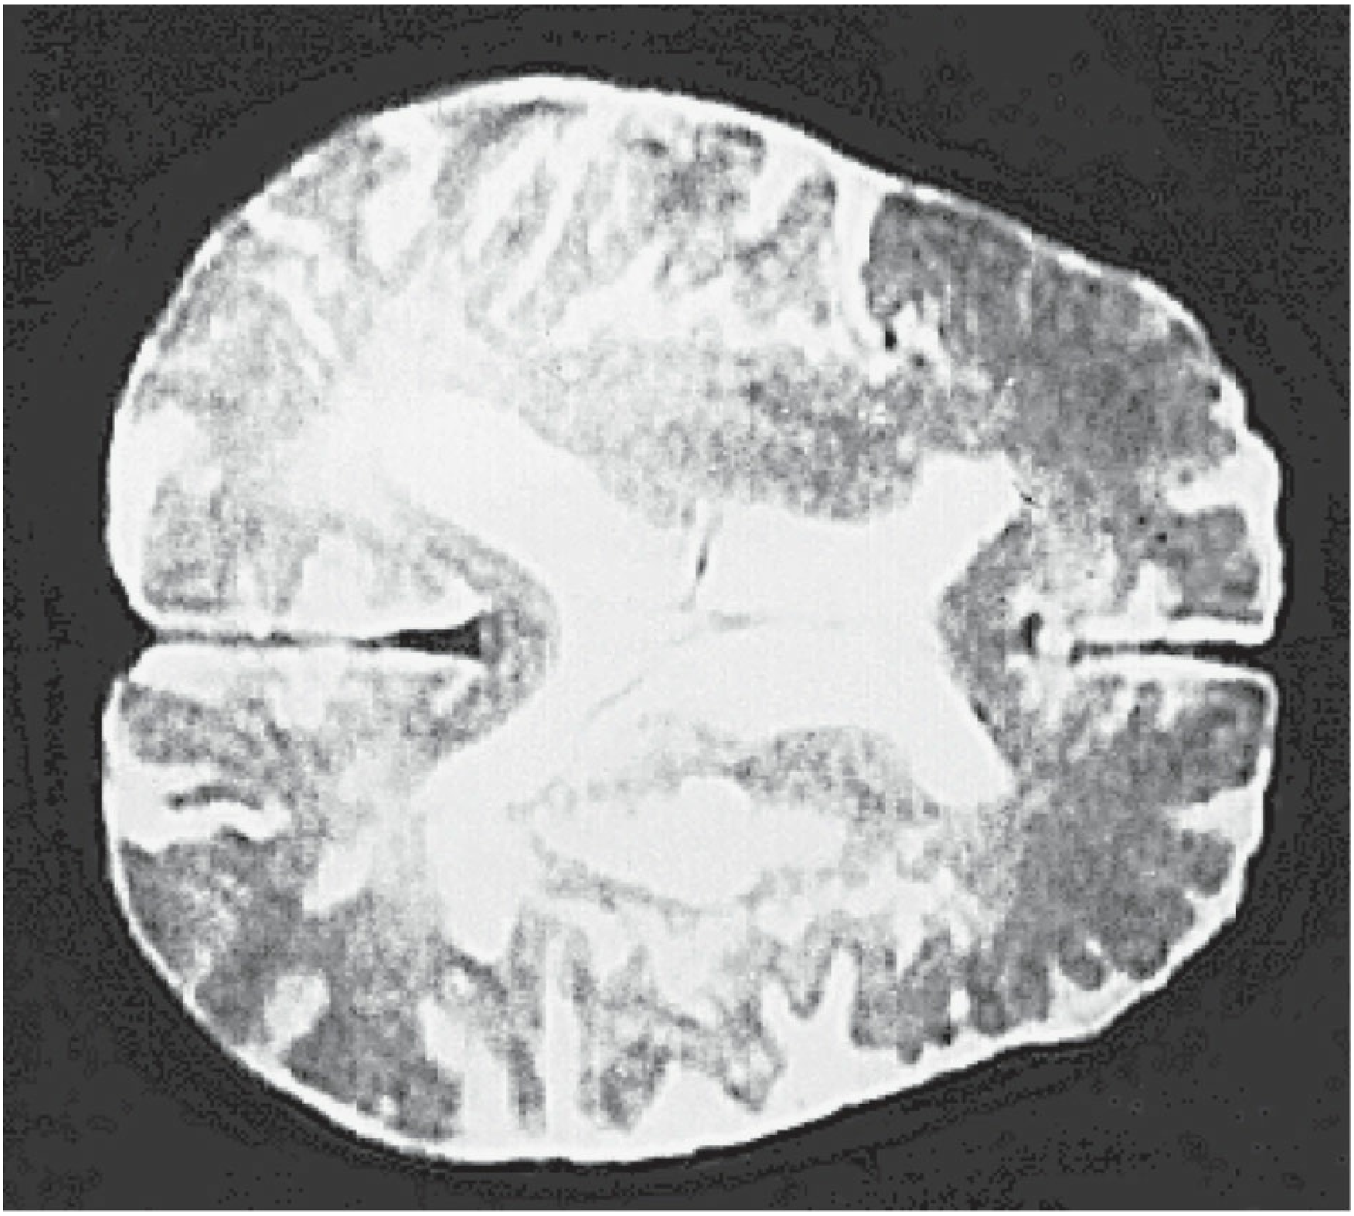

Figure 108-3 A large stroke is visible to the right of the ventricles. There is evidence of atrophy in the right temporal area.

Clinical Presentation

CASE 108-3

QUESTION 1: D.V., a 73-year-old man, is accompanied by his daughter for evaluation of "fuzzy thinking." Although his chief complaint is impaired memory, he denies significant impact on his daily routine. D.V. states his memory problem began 2 years ago after a dizzy spell and subsequent fall. However, his daughter states that the impairment began approximately 1 year before that episode. The memory loss has been slowly progressive. D.V. states that he feels useless because of his memory problems and his "boring" daily routine. Although D.V. is generally independent, he relies on his daughter for assistance with most financial matters. He has voluntarily quit driving because of a lack of confidence in his abilities. D.V.'s daughter reports that according to her mother, D.V. is sometimes disoriented at night when he awakens to urinate. He has no history of urinary incontinence. D.V. has a questionable history of TIAs, but no focal neurologic deficits. He has a long history of mild hypertension, which is treated with a diuretic. He drinks alcohol occasionally and smokes about half a pack of cigarettes per day. His medical history is unremarkable except for the possible TIAs, hypertension, and a mildly enlarged prostate. His family history is positive for diabetes and heart disease.

On physical examination, D.V. is found to be a mildly obese man who is well dressed and groomed, alert, and oriented to person. His BP is 160/92 mm Hg sitting and 168/95 mm Hg standing. Cardiac examination is normal. Neurologic findings include somewhat diminished extraocular movements laterally and slightly asymmetric reflexes, with right greater than left. Muscle tone is normal in the lower extremities. He has a mild shuffling gait. Vibratory sensation is diminished but within normal limits for his age. His score on the Folstein MMSE was 22/30, including errors in orientation and recall. Psychologic evaluation found him to be mildly depressed.

A full laboratory analysis was generally within normal limits. D.V.'s serum potassium (3.8 mEq/dL) and sodium (138 mEq/dL) were in the low normal range, and his blood urea nitrogen (18 mg/dL) was in the upper normal range. Serum total cholesterol was 246 mg/dL, and fasting triglycerides were 230 mg/dL. A chest radiograph revealed a mildly enlarged heart; his electrocardiogram was normal. An MRI scan of the brain indicated generalized atrophy with enlarged ventricles, periventricular white matter ischemic changes, bilateral basal ganglion lacunar infarcts, and small cortical infarcts in the right parietal lobe.

What subjective and objective evidence exists for a diagnosis of dementia in D.V.?

D.V.'s major complaint is "fuzzy thinking" and impaired memory that he attributes to his dizzy spell and fall. However, his family began to note problems a full year before that episode, with progression over time. Although D.V. denies that his impairment significantly affects his daily routine, he has voluntarily stopped driving and relies on his daughter for assistance with financial matters. His memory difficulties appear to have affected his mood and made him feel useless. D.V. is disoriented at night when he awakens to urinate. These factors satisfy the DSM-V criteria for interference with normal activities.[1]

Multiple deficits are present on both the Folstein MMSE[17] (orientation, recall) and on the Blessed Dementia Scale[85] (memory, orientation), indicating impaired short- and long-term memory. D.V.'s inability to drive reflects poor judgment behind the wheel of a car; a disturbance of higher cortical function is indicated by his need for assistance with financial matters. There is no evidence of a delirium being present. Evidence of an organic cause is provided by the MRI scan.

Diagnosis

CASE 108-3, QUESTION 2: What type of dementia does D.V. have?

There is sufficient evidence to indicate that D.V. suffers from a neurocognitive disorder. DSM-V provides diagnostic criteria for VaD (Table 108-1) and it appears that the history and findings satisfies the possible VaD (unclear of temporal relationship between TIAs and decline).[1] VaDs commonly present suddenly after a cerebrovascular insult. This is followed by a period of stability and further declines after additional episodes, often in a stepwise pattern. Cognitive impairments are variable and depend on the area of the brain affected by the insult.[1,16]

With the exception of the dizzy spell and fall, D.V.'s deterioration has had a pattern that resembles a downhill slide rather than stepwise decline. Although his cognitive deficits are "patchy" (e.g., he appears to have no language difficulty), they are not particularly prominent. D.V. displays some neurologic signs and symptoms, including diminished extraocular movements, asymmetric reflexes, and a mild shuffling gait, but they are subtle and might be easily missed by an untrained observer as being related to a dementia. Reliance solely on the clear presence of diagnostic criteria may often lead to a missed diagnosis.[22] The Hachinski Ischemic Scale ranks signs and symptoms associated with cognitive impairment of cerebrovascular origin and is used to help differentiate between AD and VaD.[83] According to this scale, D.V.'s nocturnal confusion, depression, hypertension history, and focal neurologic signs and symptoms are sufficient to indicate VaD.

D.V.'s history and clinical presentation do not suggest dementia caused by a single large stroke or several small strokes. Large strokes produce significant motor damage, typically on one side of the body (the side contralateral to the stroke). Multiple smaller strokes cause prominent motor deficits in discrete areas controlled by the affected areas. Neither of these patterns describes D.V.'s condition. However, he is clearly exhibiting signs of dementia and has significant cerebrovascular disease. He possesses several risk factors for a VaD, including hypertension, smoking, and hyperlipidemia. His MRI indicates a lacunar state, with multiple small infarcts in the deep penetrating arterioles at the base of the brain, particularly in the basal ganglia, internal capsule, thalamus, and pons (see Chapter 61, Ischemic and Hemorrhagic Stroke). These MRI findings are consistent with D.V.'s long-standing hypertension and neurologic presentation.

Treatment

CASE 108-3, QUESTION 3: How should D.V. be managed?

Several treatment options that modify risk factors for VaDs are available.

SMOKING CESSATION

D.V. should be counseled to stop smoking because cigarette smoking reduces cerebral blood flow and increases the risk for stroke. Among smokers with VaD, cessation of cigarette use improves cognitive performance.[86]

ANTIHYPERTENSIVE THERAPY

Hypertension and hyperlipidemia, both present in D.V., are additional risk factors for stroke and VaD. Control of systolic hypertension reduces the risk of stroke by 36% in elderly patients,[87] and maintaining the systolic BP between 135 and 150 mm Hg is associated with improved cognition among MID patients. A systolic BP that exceeds 150 mm Hg indicates inadequate control, whereas a systolic BP less than 135 mm Hg may lead to inadequate cerebral perfusion.[88] As in non-demented individuals, nonpharmacologic treatment (e.g., diet, weight loss, exercise) is an essential component. The antihypertensive agent must be chosen carefully in this population to maximize compliance and minimize adverse reactions.[89] Both thiazide diuretics and β-adrenergic blockers may increase lipid levels, a potential complication in D.V. α-Adrenergic blockers and sympatholytic agents may cause depression or impair cognitive activity. Calcium-channel blockers or angiotensin-converting enzyme inhibitors are acceptable because they are well tolerated by elderly patients and may help preserve renal function in patients with diabetes mellitus (see Chapter 9, Essential Hypertension).

Dihydropyridine calcium-channel blockers have been shown to improve cognition in patients with dementia and reduce the risk of dementia in elderly patients with isolated systolic hypertension.[90] Because D.V. has benign prostatic hyperplasia, he may benefit from the use of an α-adrenergic blocking agent, such as doxazosin 1 mg at bedtime or terazosin 1 mg at bedtime (see Chapter 109, Geriatric Urologic Disorders). Evidence indicating an increased risk for negative cardiac outcomes, however, makes the α-adrenergic blocking agents less attractive choices.[91] The use of a vasodilating calcium-channel blocker, such as amlodipine 5 mg once daily, is an appropriate first choice. An angiotensin-converting enzyme inhibitor such as benazepril 10 mg once daily is an appropriate alternative. Both agents exhibit the advantage of once-daily dosing over some other agents within their respective classes. This feature is important for maximizing adherence in patients with declining memory.

ANTIPLATELET THERAPY

Prophylaxis against future cerebrovascular events is indicated in VaD, but few studies that have looked specifically at individuals with dementia are available. Cerebral perfusion and cognitive performance were improved in VaD patients receiving aspirin 325 mg/day for 1 year when compared with a control population.[92] Guidelines from the American Heart Association and the American Stroke Association recommend the use of antiplatelet therapy in patients with a history of

TIA or atherothrombotic stroke that is not of cardiogenic origin. Aspirin in doses of 50 to 325 mg/day, clopidogrel 75 mg daily, or aspirin 50 mg/dipyridamole 200 mg twice daily are all effective treatments for stroke prophylaxis.[93] Warfarin and possibly targeted specific oral anticoagulant (TSOACs) may be recommended after cardioembolic cerebral ischemic events. However, only aspirin has been studied specifically in VaD patients. Aspirin 81 to 325 mg daily is an appropriate first choice for D.V.

CHOLINESTERASE INHIBITORS

Deficits in cholinergic transmission and nicotinic receptor binding abnormalities have been noted in VaD.[5,94] Early clinical trials with donepezil,[95] galantamine,[96] and rivastigmine[97] have demonstrated improvement in cognition and daily function among patients with VaD. As of yet, however, the use of these agents remains investigational and controversial. Because the use of these agents is not FDA-approved for VaD, D.V. and his family should have a thorough discussion with his physician regarding the potential risks and benefits when considering ChEI treatment for him.

MANAGING FUNCTION

D.V. should be referred for physical and occupational therapy for an assessment of his strength, gait, and daily function. Physical therapy can help him maintain his strength. Occupational therapy can provide him with equipment and strategies to adapt to his dizziness and avoid falls. In addition, the use of reminder notes and labels around the house will assist him in maintaining his independence.

BEHAVIORAL DISTURBANCES IN DEMENTIA

Several types of behavioral disturbances may develop during the course of a dementia and occur in almost all patients, particularly during the later stages (Table 108-6).[38,41] Behavior symptoms include a wide range of disturbances, including agitation, apathy, wandering, verbal and physical aggression, and psychotic symptoms.[41] Agitation in dementia has been described as excessive motor activity with a feeling of inner tension that may lead to related symptoms such as anxiety, irritability, motor restlessness, and abnormal vocalization.[98] Sleep disorders and mood disorders, such as anxiety and depression, also are common.[99] Agitation and anxiety are often managed best with nonpharmacologic treatment. Pharmacologic interventions are appropriate when nondrug therapies are unsuccessful or the behavior is severe. Non-psychologic behaviors such as wandering and inappropriate motor activity respond better to environmental modification than to drug therapy.[99,100] The first step in evaluating altered behavior in patients with dementia is to ensure that the problem is not the result of an unrecognized medical problem (e.g. pain), environmental factors or caused by an adverse effect of a medication (see Chapter 107, Geriatric Drug Use).

Agitated Behaviors

CASE 108-4

QUESTION 1: T.G., a 62-year-old man, has recently been diagnosed with AD, for which he takes donepezil 10 mg at bedtime. He also has hypertension that is treated with hydrochlorothiazide 12.5 mg daily and amlodipine 5 mg daily. He no longer takes his daily walks around the neighborhood because he is afraid he will get lost; instead, he follows his wife around the house as she does her daily chores. Other times, he paces throughout the house. He also expresses worry about the burden he will place on his family as his condition worsens. Recently, he has had episodes of incontinence and awakens four to five times during the night to urinate. His concerns contribute to his nighttime awakenings, making him quite tired during the day.

How should T.G.'s agitation and anxiety be managed?

Anxiety and unfocused activity are common problems in the early stages of dementia. Agitation is a general term that, while commonly used, is subject to wide interpretation. It typically is used to describe specific behaviors such as restlessness, irritability, or unfocused motor activities. Patients are aware of their progressive cognitive decline and have sufficient insight to understand the consequences. T.G.'s shadowing of his wife indicate insecurity and anxiety; pacing through the house is an example of restlessness and unfocused behavior. T.G. is exhibiting anxiety, as evidenced by his worry about placing a burden on his family. His poor sleep is attributable to both nocturia and anxiety.

If T.G.'s behavior represents a sudden or rapid change, his physician should first evaluate him for a medical condition such as infection, pain, or a medication-related problem. Although T.G. has been taking hydrochlorothiazide without difficulty, he may no longer be recognizing the cues to urinate. The drug should be discontinued; if his blood pressure rises, the amlodipine dose can be increased. This may help with his incontinence, nocturia, and disturbed sleep.

CASE 108-4, QUESTION 2: T.G.'s mental status continues to decline to the point that he requires help with bathing and dressing. During a physician visit, he accuses his wife and children of stealing from him. He also cannot locate his coin collection, which he placed in a "safe" location when his memory began to decline; during the night, he rummages through the house looking for it. He believes his family has been plotting to steal his assets and then turn him out onto the street. T.G.'s son reports that T.G. has been verbally abusive and has threatened several members of the family recently. How should T.G.'s paranoid behavior be managed?

Once medical problems have been ruled out or corrected, he should be evaluated using a systematic approach, as behavior problems are part of a chain of events. T.G.

may be described as "agitated," but his behavior is shadowing his wife and pacing through the house. The behavior has an antecedent; because he has a dementia, he may be unable to initiate a meaningful or enjoyable activity on his own, and consequently he becomes bored. The consequence of his boredom is that he annoys his wife and paces the house. This represents what often is termed an "A-B-C" approach, for antecedent, behavior, consequence.[99] Pacing is a demonstration of unfocused energy. T.G.'s wife can give him simple tasks to perform, such as drying dishes, folding laundry, or simple gardening, to help channel his energy. It also may relieve his anxiety and insecurity. She also could accompany him on walks to alleviate his fear of getting lost. She may want to consider enrolling him in an adult day-care program. This would give him meaningful activity that might help him use up his excess energy and sleep better at night. It also will provide her with some respite and avoid or delay caregiver burnout. Appropriate strategies to manage agitated behaviors without medication are listed in Table 108-6.

When non-pharmacologic interventions are not successful in reducing anxiety, irritability, and similar behaviors, medications can be considered. Benzodiazepines are the most commonly used anxiolytics and will address T.G.'s insomnia and anxiety. However, they are associated with several negative outcomes in the elderly, including confusion, amnestic syndromes, ataxia, and falls.[101,102] Benzodiazepines, in addition to other medications, may be considered potentially inappropriate medications in older adults as described in the 2015 American Geriatrics Society Beers Criteria. If a benzodiazepine is clinically warranted, agents such as lorazepam or oxazepam, may be used, if necessary, but only for a short term and with caution.[102]

Trazodone is a sedative antidepressant that is effective for insomnia and agitated behaviors in patients with AD.[101,103] Treatment is started at 25 mg at bedtime and may be increased to a dose of 250 mg/day in divided doses. Another alternative treatment is buspirone, which does not cause the cognitive impairments associated with the benzodiazepines. Dosage begins at 5 mg three times daily and may be increased up to 15 mg three times daily. However, buspirone will not concurrently manage T.G.'s insomnia because it has no sedative effect, and there is no reliable evidence that it is efficacious in anxiety associated with dementia.[102] Citalopram has been shown to reduce agitated behaviors in people with dementia and could be used.[104] Emerging evidence suggests that dextromethorphan-quinidine combination may be efficacious in reducing agitation but caution exists in light of drug-drug interactions as well as limited data.[105]

If the nondrug strategies are ineffective in reducing T.G.'s insomnia and agitation, trazodone should be initiated at a dose of 25 mg at bedtime. It may be increased by 25 mg/day at 5- to 7-day intervals, up to 100 mg. Doses above 100 mg/day should be split into two daily doses.

Psychosis

Delusions and hallucinations are common among individuals with dementia. Paranoid symptoms, often accompanied by aggression, have been reported in more than half of dementia patients.[103] Delusions typically involve suspicion of theft by family members, which may be secondary to the patient's inability to remember where valuable items were placed and incorrectly concluding that they were stolen.[106] Another common delusion is the misidentification of people or objects.[107] Capgras syndrome, the belief that a person has been "replaced" by an identical-looking impostor or the belief that photographs or television pictures are real individuals, may occur in almost half of demented individuals.[106]

There are a few behavioral interventions that could be tried first before resorting to medications, which produce limited benefits and are accompanied by significant risk.[108,109] The first step is to conduct a person-centered examination of the symptoms. Several questions need to be answered. What is the significance or meaning of these behaviors to T.G? (For example, he cannot locate items that are valuable to him, and does not recall where they are.) What triggers his thoughts and outbursts? (He may assume the items were stolen, and believes that his family, knowing their location, has taken them for their own gain.) How is the family's response further angering him? (If the family searches for and finds the items, it may reinforce his delusion that they stole them.) The family should be educated that paranoid behavior is common in dementia, and that it is likely to pass as the disease progresses. Depending on how fixed the paranoia is, distraction or redirection, such as changing the subject to something more pleasant, or initiating a pleasant activity, could resolve the problem. Regardless of the strategy, they need to be taught not to argue or debate with T.G. but to share his concern. When these strategies fail, then, depending on severity, it may be necessary to resort to medication.

Paranoid symptoms respond best to antipsychotic agents, although these are not highly effective, and no single antipsychotic is more effective than any other. Delusions, hallucinations, aggression, and uncooperativeness symptoms respond best, but overall improvement occurs in only a minority of patients.[102,109] The CATIE-AD trial compared olanzapine, quetiapine, risperidone, and placebo for the treatment of psychosis, aggression, and agitation for up to 36 weeks in patient with AD. Improvement was noted in 32%, 26%, 29%, and 21%, respectively. The authors concluded that efficacy of the agents was offset by adverse effects.[109] There are no antipsychotic medications that are approved by the FDA for use in the management of behavior symptoms in people with dementia. Black-box warnings are present for all agents because of the increased risk for stroke and mortality when used in this population.[108,110,111] Consequently, any use of these drugs in a person with dementia is for an unapproved use and requires a full discussion between the physician, patient, and caregivers.

Table 108-6

Behavior Disturbances in Dementia

Behavior	Typical Presentation	Nonpharmacologic Treatment	Pharmacologic Treatment
General strategies		Safety-proof living areas Issue one-step commands for directions Maintain a daily routine of activities Avoid arguing incorrect statements Avoid startling the patient Limit unusual or overly stimulating environments	
Anxiety	Excessive worrying, sleep disturbances, rumination	Listen to, and acknowledge frustrations Redirection Exercise Engage in enjoyable activities Sleep hygiene practices Limit noise and distractions	Trazodone Buspirone (if no insomnia) Short-acting benzodiazepine SSRI antidepressant
Depression	Withdrawal, loss of appetite, irritability, restlessness, sleep disturbances	Exercise Engage in meaningful activities	Trazodone SSRI antidepressant
General agitation and restlessness	Repeated questions, wandering, pacing	Distraction and redirection Break down tasks into simple steps Provide enclosed area for exercise	Often unresponsive to medications
Paranoid behaviors	Delusions (often of theft), hallucinations, misperceptions	Reassurance Distraction, rather than confrontation Remove potential sources of confusion (e.g., mirrors and other reflective surfaces)	Atypical antipsychotic, if not responsive to other strategies and person is harmful to self or others SSRI antidepressant, if associated with withdrawal, tearfulness, themes of loss
Aggressive behaviors	Physical or verbal aggressiveness toward others, excessive yelling and screaming, manic features	Identify the precipitating cause or situation Focus on the patient's feelings and concerns Avoid getting angry or upset Maintain a simple, pleasant, and familiar environment Use music, exercise, etc., as a calming activity Shift the focus to another activity	Anticonvulsant, such as divalproex or carbamazepine, possibly in combination with an atypical antipsychotic when other strategies do not work

Kales et al. Assessment and management of behavioral and psychological symptoms of dementia. BMJ. 2015;350:h369; Tariot PN et al. Pharmacologic therapy for behavioral symptoms of Alzheimer's disease. Clin Geriatr Med. 2001;17: 359; Herrmann N, Lanctot KL. Pharmacologic management of neuropsychiatric symptoms of Alzheimer disease. Can J Psychiatry.2007;52:630; Gray KF. Managing agitation and difficult behavior in dementia. Clin Geriatr Med. 2004;20:69; Teri L et al. Exercise plus behavioral management in patients with Alzheimer disease: a randomized controlled trial. JAMA. 2003;290:2015.

The risks and potential benefits of therapy must be carefully weighed for T.G. before determining the appropriate treatment. The choice of an antipsychotic agent is determined by the symptoms displayed by the patient as well as the potential for adverse effects. T.G. is experiencing a delusion of theft, suspiciousness, and aggressive behavior. It is possible that the verbal abuse and threats are consequences of fear brought on by the false belief that his family is stealing from him and plans to abandon him.

T.G. has no major contraindications to the use of any antipsychotic agent, and his target symptoms will probably respond to any of the available agents. Therefore, a therapeutic trial is appropriate. The choice can be made according to which antipsychotic agent is least likely to cause intolerable adverse effects. Risperidone has been evaluated in a case series and in a large double-blind, placebo-controlled trial.[112,113] In the case study series, symptoms improved in half of the patients taking dosages ranging from 0.5 mg every other day to 3 mg twice daily. However, 50% also experienced EPS, even at the lowest dosage used.[112] Subjects in the double-blind trial received either placebo or risperidone at dosages of 0.5 mg/day, 1 mg/day, or 2 mg/day for 12 weeks. Daily doses of 1 or 2 mg reduced psychosis and improved behavior, but EPS and somnolence were common adverse effects.[113] Low doses of olanzapine, 5 to 15 mg/day, were superior to placebo for reducing agitation, aggression, and psychosis during a 6-week study among nursing facility residents.[114] Somnolence and gait disturbances were the most common adverse effects. Quetiapine has been shown to reduce agitated and psychotic behaviors at doses of 100 to 200 mg/day.[115] Clozapine poses significant risk for hematologic toxicity and requires careful monitoring. Because T.G. does not have cardiovascular or cerebrovascular risk factors and does not have gait or balance problems, either risperidone 0.25 mg at bedtime or quetiapine 25 mg at bedtime can be initiated. Doses of risperidone may be increased by 0.25 mg/day in weekly intervals, up to 2 mg/day; quetiapine doses can be increased by 25 mg/day, up to 200 mg/day in divided doses. Once his behavior has stabilized, the medication should be continued for about 3

months. At that time, the dose should be decreased in weekly intervals to determine whether the medication is still required. T.G. should be monitored closely for adverse effects, including EPS, which can occur with the atypical antipsychotics.[110,116]

Aggressive Behaviors

CASE 108-4, QUESTION 3: After 3 months, T.G.'s delusions have subsided, but he continues to be verbally abusive and often displays angry, emotional outbursts, especially when he requires help with bathing or toileting. At other times, he is withdrawn and apathetic. He has also been found wandering in the neighborhood on three occasions. These behaviors persist despite treatment with quetiapine 100 mg twice daily. What alternative treatments can be attempted?

Although psychotic symptoms respond to antipsychotic agents, many other behaviors do not. Up to 90% of patients with dementia exhibit at least one disruptive behavior such as angry outbursts, screaming, and abusive language, and many display multiple aggressive behaviors.[110] As many as 32% exhibit moderate to severe behaviors.[110] Such behaviors are typically directed at caregivers, precipitated by receipt of assistance with activities of daily living such as bathing and toileting, and increase in frequency with dementia severity.[99,117] Several of these behaviors may be merely defensive responses to perceived threats in cognitively impaired individuals.[117] Behavioral disturbances must be addressed because they can have a negative effect on the patient's ability to perform activities of daily living.[99]

Some behaviors exhibited by T.G. are not likely to respond to medications. Wandering is typically unaltered by the use of medications unless the patient is oversedated. Non-pharmacologic treatments, such as periods of physical exercise and rest, or environmental modification is much more effective.[99,103,118] T.G.'s reactions to assistance with bathing and toileting may be caused by confusion and fear. Breaking the tasks down to step-by-step procedures, accomplished individually, often helps modify aggressive behaviors.[41]

Verbal abuse and aggressiveness place both the patient and the caregiver at risk for injury, and may lead to abuse. In these situations, the patient and the caregiver may each be a precipitator or a target of abuse.[119] In some small studies, anticonvulsant agents have been shown to reduce rage and aggressive behaviors in patients resistant to treatment with antipsychotics. Carbamazepine and valproic acid (including divalproex) are the most well-studied agents.[110,116] Although initial trials were promising, later studies did not establish efficacy. The lack of benefit plus concerns about toxicities with each agent have led to recommendations that these agents not be used.[95,109] The addition of an antidepressant medication may be helpful, as described below. Wandering typically does not respond to pharmacologic intervention. Appropriate strategies include environmental modification, such as placing child-safety locks on exit doors; providing activities and other distractions; and having a safety plan, such as the Safe Return program. As described for his paranoid behavior, a person-centered evaluation using the A-B-C approach should be conducted to determine the cause and effects of his aggressiveness. If T.G.'s aggressive behaviors continue, his family may need to consider obtaining in-home assistance or placement in an assisted-living facility designed for the care of patients with dementia.

Depression

CASE 108-4, QUESTION 4: How should T.G.'s social withdrawal and apathy be treated?

Depression often accompanies dementia and may significantly impair a patient's functional capacity, cognitive abilities, and communication.[95,109] T.G. is withdrawn and apathetic, symptoms suggestive of depression. Screaming and irritability may be considered symptoms of depression in individuals with dementia, perhaps reflecting feelings of loneliness, boredom, or the need for attention.[120] Because a definite diagnosis of depression relies heavily on a patient interview and response to questions, a formal diagnosis in patients with dementia is difficult. Therefore, patient observation is an important component for making a clinical evaluation. It is possible that he is reacting to a sense of loss of not only his memory and function, but also a loss of self. He also may feel isolated by the inability to communicate with others or participate in the outside world. Helping him to engage in meaningful activities and social engagement, perhaps as simple as going on a walk or attending adult day care, may help alleviate his apathy and reverse his withdrawal. Such a strategy is appropriate to try before considering an antidepressant.

The selective serotonin reuptake inhibitors have not been well studied in patients with dementia, but are effective antidepressants with adverse effects that are better tolerated than those of the tricyclic antidepressants. Sertraline, in doses of 50 to 150 mg/day, was superior to placebo in reducing depression in AD patients during a 12-week trial.[121] Citalopram has also demonstrated effectiveness; in contrast, fluoxetine and fluvoxamine have not demonstrated benefit.[104,110] Either sertraline 50 mg daily or citalopram 10 mg daily are reasonable choices to treat T.G.'s symptoms of depression if he does not respond to nonpharmacologic strategies. He should be reassessed in 1 month; if he has not responded, the dose may be increased. Dosages may be increased weekly up to a maximum of 150 mg/day or 20 mg/day, respectively. A full therapeutic trial requires a minimum of 3 months.

Social Support

CASE 108-4, QUESTION 5: T.G.'s family indicates that caring for him at home has become so burdensome that they are considering placing him in an institution. What social support services are available to families facing this decision?

Institutionalization is a typical outcome for patients in the late stages of dementia. The total care required to manage a dementia patient usually becomes unmanageable for most families as the disease progresses. Caregiver stress is often exacerbated by the patient's declining memory, inability to communicate, physical decline, and incontinence, as well as the caregiver's loss of freedom and depression. Caregivers commonly experience anger, helplessness, guilt, and worry, and suffer from physical stressors such as fatigue and illness.[41]

Outside assistance is essential to families caring for a patient with dementia. Families should be referred to the Alzheimer's Association as soon as a diagnosis of dementia is received. The association has local affiliates in most major cities. The book The 36-Hour Day is a valuable resource for families as well.[122] It describes the symptoms, behaviors, and problems that can be encountered when caring for a patient with dementia.

Support groups, individual and family counseling, and other sources of support are useful and may help families cope for a longer period. However, the key intervention to reduce caregiver stress is respite care, which allows a family time away from the responsibilities of taking care of a frail individual. Respite care brings a person into the home or allows the patient to go to a day-care center or similar environment on a regular schedule. Such programs may delay the need to institutionalize a patient.[41,42,122]

Geriatric Urologic Disorders

Tran H. Tran

CORE PRINCIPLES	CHAPTER CASES
URINARY INCONTINENCE	
1 Urinary incontinence is a common condition in older adults and can be classified as acute or persistent. Persistent incontinence can further be classified as urge, stress, overflow, or functional.	**Case 109-1 (Questions 1, 2)**
2 Urge incontinence is managed with nonpharmacologic interventions, such as a toileting schedule, and the use of anticholinergic medications.	**Case 109-1 (Questions 3, 4)**
3 Stress incontinence is managed with local estrogens, tricyclic antidepressants, and duloxetine.	**Case 109-2 (Questions 1, 2)**
BENIGN PROSTATIC HYPERPLASIA	
1 Benign prostatic hyperplasia (BPH) is the most common urologic condition in aging men. A wide range of signs and symptoms occurs in BPH that causes patients to seek care.	**Case 109-3 (Questions 1–3)**
2 Management of BPH includes the use of α_{1A}-adrenergic receptor antagonists and 5α-reductase inhibitors, either alone or in combination. Nonpharmacologic treatment and surgery may also be considered for some patients. In general, the use of over-the-counter medications should not be used to treat symptomatic BPH.	**Case 109-3 (Questions 4–7)**
ERECTILE DYSFUNCTION	
1 Erectile dysfunction (ED) is a condition that can be a result of neurogenic, hormonal, or vascular disorders. It is therefore essential that a complete urologic workup is conducted to assess the underlying pathophysiology. Underlying conditions should be addressed and treated before symptomatic therapy is initiated.	**Case 109-4 (Questions 1–6)**
2 Treatment for ED consists of a variety of pharmacologic agents, which include phosphodiesterase inhibitors, intracavernous injections, and alprostadil.	**Case 109-4 (Questions 7–14)**

URINARY INCONTINENCE

Neurophysiologic Considerations

The bladder can be thought of as a “balloon” with a narrow outlet, wrapped with a muscular layer, the detrusor muscle. The detrusor and the bladder outlet functions are coordinated neurologically to allow for storage and expulsion of urine.[1] The detrusor muscle is innervated by the parasympathetic nervous system, and the bladder neck is innervated by the sympathetic nervous system (α-adrenergic) (Fig. 109-1). The proximal smooth muscle (internal) sphincter in the bladder neck also is innervated through the sympathetic nervous system (α-adrenergic). The distal striated muscle (external) sphincter of the urethra is supplied by the somatic nervous system.

Urine storage is the result of detrusor muscle relaxation and closure of both the internal and external sphincters. Detrusor relaxation is accomplished by central nervous system (CNS) inhibition of the parasympathetic tone; sphincter closure is mediated by a reflex increase in α-adrenergic and somatic activity. Voiding occurs when detrusor contraction is coordinated with sphincter relaxation. Detrusor contraction is mediated by the parasympathetic nervous system, and relaxation requires inhibition of somatic and sympathetic nerve impulses to the outlet. The bladder capacity is ~300 mL in the elderly and ~400 mL in young adults. The relationship between the detrusor and the outlet is coordinated by a micturition center located in the CNS, perhaps in the pons.[2] The cortex and diencephalon also permit inhibition of what would otherwise be a reflex contraction of the detrusor muscle in response to bladder distension.

Age-Related Changes

Aging affects the lower urinary tract in several ways (Table 109-1), including both structural and functional changes. Bladder capacity, the ability to postpone voiding, urethral and bladder compliance, maximal urethral closure pressure (the maximal difference between the urethral and the intravesical pressure), and urinary flow rate all are reduced with normal aging.[2,3] For women, these changes are correlated with the postmenopausal decline of estrogen production. Estrogen has trophic effects on the epithelium and on tissues lining and surrounding the urethra, bladder outlet, and vagina. Atrophy of these tissues can result in friability, inflammation, susceptibility to infection, diminished periurethral blood flow, and prolapse of pelvic structures. All of these effects can precipitate symptoms of urinary incontinence. For men, the age-related changes in the prostate gland are responsible for many of the changes in urination. The most common age-related change, in both women and men, is involuntary bladder contractions (detrusor motor instability). These involuntary bladder contractions occur in up to 20% of asymptomatic, neurologically normal, continent elderly patients.[4–7]

Causes of Incontinence

	Mnemonic: DIPPERS
D	Delirium
I	Infection
P	Psychological
P	Pharmaceuticals
E	Excess urine output
R	Reduced mobility
S	Stool impaction (and other factors)

Source: Wagg A et al. Urinary incontinence in frail elderly persons: report from the 5th International Consultation on Incontinence. Neurourol Urodyn. 2015;34(5):398–406.

Each of these changes predisposes people to incontinence, but none alone precipitates it. This predisposition to incontinence, together with the increased likelihood that an older person will be subjected to additional pathologic, physiologic, or pharmacologic insults, underlies the higher incidence of incontinence in the elderly. The onset or exacerbation of incontinence in an older person is likely to be caused by a precipitating factor outside the lower urinary tract.[8] Common treatable causes of urinary incontinence in the elderly can be described with the mneumonic DIPPERS (Table 109-2).[9] Correspondingly, reversal of the precipitating factor may be sufficient to restore continence without correction of the underlying urologic abnormality.

Loss of bladder control in the elderly was reported in 36.7% of short-term residents and 70.3% of long-term residents in nursing homes.[10] Moderate, severe, and very severe levels of bladder incontinence were identified in 24.0% of noninstitutionalized elderly patients.[10] Incontinence has economic costs, and medical (e.g., cystitis, urosepsis, pressure sores, perineal rashes, falls) and psychosocial (e.g., embarrassment, isolation, depression, predisposition to institutionalization) consequences. Nevertheless, incontinence often is a neglected condition. Patients may not report incontinence to their primary-care providers because of embarrassment or misconception regarding treatment. Incontinence is not an inevitable consequence of aging. It is a pathologic condition that, when rationally approached, usually can be ameliorated or cured, often without invasive tests or surgery and almost invariably without an indwelling catheter.[11,12]

Classification

Urinary incontinence can be classified in several different ways. The two most basic types of urinary incontinence are (a) acute

(or transient) and reversible and (b) chronic and persistent. Persistent urinary incontinence (PUI), which refers to incontinence that is not acute and occurs for a long time, can be classified further into four subgroups: (a) urge, (b) stress, (c) overflow, and (d) functional.

ACUTE INCONTINENCE

Urinary incontinence that is of relatively recent onset or associated with an acute medical problem should prompt a review for reversible factors. These include the following: (a) cystitis, atrophic vaginitis, and urethritis; (b) heart failure; (c) polyuria from diabetes; (d) delirium and acute confusional states; (e) immobility; and (f) medication side effects (discussed subsequently). The management of acute forms of urinary incontinence depends on the identification and elimination of the reversible factor.

For women with urethritis and atrophic vaginitis with irritative voiding symptoms, estrogen replacement can be very helpful. An intravaginal estrogen cream is administered nightly for 7 days, followed by at least once-a-week application.[13] In keeping with the Women's Health Initiative trial, serious risks, including breast cancer and cardiovascular disease, appear to outweigh long-term benefits of systemic combination of hormone therapy. Therefore, topical therapy is preferred.[14]

Drug-Induced Urinary Incontinence

Several medications are associated with acute-onset urinary incontinence, including diuretics, α-adrenergic agonists (e.g., pseudoephedrine), α-adrenergic antagonists (e.g., terazosin), anticholinergics, and neuroleptics.

Reports of female stress incontinence from α_1-adrenergic receptor antagonists, which have a relaxant effect on urethral smooth muscle, have appeared in the medical literature.[15–17] In one study, the incidence of genuine stress incontinence was significantly higher in women taking prazosin (86.2%) than in the group without prazosin (65.7%; $p < 0.01$). In 55% of the women contacted in the prazosin group, urinary incontinence was reduced or cured by prazosin withdrawal.[18] There was a significant increase in functional urethral length, maximal urethral closure pressure, and abdominal pressure transmission to the urethra after prazosin withdrawal. In one case report, switching from doxazosin to enalapril briefly reduced the female patient's stress incontinence; however, she experienced a persistent dry cough (from the enalapril) that continued to cause episodic stress incontinence. Her cough and stress incontinence resolved when she was switched to amlodipine.[19]

PERSISTENT URINARY INCONTINENCE

Urge Incontinence

Urge incontinence, the most common form of incontinence affecting the elderly, occurs when involuntary voiding is preceded by a warning of a few seconds to a few minutes. Urge PUI is characterized by precipitous urine leakage, most often after the urge to void is perceived. Urge PUI can be caused by a variety of genitourinary and neurologic disorders. It most often, but not always, is associated with detrusor motor instability (involuntary contraction of the bladder) or detrusor hyper-reflexia (detrusor motor instability caused by a neurologic disorder). The most common causes are local genitourinary conditions, such as cystitis, urethritis, tumors, stones, bladder diverticula, and outflow obstruction. Neurologic disorders, such as stroke, dementia, parkinsonism, and spinal cord injury, can be associated with urge PUI.[8] Overactive bladder is a medical syndrome defined by symptoms of urgency, with or without urge urinary incontinence, usually with frequency and nocturia. By definition, overactive bladder is a syndrome and not a diagnosis.

Stress Incontinence

Stress incontinence is the involuntary leakage of urine that occurs when an abrupt increase in intra-abdominal pressure (“stress,” e.g., coughing, sneezing, laughing, lifting) overcomes urethral resistance. Stress incontinence is common in elderly women but uncommon in men (unless the sphincter has been damaged during a transurethral resection of the prostate [TURP] or a prostatectomy). Typical stress PUI is characterized by daytime loss of small-to-moderate amounts of urine, infrequent nocturnal incontinence, and a low postvoid residual volume in the absence of a large cystocele. Stress incontinence can be diagnosed by the “tissue test” in which a tissue is placed just below the urethra and the patient is asked to cough, resulting in the loss of a small amount of urine. The usual cause of stress PUI is urethral hypermobility owing to weakness and laxity of pelvic floor musculature, but other conditions, such as sphincter incompetence, urethral instability, or stress-induced detrusor instability, occasionally are responsible.[2] Obesity or TURP in men also can predispose individuals to stress incontinence. Many factors have been suggested to contribute to the development of urinary stress incontinence in women, including estrogen deficiency and a genetic defect in the connective tissue in such patients. The prevalence of urinary stress incontinence among first-degree relatives of patients with urinary incontinence is 3 times ($p < 0.005$) that of matched control groups of women without micturition disorders.[20]

Overflow Incontinence

Overflow incontinence occurs when the weight of urine in a distended bladder overcomes outlet resistance. Leakage of small amounts of urine (dribbling) is common throughout the day and night. The patient may complain of hesitancy, diminished and interrupted flow, a need to strain to void, and a sense of incomplete emptying. The bladder usually is palpable, and the residual urine volume is large.

Overflow incontinence results from an anatomic outlet obstruction or an acontractile (or atonic) bladder.[8] Common causes are benign prostatic hyperplasia (BPH), urethral stricture, bladder sphincter dyssynergia, diabetic neuropathy, fecal impaction, and anticholinergic medication use. If the cause is neurologically mediated, control of the perianal sphincter may be impaired.[21]

Functional Incontinence

Functional incontinence occurs when a continent individual is unable or unwilling to reach the toilet to urinate. Common causes are musculoskeletal disorders, muscle weakness, impaired mental status, use of physical restraints, psychological impairment, environmental barriers, and medications (e.g., sedatives, neuroleptics).

Clinical Presentation and Evaluation

CASE 109-1

QUESTION 1: H.K., an 83-year-old female resident of a nursing facility with moderate dementia, had urinary incontinence 3 years before admission. She has been managed with adult diapers (briefs) and bladder training. What objective and subjective data are needed to determine the pathophysiology (and hence the classification) of H.K.'s urinary incontinence?

The rationale for the clinical evaluation of H.K. is to classify the imbalance between bladder pressure and bladder sphincter resistance and, as a result, institute appropriate medical or surgical management of her urinary incontinence.

Documentation of H.K.'s urinary incontinence is accomplished most easily by keeping an incontinence record. Observations should be recorded every 2 hours regarding whether she is wet or dry, as well as associated symptoms or circumstances. A record maintained for 3 to 4 days will facilitate assessment of the voiding pattern. Knowledge of the voiding pattern can be used to design bladder training programs and to detect iatrogenic causes (e.g., diuretic ingestion, use of restraints). Successful bladder training relies on estimating when the bladder is full.

Physical examination, including a neurologic assessment, of H.K. is needed to determine the cause and classification of her urinary incontinence. Clinical findings may identify specific pathophysiologic abnormalities. H.K. should have a thorough pelvic examination to determine the contribution of atrophic vaginitis, uterine prolapse, and bladder anatomy. Funneling of the bladder neck suggests stress incontinence, and palpation of the bladder suggests overflow incontinence. The presence of physical restraints or musculoskeletal disability would suggest functional incontinence.

H.K.'s bladder should be catheterized immediately after urination to determine residual urine volume. Alternatively, if a bladder ultrasound is available, the volume can be measured noninvasively. Volumes in excess of 50 to 100 mL in the elderly are abnormal and may indicate retention due to obstruction or an adynamic detrusor muscle. If urinary retention is chronic, the patient may require clean intermittent self-catheterization. Although urodynamic studies are widely recommended and used, little evidence suggests that these produce clinically useful data for institutionalized geriatric patients. A urinalysis, blood chemistries, renal function, and postprandial glucose tests should be performed. An abnormal urinalysis may suggest pathology (e.g., infection) that can be managed medically. Urinary tract infection is common in the incontinent patient.

Treatment options exist for each type of urinary incontinence (Table 109-3).

Proper evaluation should guide the clinician in choosing the optimal course of drug therapy. Drug therapy should be based on sound principles of neurophysiology, urology, and pharmacology. Drug therapy is directed at decreasing bladder contractility (detrusor instability) or increasing bladder outlet resistance (bladder neck and proximal urethra).

Table 109-3

Drug Therapy of Persistent Urinary Incontinence

Type	Treatment With Initial Doses
Urge	Oxybutynin 2.5 mg every day to TID; 5–30 mg XL every day Oxybutynin transdermal patch 3.9 mg/24 hour 1 patch 2×/week Oxybutynin 10% topical gel 100 mg/g every day Oxybutynin 3% topical gel 84 mg (3 pumps) every day Tolterodine 1–2 mg every day; 2–4 LA every day Trospium 20 mg BID; 60 mg ER every day Darifenacin 7.5 mg every day Solifenacin 5 mg every day Fesoterodine 4 mg every day
Stress	Pseudoephedrine 15–30 mg BID–TID Imipramine 25 mg every day Vaginal estrogen cream 0.5–1.0 g 2 to 3 times/week Duloxetine 40–80 mg every day divided in one or two doses
Overflow	Terazosin 1–5 mg every day (usually at bedtime) Doxazosin 1–8 mg every day Tamsulosin 0.4–0.8 mg every day Alfuzosin 10 mg every day Silodosin 4–8 mg every day Bethanechol 10 mg TID
Functional	None

BID, 2 times daily; LA, long acting; TID, 3 times daily; XL, extended release.

CASE 109-1, QUESTION 2: The incontinence record maintained by the nursing staff indicates that H.K. has urinary urges quite frequently, resulting in urine leakage. Throughout the day and night, H.K. urinates 4 to 5 times. Physical examination reveals atrophic vaginitis, no funneling of the bladder neck, and no bladder distension. H.K. does have a history of stroke. The urinalysis is normal, as are the blood chemistries. Postvoiding bladder scan revealed a residual urine volume of 30 mL. What is the pathophysiology and classification of H.K.'s incontinence?

Most neuropathic disease processes can change bladder function. As illustrated by H.K., a cerebrovascular accident is commonly associated with bladder dysfunction and incontinence in the elderly. Neurologic injury above the level of the micturition center in the spinal cord, in most cases, results in bladder spasticity. Sacral reflexes are intact, but loss of inhibition from higher CNS centers results in spastic bladder and inappropriate sphincter behavior. The degree of spasticity varies between the bladder and sphincter, as well as from patient to patient with the same CNS lesions. H.K. has a spastic detrusor muscle resulting from an unchecked sacral reflex. H.K.'s bladder dysfunction is classified as urge urinary incontinence of the persistent type.

Nonpharmacologic Therapy

A number of nonpharmacologic options are available that may help improve the symptoms of PUI. The first step is to educate patients about bladder function, appropriate fluid intake, and avoidance of caffeine and other bladder irritants. The patient can then keep a bladder diary in which they record their fluid intake, voiding pattern, and incontinence episodes. Bladder training refers to scheduled voiding, urge-suppression techniques, and pelvic muscle exercises. Scheduled voiding can be used in both cognitively intact and impaired individuals. The patient is instructed to void on a schedule (e.g., every 2 hours), thereby minimizing the volume of urine in the bladder and making incontinence episodes less likely. The same principle can be used in cognitively impaired patients by prompting them to toilet. Urge-suppression techniques can be used to retrain the bladder; the scheduled toiletings are adjusted for longer or shorter times, depending on the patient's voiding pattern. The goal is to achieve an interval during which the patient is continent and does not need to void. In most patients, this is approximately 2 hours. Pelvic floor muscle exercises, also known as Kegel exercises, work by increasing the strength and tone of the pelvic floor muscles. In randomized trials, incontinence episodes were reduced by 54% to 75% compared with 6% to 16% with no treatment.[22] The patient should receive adequate instruction on how to identify the pelvic floor muscles and then practice these exercises 3 times a day.

CASE 109-1, QUESTION 3: What nonpharmacologic therapy should be recommended for H.K.?

H.K. should have a comprehensive review of her medications completed to determine any temporal relationship between medications and incontinence episodes. She should then be placed on a toileting schedule in which she is prompted to void every 2 hours. The nursing staff should continue to keep a bladder diary in which they record fluid intake and when she is wet and dry. This information can be used to tailor her toileting schedule to make sure H.K. has the best outcome while at the same time being practical, based on staffing at the institution. Because of H.K.'s moderate dementia, the teaching of pelvic floor muscle exercises may not be feasible.

Drug Therapy

ANTICHOLINERGIC AGENTS

CASE 109-1, QUESTION 4: What drug therapy should be prescribed for H.K.?

H.K. has detrusor instability that may respond to anticholinergic drug therapy if nonpharmacologic measures do not produce desired results. The major neurohormonal stimulus for physiologic bladder muscle contraction is acetylcholine-induced stimulation of postganglionic parasympathetic cholinergic receptor sites on bladder smooth muscle. Atropine and atropine-like substances depress true involuntary bladder contractions of any etiology by the interaction at the muscarinic receptor.[23] Of the five known muscarinic subtypes (M_1 through M_5), M_3 appears to be the most clinically relevant in the human bladder. M_2 muscarinic receptors are the predominant subtype (comprising about 80% of all muscarinic receptors); however, contraction of smooth muscle, including muscles in the urinary bladder, is mediated mainly by M_3 receptors. M_3 receptors are also involved in contraction of the gastrointestinal smooth muscle, saliva production, and iris sphincter function.[24] Inhibition of the muscarinic receptors in the urinary bladder results in decreased urinary bladder contraction, increased residual urine volume, and decreased detrusor muscle pressure.

Oxybutynin Chloride

Oxybutynin is available as an oral immediate-release tablet, an extended-release tablet, a transdermal system, and a topical gel. Oxybutynin has been described as a strong independent smooth muscle relaxant with local anesthetic activity and anticholinergic effects.[23,25] This agent has been used successfully to depress uninhibited detrusor contractions in patients with and without neurogenic bladder dysfunction. Oxybutynin improves symptoms, total bladder capacity, neuropathic voiding dysfunction, and bladder filling pressure.[26–28] The oral dosage of oxybutynin chloride suggested for the elderly is 2.5 mg up to 3 times a day; in some cases, the dosage may need to be increased to 5 mg 3 times a day. Because oxybutynin is a tertiary-amine anticholinergic compound and also blocks central M_1 receptors, the potential for CNS toxicity increases as the dose is increased. Once-daily, controlled-release oxybutynin at doses of 5 to 30 mg reduced the number of incontinence episodes.[29,30] Maximal benefit was demonstrated by maintenance week 4 and was sustained as long as the patient continued therapy.[31]

The transdermal system is available both in a prescription and over-the-counter version and contains 36 mg of active drug and delivers 3.9 mg of oxybutynin per day when dosed twice a week.[32] The transdermal system should be protected from moisture and humidity. Common side effects from the transdermal system at the application site are pruritus (14%) and redness (8.3%). A comparison study of immediate-release oxybutynin and the transdermal system indicated that patients using the transdermal system experienced fewer side effects. Dry mouth was reported in 38% of the oxybutynin transdermal system users in contrast to 94% of those who used immediate-release tablets.[33] Oxybutynin is also available as a 10% topical gel in 1-g unit dose sachets. One sachet delivers 100 mg and is applied per day to the abdomen, thigh, upper arm, or shoulder. It is also available as a 3% gel in a multi-dose container. The dose is three pumps (84 mg) daily. Application site reactions were reported in 5.4% of patients, and dry mouth was reported in 6.9% of patients.[34]

Tolterodine Tartrate

Tolterodine is a competitive muscarinic receptor antagonist that is relatively selective for M_2 and M_3 receptors. It is indicated for the treatment of overactive bladder symptoms of urinary frequency or urge incontinence. At doses of 1 to 2 mg twice a day, compared with a placebo, the number of urinary voids per 24 hours decreased ($p = 0.0045$), the volume of urine per void increased ($p < 0.001$), and the mean number of incontinence episodes decreased by 50% ($p < 0.19$).[35] Although tolterodine can modestly prolong the QT interval, no clinical or electrocardiographic evidence was seen of significant cardiac adverse events in the group studied.[35,36] The onset of pharmacologic action of tolterodine is less than 1 hour, and therapeutic efficacy is maintained during long-term treatment.

Despite short terminal half-lives of 2 to 3 hours and 3 to 4 hours for tolterodine and its active 5-hydroxy metabolite, respectively, twice-daily dosing is effective because of the drug's long pharmacodynamic effects.[37] Dosage adjustment is recommended in the presence of renal or hepatic impairment and during concurrent therapy with drugs that inhibit cytochrome P-450 (CYP) 2D6 and CYP3A4 isozymes. The usual dose for the elderly is 1 to 2 mg twice daily of the immediate release or 2 to 4 mg once daily of the long-acting formulation. The incidence of dry mouth with the long-acting formulation is 23%.[36]

Fesoterodine

Fesoterodine is an antimuscarinic prodrug that is converted into the same active metabolite as that of tolterodine. The efficacy and safety of fesoterodine appear comparable to those of tolterodine.[38] The recommended starting dosage of fesoterodine is 4 mg once daily and may be increased to 8 mg in patients with an insufficient response. Patients with severe renal impairment (creatinine clearance <30 mL/minute) or those taking a strong CYP3A4 inhibitor should not take more than 4 mg/day.

Trospium Chloride

Trospium is a quaternary ammonium antimuscarinic agent with relative selectivity for M_2 and M_3 receptors. It is used for the management of overactive bladder and urge incontinence. The hydrophilic properties of trospium minimize the passage of the drug through the blood–brain barrier, thereby causing fewer CNS and cognitive adverse events.[39] No significant differences were found in urodynamic outcomes between trospium and oxybutynin in a 52-week study.[40] The reduction in 24-hour micturition frequency and urgency episodes at 26 and 52 weeks of treatment was also not significant. However, the incidence of dry mouth and gastrointestinal adverse events was significantly lower in the trospium group. The medication should be administered at a dose of 20 mg twice daily or 60 mg of the extended-release product once daily. For patients with severe renal insufficiency (creatinine clearance <30 mL/minute), the dose should be reduced to 20 mg once daily. Trospium has no CYP-related drug interactions and should be taken on an empty stomach to avoid decreasing absorption.

Darifenacin

Darifenacin is a selective M_3 muscarinic receptor antagonist indicated for the treatment of overactive bladder with symptoms of urinary incontinence, urgency, and frequency. A pooled analysis of three 12-week, double-blind, placebo-controlled trials (n = 1,059) demonstrated that darifenacin reduced the median number of incontinence episodes per week ($p < 0.01$) versus placebo.[41] Dry mouth and constipation were the most common reasons for discontinuation. The recommended starting dose is 7.5 mg once daily. Based on the individual response, the dose may be increased to 15 mg daily after 2 weeks.

Solifenacin

Solifenacin is a competitive muscarinic receptor antagonist that is selective for M_3 receptors. It is used for the treatment of overactive bladder with symptoms of urinary incontinence. In clinical trials, solifenacin showed significant reduction in the symptoms

of urinary frequency, urgency, and urge incontinence compared with placebo.[42,43] Safety concerns with solifenacin include an increased risk of QT interval prolongation in patients with a known history of QT interval prolongation or patients who are taking medications known to prolong the QT interval. The recommended dose of solifenacin is 5 mg once daily, which can be increased to 10 mg once daily if needed. However, in those with renal and hepatic impairment or on CYP3A4 inhibitors, the dose should not exceed 5 mg once daily.

β-ADRENERGIC AGENTS

Mirabegron is a first in class β_3-adrenergic agonist approved for use in overactive bladder. The human bladder muscle has $\beta_{1,2,3}$-adrenergic receptors; however, β_3-adrenergic receptors account for 95% of the β-receptors and are most likely responsible for detrusor relaxation.[44] Compared to placebo, mirabegron was able to reduce the mean number of incontinence episodes per 24 hours by –0.44 (95 %

confidence interval (CI) –0.59 to –0.29, $p < 0.00001$).[45] The efficacy of mirabegron is sustained at 12 months, and its safety is notable for significantly less dry mouth and constipation compared to antimuscarinics.[46] Although mirabegron has not been studied in patients with dementia, clinical trials have not reported any CNS adverse effects with mirabegron. Mirabegron can be used alone or in combination with antimuscarinics for those who cannot tolerate an increase in the antimuscarinic dose or are already on a maximum dose. Mirabegron is initiated at 25 mg once daily and can be titrated up to 50 mg once daily in 2 to 4 weeks. Patients with renal or hepatic impairment should not receive doses higher than 25 mg once daily. Blood pressure increases have been reported with mirabegron (>10%) particularly in patients with uncontrolled hypertension and thus warrant careful monitoring.[47] Mirabegron is also a CYP2D6 inhibitor, and drugs that are CYP2D6 substrates taken concomitantly may require dose adjustments.

Although any of the aforementioned drugs may be useful for H.K., a careful consideration of adverse event profile should be considered before prescribing an anticholinergic agent. The rate of decline in activities of daily living and cognition in patients with dementia was 50% faster when anticholinergic medications were combined with acetylcholinesterase inhibitors than when acetylcholinesterase inhibitors were used alone.[48] Even though H.K. is not treated with an acetylcholinesterase inhibitor, she does have moderate dementia and would likely have pronounced anticholinergic side effects. In addition, the limited efficacy of anticholinergic medications needs to be carefully considered before starting treatment in H.K. A comprehensive review of placebo-controlled trials of anticholinergic medications for overactive bladder estimated that, as a class, even long-acting agents have a very limited effect on symptoms, with approximately one fewer incontinent episode and one fewer voiding episode per 48 hours.[49] Given the potential for side effects and the limited efficacy, it would be prudent to use nonpharmacologic measures (i.e., prompted voiding) to manage H.K. If the desired end points are not achieved, a trial of an anticholinergic medication could be considered. Mirabegron may potentially be a safe option in patients with dementia; however, future studies to promote its use over anticholinergics in this population would be beneficial. All agents in this group should be prescribed for a 2-week trial period with careful monitoring for efficacy and side effects.

INCREASING BLADDER OUTLET RESISTANCE

CASE 109-2

QUESTION 1: M.K., a 68-year-old woman, has been diagnosed with urinary stress incontinence. What therapy would be appropriate for this type of PUI?

M.K. should initially be educated on pelvic floor muscle or Kegel exercises. Several methods have been effectively used to help patients identify and correctly exercise the pelvic floor muscles, including self-help books, biofeedback, electrical stimulation, and verbal feedback during physical examination by a physician.[22] Once the pelvic floor muscles have been identified, M.K. should empty her bladder and sit or lie down. She should contract her pelvic floor muscles, holding the contraction for 5 seconds, and then relax for 5 seconds. This should be repeated 5 times with a goal of 10-second contractions for M.K. She should practice these exercises 3 times a day.

CASE 109-2, QUESTION 2: M.K. has incomplete resolution of her stress incontinence symptoms. Physical examination indicates urogenital atrophy. What are the pharmacologic options for stress incontinence?

Imipramine Hydrochloride

The pharmacologic mechanism of tricyclic antidepressants (TCAs) in treating PUI at best is speculative.[50] All the TCAs have some degree of anticholinergic effect, both centrally and peripherally, but not at all sites. Imipramine has significant systemic anticholinergic effects, but it has weak anticholinergic effects at the detrusor muscle.[51] Imipramine has a significant inhibitory effect on the detrusor muscle that is mediated by neither anticholinergic nor adrenergic mechanisms. Its detrusor inhibitory effect may be the result of peripheral blockade of norepinephrine reuptake. The ability of imipramine to increase bladder outlet resistance is believed to be attributable to enhanced α-adrenergic effects in the smooth muscle of the bladder base and proximal urethra, where α-receptors outnumber β-receptors. The significant anticholinergic side effects associated with imipramine make it a poor treatment option in the elderly.

α-Adrenergic receptor stimulation at the detrusor muscle and proximal urethra will increase the maximal urethral closure pressure.[52] However, α-adrenergic agonists, such as pseudoephedrine, have a minimal role in the treatment of stress urinary incontinence because the risk of adverse events exceeds the limited benefit it is likely to provide.

Duloxetine

Duloxetine is a serotonin and norepinephrine reuptake inhibitor that has shown efficacy in patients with stress incontinence. Duloxetine also treats depression, and though not FDA-approved for the treatment of stress incontinence, it could be a reasonable option for a woman with both depression and stress incontinence. A meta-analysis of nine trials including 3,063 women predominately with stress incontinence showed duloxetine-treated patients had a reduction in the incontinence episode frequency by approximately 50%; however, the absolute reduction (10.8% vs. 7.7%) in incontinence episodes was small, suggesting that any benefits would be modest. Adverse effects were common, with 71% of duloxetine-treated patients reporting side effects and approximately one in eight patients discontinuing treatment.[53] The most common adverse effect with duloxetine is nausea, which tends to resolve with time. The dose of duloxetine that has been studied for stress incontinence is 40 to 80 mg/day in one or two doses. The clinical effects of duloxetine appear to be modest and need to be weighed against the risk of adverse events.

Estrogens

Estrogens affect many aspects of uterine smooth muscle, including excitability, receptor density, and transmitter metabolism, especially adrenergic nerves.[54] The detrusor and urethra are embryologically related to the uterus, and significant work has been done on estrogenic hormone effects on the lower urinary tract.

α-Adrenergic stimulation of the urethra is estrogen dependent,[55] and several studies have demonstrated the relationship of estrogen with α-adrenergic receptor density in the lower urinary tract.[56] Estrogen therapy, in the form of vaginal suppositories (10 mcg/day), facilitates urinary storage in some postmenopausal patients by increasing urethral outlet resistance, and it has an additive effect with α-adrenergic therapy.[15] Additional preparations of estrogen include a vaginal ring that is inserted into the vagina and removed after 90 days. The ring releases 7.5 mcg of estradiol each day over a 90-day period. The use of estrogen in the treatment of stress PUI requires further study. The use of long-term estrogen treatment must be considered carefully in light of the controversy about whether estrogen therapy predisposes to the development of endometrial carcinoma. If estrogen is combined with α-adrenergic agonist therapy, the lowest effective maintenance dose should be prescribed.

M.K.'s incomplete resolution of stress incontinence symptoms is probably caused by urogenital atrophy. She would respond well to an intravaginal estrogen cream, which will improve local blood flow and dryness. An estrogen cream such as estradiol should be prescribed at a dose of 0.5 g of cream 3 times a week. The combination of local estrogen therapy and pelvic floor muscle exercises should eliminate M.K.'s symptoms.

DECREASING BLADDER OUTLET RESISTANCE

Overflow incontinence in female patients resulting from outlet obstruction or weak detrusor muscle is now being treated with α_{1A}-blockers by many urologists. Most α_{1A}-receptors are found in prostate tissue; however, these same receptors are also located in the spinal cord, bladder neck, urethra, and periurethral tissue in women.[57] The urinary symptoms suggestive of prostatism are not sex-specific. Well-controlled, randomized, crossover studies are needed to determine the efficacy of α_{1A}-blockers in overflow incontinence. If detrusor underactivity is the known cause of overflow incontinence, bethanechol can be considered. As a cholinergic agent, bethanechol increases bladder muscle tone causing contractions that initiate urination. Common adverse effects with bethanechol include flushing, tachycardia, abdominal cramps, and malaise.

BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia (BPH), a common cause of urinary dysfunction symptoms in elderly men, results from proliferation of the stromal and epithelial cells of the prostate gland.[58,59] There is both a static and a dynamic component to prostate enlargement. The static component increases the prostate size by smooth muscle cell proliferation in the prostate stroma, whereas the dynamic component contributes to an enlarged prostate through an increase in smooth muscle tone in the prostate and bladder neck. The term benign prostatic hypertrophy often is used inappropriately because the prostate gland pathology results from hyperplasia rather than hypertrophy. BPH rarely is detected in men younger than 40 years of age. After age 40, the prevalence of BPH is age dependent.[60] Approximately 75% of men who live to the age of 70 exhibit clinical symptoms of BPH that are sufficiently severe to necessitate medical attention, and approximately 90% of octogenarians have evidence of BPH. Essentially, all men will experience BPH if they live long enough. The microscopic incidence of BPH is fairly constant among several Western and developing countries,[61] suggesting that the initiation of BPH may not be environmentally or genetically influenced. Although BPH and prostatic cancer often coexist, no compelling evidence indicates that BPH predisposes patients to the development of prostate cancer.[62] The appearance of atypical prostatic hyperplasia correlates, however, with the presence of latent prostatic carcinoma.[63]

The cause of BPH is unclear; however, most hypotheses are based on hormonal and aging processes. This is because intact, normally functioning testes are essential for BPH to develop,[64] and castration before puberty prevents the development of BPH. The prostate is dependent on androgens both for embryologic development and for maintenance of size and function in the mature male.[65] Testosterone, the major circulating androgen, is metabolized to dihydrotestosterone (DHT) by 5α-reductase. The two isoenzymes of 5α-reductase are designated as type 1 and type 2. Type 2 is found predominantly in the prostate and other genital tissues, whereas type 1 is found throughout the body, as well as in the prostate.[66] For testosterone to be active in the prostate, it must be converted to DHT; therefore, DHT is the obligate androgen responsible for normal and hyperplastic prostate growth. Within the prostate, DHT initiates RNA synthesis, protein synthesis, and cell replication. The exact role of testosterone may be only to initiate fibroadenomatous hyperplasia, eventually resulting in glandular enlargement.

Stromal hyperplasia in the prostate periurethral glands is one of the earliest microscopic findings in men with BPH.[61] As men increase in age, testosterone serum concentrations decrease and the peripheral conversion of testosterone to estrogen increases. At one time, estrogens were thought to initiate stromal hyperplasia, which in turn induces epithelial hyperplasia. It is now known, however, that estrogens do not have a direct effect on the development of BPH and prostatic carcinoma, but progesterone does play a role in their pathogenesis. Progesterone receptors have been shown to exist in prostate stromal cells, whereas estrogen receptors were essentially nonexistent.[67]

Pathophysiology and Clinical Presentation

CASE 109-3

QUESTION 1: G.M., a 72-year-old man, presents to the emergency department with severe lower abdominal discomfort of 4 days' duration. His history consists of having increasing difficulty initiating urination, a significant decrease in the force of his urinary stream, occasional midstream stoppage, and postvoid dribbling. Physical examination is unremarkable except for the abdominal and rectal examination. Abdominal examination reveals distension, tenderness, and increased dullness in the hypogastrium with a large mass, believed to be the bladder. On rectal examination, the prostate is found to be severely enlarged, firm, and rubbery without nodules or undue hardness. G.M. gives a history of nocturia (approximately 4 to 5 times a night) and daytime urinary frequency (8 to 10 times a day). G.M. indicates that when he is able to urinate he has a weak stream and difficulty maintaining flow, and does not feel relieved. Laboratory findings are as follows:

Blood urea nitrogen (BUN), 45 mg/dL
Serum creatinine (SCr), 3.2 mg/dL
Serum prostatic acid phosphatase, 3 units/L
Serum prostate-specific antigen (PSA), 7.1 ng/mL

A urethral catheter was inserted, and 900 mL of urine was obtained. G.M. subsequently was scheduled for a urologic workup. What is the pathophysiologic basis for G.M.'s symptoms?

Symptoms of BPH can be both obstructive and irritative, and descriptions of the symptoms need a frame of reference for standardization. The Boyarsky index, a questionnaire consisting of nine questions to quantify the severity of BPH, has been developed.[68] Five questions are designed to assess obstructive symptoms and

four to assess irritative symptoms. Although some limitations to the use of this questionnaire (Table 109-4) may exist, it is one of the most common measures used to quantify symptoms in BPH studies, and it correlates well with the pathophysiology of BPH.[61] The format of the Boyarsky index is designed to help the clinician educate the patient about the obstructive and irritative symptoms of BPH. The Boyarsky index was the first of three patient questionnaires developed to quantitatively assess BPH and the effectiveness of individual treatment.[65] As such, this questionnaire has been used in numerous clinical trials to measure the outcome of interventions. The Boyarsky index is not useful in comparing different treatment therapies among BPH patients because it has not been sufficiently validated for this purpose; rather, it is useful in evaluating an individual's response to therapy.

The Multidisciplinary Measurements Committee of the American Urologic Association (AUA) also has published a urinary symptom index for prostatism.[69] The index is useful to assess the baseline severity of prostatism, disease progression, and effectiveness of different therapies. The AUA symptom index allows comparison among therapies and is the preferred questionnaire for BPH research. It has been validated through internal consistency reliability, constructive reliability, test–retest reliability, and criterion reliability.[65] The AUA index, however, may not be BPH specific.[70] When 101 men and 96 women between the ages of 55 and 79 used the AUA index, urinary symptoms and severity of urinary symptoms were similar in both groups. Therefore, symptoms associated with prostatism can be associated with aging as well as BPH. The National Institutes of Health convened a chronic prostatitis workshop to come to consensus on a new classification system for the diagnosis and management of prostatitis.[71] This group developed a symptom index that provides a valid outcome measure for men with prostatitis. This index attempts to quantify the pain and discomfort associated with prostatism and should help differentiate prostatism from prostatic hyperplasia. The symptom index is self-administered.

CASE 109-3, QUESTION 2: What objective findings in G.M. are associated with BPH?

G.M. presents with obstructive symptoms consistent with BPH as follows: (a) a history of difficulty in initiating urination (hesitancy), (b) a decrease in urinary force, (c) occasional midstream stoppage, (d) postvoid dribbling, and (e) a feeling of incomplete bladder emptying. The common obstructive symptom of decreased force and size of urine stream is caused by urethral compression from prostate gland hyperplasia. Hesitancy, another obstructive symptom, is the result of the bladder detrusor muscle taking a longer time to generate the initial increased pressure to overcome urethral resistance. Urinary stream intermittency is caused by the inability of the bladder detrusor muscle to sustain the increased pressure until the end of voiding. Terminal dribbling and incomplete emptying occur for the same reason, but also may be caused by obstructive prostatic tissue at the bladder neck, causing a "ball-valve" effect.

G.M. also has a history of classic irritative symptoms that are consistent with BPH as follows: (a) nocturia approximately 4 to 5 times a night and (b) daytime urinary frequency of 8 to 10 times a day. Incomplete emptying of the bladder results in shorter intervals between voiding, explaining the complaint of frequency. Also, a large prostate gland provokes the bladder to trigger a voiding response more frequently. This response is more pronounced if the prostate is growing intravesically and compromising the bladder volume. The bladder detrusor muscle becomes hypertrophied as a result of the greater bladder residual urine volume, which can result in increased detrusor muscle excitability. Clinically, this excitability may result in bladder instability. The symptoms of urinary frequency are more pronounced at night because cortical inhibitions are lessened and bladder sphincter tone is more relaxed during sleep. Obstructive symptoms are associated more with an enlarged prostate, and the predominance of irritative symptoms could suggest voiding dysfunctions in addition to those of BPH.

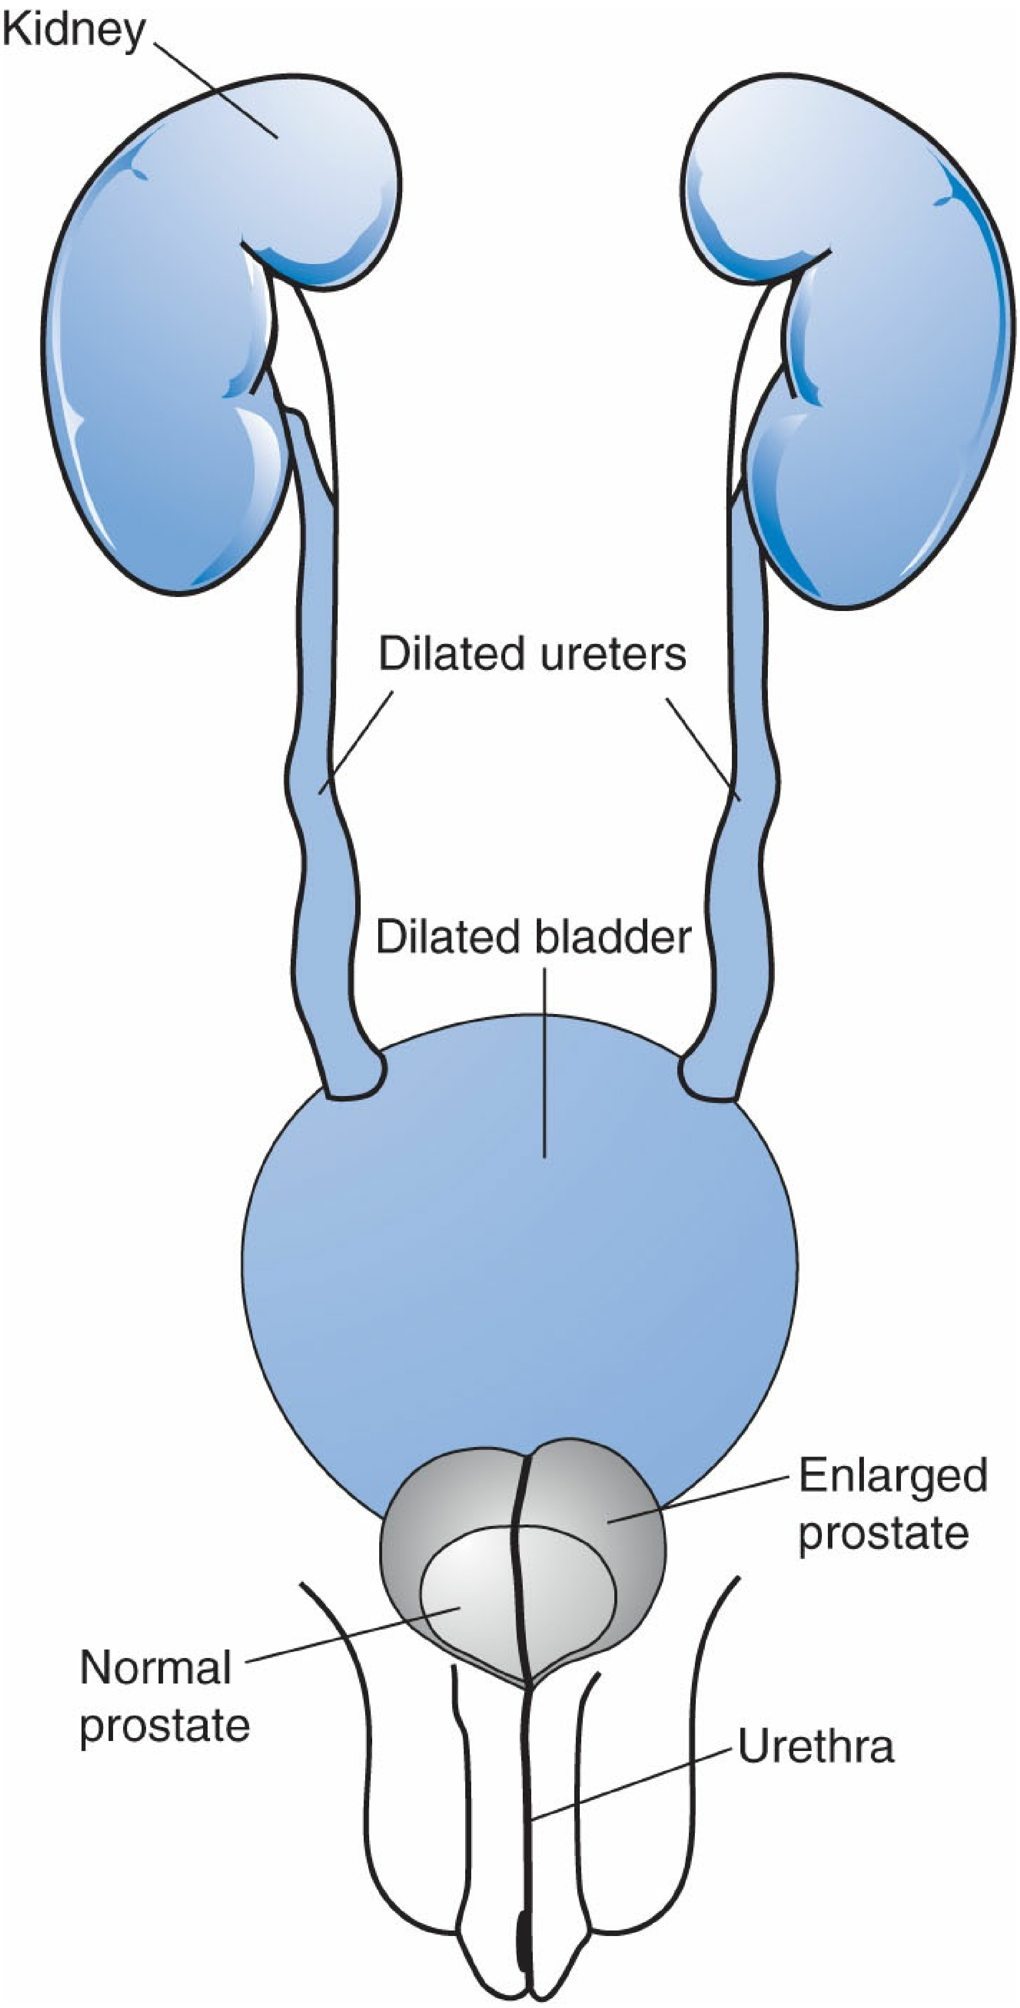
Table 109-4

Benign Prostatic Hyperplasia Symptom Scoring System (Boyarsky Index)[a]

Nocturia	
0	Absence of symptoms
1	Urinates 1 time/night
2	Urinates 2–3 times/night
3	Urinates ≥4 times/night
Daytime Frequency	
0	Urinates 1–4 times/day
1	Urinates 5–7 times/day
2	Urinates 8–12 times/day
3	Urinates ≥13 times/day
Hesitance (lasts ≥1 minute)	
0	Occasional (≤20% of the time)
1	Moderate (20%–50% of the time)
2	Frequent (≥50% of the time)
3	Always present
Intermittency (lasts ≥1 minute)	
0	Occasional (≤20% of the time)
1	Moderate (20%–50% of the time)
2	Frequent (≥50% of the time)
3	Always present
Terminal Dribbling (at end of voiding)	
0	Occasional (≤20% of the time)
1	Moderate (20%–50% of the time)
2	Frequent (≥50% of the time)
3	Always present (may wet clothes)
Urgency	
0	Absence
1	Occasionally difficult to postpone urination
2	Frequently difficult to postpone urination
3	Always difficult to postpone urination
Impairment of Size and Force of Urinary Stream	
0	Absence
1	Impaired trajectory

2	Most of the time size and force are restricted
3	Urinates with great effort and stream is interrupted
Dysuria	
0	Absence
1	Occasional burning sensation during urination
2	Frequent (>50% of the time) burning sensation
3	Frequent and painful burning sensation during urination
Sensation of Incomplete Voiding	
0	Absence
1	Occasional sensation
2	Frequent (>50% of the time) sensation
3	Constant and urgent sensation, no relief on voiding

[a] Symptom scoring provides the clinician with a tool to measure the relative need for, and efficacy of, different interventions. No specific score is associated with the need for a specific intervention. A low symptom score in the absence of significant urine retention generally indicates that medical management can be attempted before considering surgical intervention.



Kidney
Dilated ureters
Dilated bladder
Enlarged prostate
Normal prostate
Urethra

Figure 109-2 Flow of urine is interrupted by compression from a prostate that has enlarged from normal size. In this diagram, the ureters and bladder are dilated by backed-up urine.

Urinary incontinence is not a common symptom of BPH. With advanced BPH, a large residual volume of urine in the bladder weakens the bladder sphincter and allows the escape of small amounts of urine when the bladder is full. Because the residual bladder volume increases, the ureters will dilate, resulting in stasis of urine in the ureters. The end result may be ascending hydronephrosis caused by the transmission of high pressure to nephrons, which produces renal damage (Fig. 109-2). This can account for abdominal discomfort and flank pain during voiding and ascending urinary tract infections.

Acute urinary retention in BPH can occur as a result of increasing size of the prostate gland. Independent of gland size, drugs may precipitate acute urinary retention. Drugs, such as alcohol, anticholinergic agents, α-adrenergic agents, and neuroleptics, all have been associated with acute urinary retention in men with BPH. Commonly, when advanced BPH is present, acute urinary retention is exacerbated if the patient does not void at the first sign of urgency. G.M. is not taking any drugs commonly associated with urinary retention.

Clinical Findings

G.M. presents with classic symptoms of BPH. The increasingly severe symptoms culminated in an episode of acute urinary retention as evidenced by inability to void and lower abdominal discomfort. Objective symptoms associated with G.M.'s BPH include (a) abdominal tenderness with increased dullness in the hypogastrium; (b) the finding of an enlarged bladder; (c) an enlarged, firm, and rubbery prostate gland; and (d) a return of 900 mL of urine via urinary catheter. The normal serum acid phosphatase, slightly elevated PSA, and digital rectal examination of the prostate suggest that G.M. does not have prostatic carcinoma at this time (see the Prostate-Specific Antigen section later in this chapter). The elevated BUN and SCr may suggest hydronephrosis as a result of his BPH.

CASE 109-3, QUESTION 2: What objective findings in G.M. are associated with BPH?

URINALYSIS

Because patients with BPH also may have a urinary tract infection, a urinalysis with microscopic examination is essential. It is mandatory that G.M. gives a urine specimen for urinalysis before the digital rectal examination of the prostate gland because examination of the prostate causes prostatic secretions to be expelled into the urethra, which may contaminate the urine specimen and make it difficult to determine the source of an infection. The presence of white blood cells and bacteria in the urine necessitates a workup for infection. Similarly, hematuria requires a workup for urinary tract pathology other than BPH. Because BPH also can cause hydronephrosis, renal function and serum electrolytes should be evaluated.

DIGITAL RECTAL EXAMINATION

A serum PSA followed by a digital rectal examination of the prostate remains a fundamental part of evaluating a man with prostatism. The prostate examination should determine the size, shape, consistency, and nodularity of this gland. Prostatic hyperplasia results in a large, palpable prostate with a smooth mucosal surface rectally. The discernment of the right and left prostate lobes is lost in BPH. The digital rectal examination of a patient with BPH commonly finds asymmetry of the prostate, with one side being larger than the other. Prostatic enlargement can be in both an anteroposterior and a superoinferior direction. As a result, on digital rectal examination, the upper extent of prostate hyperplasia is not palpable. Occasionally, the degree of enlargement felt by digital rectal examination may be misleading because a substantial portion of enlargement may be intravesicular. The consistency of the gland may be soft or firm, depending on the predominance of glandular or fibromuscular elements.[72] The presence of firm-to-hard nodules, irregularities, induration, or a stony, hard prostate suggests possible prostate cancer. In those cases in which the prostate gland size or shape may be questioned, the patient should have a transrectal ultrasound (TRUS) to determine the gland volume.

PROSTATE-SPECIFIC ANTIGEN

PSA is a glycoprotein enzyme (molecular weight, 33,000) that is secreted in the cytoplasm of the prostatic cells; it aids in the liquefaction of semen. Some claim that this enzyme is specific for prostate origin, although a few isolated instances of elevation in nonprostate tumors have been reported. PSA correlates reasonably well, on average, with prostate weight owing to benign prostate glandular hyperplasia.[73] Prostate cancer, however, produces approximately 10 times the amount of PSA on a tissue volume basis than does BPH.[74] Men 50 years of age or older have been encouraged to have an annual measurement of serum PSA and a digital rectal examination as a basic screen for prostate cancer and to monitor the growth of the prostate gland. Several investigators have proposed age-adjusted PSA reference ranges, which reflect the size of the prostate gland (Table 109-5).[75–77] Studies have resulted in several formulas that try to adjust the PSA for the effect of BPH. The best-known formula for predicting the PSA level (PSA serum density) is as follows[78]:

Table 109-5

Age-Adjusted Prostate-Specific Antigen Values

Age Range (years)		PSA Density

	PSA Upper Limit (ng/mL)	
40–49	2.5	0.08
50–59	3.5	0.10
60–69	4.5	0.11
70–79	6.5	0.13

PSA, prostate-specific antigen.

$$\text{PSA (in ng/mL or mcg/mL)} = 0.12 \times \text{gland volume (in mL by TRUS)} \quad \text{(Eq. 109-1)}$$

$$\text{TRUS gland volume} = \text{prostate height} \times \text{width} \times \text{length} \times 0.523 \quad \text{(Eq. 109-2)}$$

The PSA result for G.M. is slightly above the upper limit for his age. As such, he should have a TRUS to determine the prostate gland volume and, hence, the PSA density. Once the prostate gland volume is determined, the significance of his PSA level of 7.1 ng/mL can be determined.

Drug Therapy

α1-ADRENERGIC RECEPTOR ANTAGONISTS

CASE 109-3, QUESTION 4: What drug therapy should be prescribed to treat G.M.'s prostatic hyperplasia?

G.M. most likely will be scheduled for a TURP, because he presents with acute urinary retention and hydronephrosis owing to a moderately enlarged prostate gland (i.e., >40 g and <80 g). He should be started and maintained on an α_1-adrenergic receptor antagonist to reduce the tension of the bladder neck, the prostate adenoma, and the prostatic capsule. Similarly, he should receive a 5α-reductase inhibitor to induce atrophy of the prostate gland and halt progression of the disease.

The prostatic capsule and hyperplastic prostate have plentiful α_{1A}-adrenergic receptors. The three known subtypes of the α_1-adrenergic receptor are α_{1A}, α_{1B}, and α_{1D}. Inhibiting the α_{1A}-adrenergic receptors can reduce the smooth muscle tone of the prostatic urethra, thereby reducing the functional component of urethral constriction and obstruction.

Terazosin

Terazosin, a long-acting α_1-adrenergic receptor antagonist, has significantly reduced obstructive symptoms and improved urinary flow rates at doses of 1 to 5 mg/day.[65,79] The α_1-blockade alone does not account for the long-term clinical responses exerted by this drug in the treatment of BPH. Terazosin has been shown to induce prostate smooth muscle cell apoptosis, resulting in reduced urinary symptoms. Terazosin (and doxazosin) has a quinazoline nucleus, which may account for this effect. Tamsulosin, which is not a quinazoline, does not induce prostate smooth muscle cell apoptosis.[80]

In most patients, the dose of terazosin should be started at 1 mg once daily at bedtime and titrated over several weeks to 5 to 10 mg once daily to obtain desired results. Orthostatic hypotension may occur in the beginning days of therapy or during dosage adjustment periods. In patients who stop their terazosin therapy for 2 or more days, therapy should be reinstituted cautiously to avoid the "first-dose" adverse effect of syncope.

Terazosin has demonstrated sustained improvement in BPH symptom scores for a 30-month period. Only 10% of the patients experienced treatment failure.[65] In this long-term study, the systolic blood pressure in normotensive and hypertensive patients was decreased by 4 and 18 mm Hg, respectively. Apparently, terazosin typically only lowered the blood pressure significantly in the hypertensive patients.

Doxazosin

Doxazosin, another quinazoline derivative, is a long-acting α_1-adrenergic receptor antagonist structurally related to prazosin and terazosin (Table 109-3). Prazosin has a relatively short half-life and is not recommended for use in BPH. Doxazosin originally was prescribed primarily for hypertension and currently is not considered a first-line antihypertensive agent. (For a discussion of the current use of α-blockers in hypertension, see Chapter 14, Essential Hypertension.) Hypertension and BPH are linked by the sympathetic nervous system. As with terazosin, doxazosin improves urinary flow rates and symptoms in patients with BPH. These effects have been demonstrated in controlled clinical studies, within weeks, and for the long-term. Doxazosin should be started at 1 mg/day. After 1 to 2 weeks, the dose can be increased over several weeks to 8 mg/day. As with other long-acting α_1-adrenergic receptor antagonists, the first dose should be taken at bedtime to minimize lightheadedness and syncope (the first-dose effect), and the blood pressure of the patient should be monitored periodically during therapy. Most patients require between 4 and 8 mg/day for effective control of the urinary symptoms of BPH. Dosages greater than 4 mg/day are associated with a greater frequency of dizziness, orthostatic hypotension, and syncope.[79,81]

Tamsulosin

Tamsulosin, a nonquinazoline, is a long-acting selective α_{1A}-adrenergic receptor antagonist similar to doxazosin, terazosin, and prazosin. Tamsulosin and its metabolites are more specific for the prostatic α_{1A}-adrenergic and less specific for the vascular α_{1A}-adrenergic receptors responsible for orthostatic hypotension. Consequently, no need exists to titrate tamsulosin to the recommended daily dose range of 0.4 to 0.8 mg. Coadministration of tamsulosin with antihypertensive agents does not require dosage adjustment of the antihypertensives. Tamsulosin is very effective in treating bladder outlet obstruction associated with BPH.[82,83]

More than 90% of tamsulosin is absorbed after oral administration of a 0.4-mg dose under fasting conditions. Administration with food decreases the bioavailability by 30% and increases time to peak plasma concentration. Tamsulosin is hepatically metabolized by CYP3A4 and CYP2D6.[84] Impaired renal function increases the total tamsulosin plasma concentration by approximately 100% during steady state. However, active unbound drug levels are not affected; thus, renal dose adjustment is not required.[85] Tamsulosin appears to reduce mean ejaculatory volume in 90% of patients.[86] As with all α_1-adrenergic receptor antagonists, tamsulosin does not affect the PSA and must be taken indefinitely to maintain its therapeutic effect.[87]

Alfuzosin

Alfuzosin is another quinazoline α_1-adrenergic receptor antagonist. It displays a lower rate of hypotensive effects than doxazosin and terazosin. A lack of penetration of alfuzosin into the brain has been hypothesized to contribute to the decreased CNS effects such as somnolence. Unlike tamsulosin, alfuzosin will not cause ejaculatory dysfunction; the incidence is comparable to placebo.[86] Alfuzosin is available as an extended-release tablet that has a recommended daily dose of 10 mg given after the same meal each day.

Silodosin

Silodosin is another α_1-adrenergic receptor antagonist that is selective for the α_{1A}-receptor in the lower urinary tract. Silodosin has a strong affinity for prostatic tissue and is 20 times more "uroselective" than tamsulosin.[88] However, the only study comparing silodosin with tamsulosin was a noninferiority trial which found silodosin to be as effective as tamsulosin in controlling lower urinary tract symptoms in men with BPH.[89] The most common side effect with silodosin is retrograde ejaculation, reported in 21% of patients in an open-label extension study.[90] Silodosin is available as 4- and 8-mg capsules, and the recommended dose is 8 mg once daily. In patients with a creatinine clearance of less than 50 mL/minute, the dose should be decreased to 4 mg once daily.

PHOSPHODIESTERASE-5 INHIBITORS

Tadalafil

Tadalafil is a selective inhibitor of phosphodiesterase-5 and has indications for erectile dysfunction and use as monotherapy or combination therapy in BPH. Its mechanism in BPH is unclear; however, compared to placebo, tadalafil 5 mg once daily was shown to improve BPH symptoms compared to placebo. Combining tadalafil with α-adrenergic receptor antagonists is not recommended because it has not been adequately studied and may increase the risk of low blood pressure. Similarly, patients on antihypertensives, nitrates, or drinking 5 or more units of alcohol are also at increased risk of hypotension with tadalafil. Tadalafil should be taken at the same time every day without regard to meals. Additional information on tadalafil can be found under pharmacotherapy for erectile dysfunction later in this chapter.

ANDROGEN SUPPRESSION

Maintenance of morphology and functional activity of the adult human prostate is controlled by, and dependent on, androgens. Prostatic regression after androgen deprivation is an active process that requires the synthesis of macromolecules.[91] As a result of androgen deprivation, the loss of stromal and epithelial prostate cells is disproportionate, with 4 times greater loss of epithelial cells. Testosterone serves as the prohormone for the two active metabolites, DHT and 17-β-estradiol. Testosterone is metabolized to DHT by the enzyme 5α-reductase (types 1 and 2). Thus, conversion of testosterone to DHT precludes its conversion to estrogen by the aromatase enzyme, and the relative activity of these two enzymes is of paramount importance in prostate homeostasis.[92]

Although the mean plasma testosterone level in men falls after the age of 60, the level of testosterone in subjects with BPH and age-matched control subjects is not different.[93] Moreover, the onset of BPH starts some 10 to 20 years before the plasma testosterone levels decrease. The serum concentration of DHT is increased, however, in men with BPH.[91,94,95] The mechanism responsible for accumulation of DHT has not been established, but a significant increase in 5α-reductase activity occurs, which is known to produce DHT.[96,97]

One other major hormonal change associated with aging is the increased formation of estrogen from circulating androgens in both the testes and the peripheral adipose tissue. Androgen conversion to estrogen via aromatase begins in men at approximately the third decade of life and increases with age,[98] but the plasma estrogen concentration is the same in men with BPH and age-matched control subjects without BPH.[94] Estrogen receptors are abundant in stroma cells,[99,100] more so in patients with prostatic carcinoma than in patients with BPH.[101] Estrogen stimulation of stromal tissue was once believed to explain the prostatic growth that continued with age despite the decline in testosterone secretion by the testes. Progesterone receptors, however, appear to be more abundant than estrogen receptors in the stromal and epithelial cells of prostate tissue of patients with BPH. Thus, progesterone may play a more important role in the pathogenesis of BPH than estrogen. The known effect of DHT in initiating the BPH process is believed to be augmented by estrogen.[102] The number of prostate androgen receptors can be increased by estrogens and can be reversed by the administration of antiestrogens.[93] The increase in androgen receptors induced by estrogens may allow for continued androgen-mediated growth despite the declining amount of testosterone produced with advancing age.

5α-REDUCTASE INHIBITORS

Finasteride

Finasteride, a competitive inhibitor of 5α-reductase (type 2), decreases the conversion of testosterone to DHT, the principal androgen responsible for stimulation of prostatic growth. After 7 days of treatment with all doses of finasteride, prostatic tissue DHT declined to 15% or less of control levels, and the testosterone concentration increased in a reciprocal manner.[103] When finasteride was administered in 1- and 5-mg doses to men with BPH for a total of 12 months, the symptom score and urinary flow improved significantly. Finasteride 5 mg daily decreased the median prostate volume by 24% and improved the maximal urinary flow rate by 2.9 mL/second.[104] Adverse effects in the finasteride groups occurred in less than 5%, and side effects, such as decreased libido and ejaculatory dysfunction, were dose related.[105] The efficacy of daily finasteride 5 mg was evaluated in 298 men for 24 months and found a slight improvement compared with the results reported at the end of the 12-month period.[106] The median DHT levels had declined by 74.5% compared with 69.3% at 12 months, and prostate volume declined by 25.2% compared with 21.2% at 12 months. Patient symptom scores indicated slightly more improvement at 24 months compared with 12 months. Obstructive symptom scores were responsible for most of the improved symptoms reported. The prevalence of sexual adverse experiences at 24 months was similar to that at 12 months. In those men who experienced finasteride-induced sexual dysfunction, 50% will experience resolution after discontinuing the medication.[107] Inhibition of DHT by 5α-reductase inhibitors does not affect testosterone-mediated functions on muscle mass, libido, or spermatogenesis. Thus, finasteride has an acceptable safety profile, halts disease progression, and improves the quality of life in patients with moderate BPH disease (i.e., enlarged prostate with symptoms of urinary obstruction, but not acute urinary retention). Finasteride improves objective pressure flow parameters after 1 year of therapy, and efficacy appears to be greatest in patients with large prostates (>40 g).[108] For those who do respond, the drug must be continued indefinitely because DHT serum concentrations return to pretreatment levels within 14 days of discontinuing finasteride, and prostate size returns to pretreatment levels within 4 months.[109,110]

Unlike leuprolide, finasteride does not affect the histologic features of BPH and prostate cancer.[111] Morphologic evaluation of patients treated with finasteride with symptomatic BPH having adenectomy showed a reduction in the size of the prostate and an increase in the stroma to epithelial and stroma to lumen ratios.[112]

Dutasteride

Dutasteride is a competitive inhibitor of both types 1 and 2 5α-reductase isoenzymes.

An advantage of dutasteride compared with finasteride is the additional inhibition of 5α-reductase (type 1) in the peripheral tissues, which produces a further decline in serum DHT. In a prospective study of 2,951 men with moderate-to-severe BPH, dutasteride 0.5 mg/day decreased DHT serum levels by 90% at 1 month in 58% of patients. At 24 months, 85% of those treated with dutasteride were noted to have a 90% reduction of serum DHT.[113] Correspondingly, the patients noted reduction in urinary symptoms as early as 3 months after treatment initiation

---

and a significant ($p < 0.001$) reduction in symptoms by the sixth month when compared with those treated with placebo. Common side effects of dutasteride are similar to those of finasteride: impotence (4.7%), decreased libido (3.0%), ejaculation disorder (1.4%), and gynecomastia (1.0%).

Combination Therapy

Owing to different mechanisms of action, it is a reasonable strategy to combine an α_1-adrenergic receptor antagonist that will work quickly to provide symptomatic relief with a 5α-reductase inhibitor that will take 6 to 12 months to reduce prostate size.

This strategy has been supported by the Medical Therapy of Prostate Symptoms (MTOPS) and Combination of Avodart and Tamsulosin (CombAT) trials. The MTOPS trial studied 3,047 men with moderate-to-severe BPH and demonstrated that combination therapy was superior to monotherapy with either an α-blocker or a 5α-reductase inhibitor in improving symptoms and urinary flow rate. The risk of clinical progression of BPH was reduced by 39% in patients treated with doxazosin alone, by 34% in patients treated with finasteride alone, and by 66% in patients treated with combination therapy.[114] The CombAT trial studied 4,844 men with risk factors for BPH progression such as larger prostates (>30 g) and higher serum PSA concentrations (1.5–10 mcg/L). Combination therapy reduced the relative risk of acute urinary retention or BPH-related surgery by 65.8% compared with tamsulosin and by 19.6% compared with dutasteride. In addition, for those patients who completed the study, the mean change in the International Prostate Symptom Score from baseline to year 4 was significantly higher for the combination therapy compared with tamsulosin or dutasteride alone.[115] Adverse drug events are more common with combination therapy, but study withdrawal rates are less than 5% and similar among treatment groups. A combination product of dutasteride 0.5 mg and tamsulosin hydrochloride 0.4 mg is commercially available.

Effect of Androgen Suppression on Prostate-Specific Antigen

CASE 109-3, QUESTION 5: G.M. has an annual PSA test. Will androgen suppression alter his results?

Antiandrogen treatment of BPH could possibly adversely affect the interpretation of the PSA screening test for prostate cancer. For example, androgen suppression with leuprolide acetate reduces prostate volume primarily by inducing involution of the epithelial elements of the prostate.[116] Because PSA primarily is produced by the epithelial cells of the prostate, these drugs can alter serum and prostate concentrations of PSA.[117] Finasteride 5 mg/day also can reduce the serum PSA level by 50%.[118] Dutasteride reduces total serum PSA by approximately 40% after 3 months of treatment and by approximately 50% after 24 months.[119] The serum PSA level reduction is predictable, however, and serum PSA levels can be recalculated during hormonal treatment for BPH. Nevertheless, patients receiving a 5α-reductase inhibitor should have (a) a digital rectal examination of their prostate periodically, (b) a PSA level measured, and (c) any suspicious findings investigated immediately.[106] Androgen suppression therapy is not contraindicated in BPH solely on the basis of its effect on serum PSA levels.[65]

CASE 109-3, QUESTION 6: G.M asks whether there are nonprescription treatments available that are effective for BPH. What over-the-counter medications are available for prostate disorders?

Two agents, saw palmetto and pygeum, have been promoted for the treatment of BPH. Saw palmetto is an herbal product obtained from the fruit of the Serenoa repens tree with antiandrogen activity. The active ingredients are phytosterols; β-sitosterol and β-sitosterol-3-O-glucosides are the most abundant. Several trials have shown that it significantly improves BPH symptoms[119–122] to a degree similar to finasteride.[123] However, a 2012 meta-analysis of 32 randomized trials failed to detect a difference in urinary symptom improvement even with triple the usual dose of saw palmetto compared to placebo.[124] The dose most often studied is 320 mg a day in one or two divided doses. Pygeum (Pygeum africanum bark extract) has been observed to moderately reduce urinary symptoms associated with enlargement of the prostate gland at a dose of 75 to 200 mg/day.[125] Pygeum has been well tolerated in most studies; however, the safety has not been extensively or systematically studied. Herbal products may be tried by men with mild symptoms that would usually be managed by watchful waiting; however, the use of complementary and alternative medicines for BPH is not currently recommended by the AUA guidelines.[126]

Nonpharmacologic Treatment

TRANSURETHRAL RESECTION OF THE PROSTATE

CASE 109-3, QUESTION 7: What are the options if drug therapy does not work for G.M.? When should prostate surgery be undertaken in general?

G.M.'s subjective and objective findings, particularly the acute urinary retention and hydronephrosis, collectively indicate the need for a TURP. G.M. has been advised by his urologist that a TURP is the treatment of choice given the severity of his presentation (e.g., large prostate gland with acute urinary retention) and that the procedure will relieve his symptoms, allow him to lead a relatively normal life, and avoid sequelae of prolonged obstruction.

TURP provides significant relief of BPH symptoms in 86%, 83%, 75%, and 75% of patients at 3 months, 1 year, 3 years, and 7 years, respectively.[127] Of patients with severe BPH, 93% report reduced symptoms 1 year after a TURP.[128] The TURP is considered the gold standard for the treatment of BPH and is used in 90% of patients with symptoms of residual urine or acute urinary retention.[61] As a result, surgical alternatives are always compared with the outcome studies of TURP.

The need for a TURP in G.M.'s situation is fairly clear. In most cases, however, the need for a TURP is less clear because the symptoms do not inevitably worsen and men often are willing to live with their symptoms. Therefore, clinicians need to talk with patients and help them answer the question of whether the discomfort, risk, and problems during the postsurgical recovery period are outweighed by the high probability that surgery will relieve symptoms.

SEXUAL DYSFUNCTION

As individuals are living longer, there is a growing interest in maintaining one's sexual health throughout later life. Nearly 39% of men and 17% of women between the ages of 75 and 85 reported being sexually active in a cross-sectional study published in 2010.[129] A nationally representative study concluded that the majority of older adults are engaged in sexual activity and regard sex as an important part of life.[130] Poor health often is cited by elderly women as a reason for not participating in sexual activity, and among men, erectile dysfunction (ED) is the leading cause

of decline in activity.[131,132] The major factors that correlate with reduced sexual activity include an older spouse, poor mental or physical health, marital difficulties, previous negative sexual experiences, and negative attitudes toward sexuality in the aged.[133] During the postmenopausal years, women undergo substantial physiologic changes (see Chapter 51, The Transition Through Menopause).

The major physiologic event of natural menopause is a decrease in estrogen production. Little doubt exists that a decline in estrogen production is associated with many of the physiologic changes causing elderly women to report a low interest in sexual activity. The medical literature is replete with research and data on elderly male sexual dysfunction, but little, if any, data exist on female sexual dysfunction.

Male Sexual Dysfunction

Aging men may experience andropause, a syndrome consisting of weakness, fatigue, reduced muscle and bone mass, impaired hematopoiesis, oligospermia, sexual dysfunction, and psychiatric symptoms.[134] The relationship between declining testosterone and andropause is not firmly established. Free testosterone levels begin to decline at the rate of 1% per year after age 40 years. By the age of 60 years, 20% of men have levels below the lower limit of normal.[135] The physiologic and psychological effects of declining hormone levels in men are less dramatic than those experienced by women.

Sexual function is considered an interaction between motivation, drive, desires, thoughts, fantasies, pleasures, experiences (referred to as the libido), penile vasocongestion, erection, orgasmic contractions, and ejaculations (referred to as potency).[136,137] Testosterone plays an important role in male libido and sexual behavior and may play some role in penile erection. Elderly men show a strong correlation between advancing age and diminishing bioavailable serum testosterone levels.[138] Testosterone progressively declines after the seventh decade, partly because of testicular and hypothalamic–pituitary dysfunction.[139]

Male sexual dysfunction, denoting the inability to achieve a satisfactory sexual relationship, may involve inadequacy of erection or problems with emission, ejaculation, or orgasm. Erectile dysfunction is the inability to achieve and maintain a firm erection sufficient for satisfactory sexual performance.[140] Premature ejaculation refers to uncontrolled ejaculation before or shortly after entering the vagina. Retarded ejaculation usually is synonymous with delayed ejaculation. Retrograde ejaculation denotes backflow of semen into the bladder during ejaculation caused by an incompetent bladder neck mechanism.

ED, once regarded as a psychosocial disorder, today is regarded as caused by a variety of medical, psychological, and lifestyle factors. It is an age-related condition, with about 30% of US men older than 40 years of age self-reporting some degree of ED in 2011.[141] Because the population ages, it is estimated that the worldwide prevalence of ED will be approximately 322 million in 2025.[142]

Approximately 80% of all cases of ED now are thought to be related to organic disease and subject to numerous influences.[136,143–145] In one study, neurologic and vascular disorders were the primary causes of ED among elderly men, and psychogenic factors were the cause in less than 10%.[138] The single most common etiology for erectile failure in the elderly is severe atherosclerosis (e.g., vascular disease and diabetes mellitus).[138] Cardiovascular disease, hypertension, diabetes mellitus, elevated low-density lipoprotein cholesterol, and cigarette smoking are associated with a greater probability of complete ED in men.[146] Therefore, prevention of cardiovascular disorders by interventions such as low-fat and low-cholesterol diets and abstinence from tobacco should minimize the development of ED.

Because ED is more likely in male patients with coronary artery disease, the understanding of the cardiovascular stresses involved with sexual intercourse can aid in patient management. Cardiac and metabolic expenditures during sexual intercourse vary depending on the type of sexual activity. Healthy males with their usual female partners generally achieve a peak heart rate of 110 beats/minute with woman-on-top coitus and an average peak heart rate of 127 beats/minute with man-on-top coitus.[147] There is significant individual variation in cardiovascular response, when measured as oxygen uptake and metabolic expenditures, for man-on-top coitus.

In a study of medication-free patients with coronary artery disease who were in New York Heart Association functional class I or II, sexual activity was compared with near-maximal exercise treadmill test.[148] Electrocardiographic changes representing ischemia during intercourse were found in one-third of the patients; however, two-thirds of these patients remained asymptomatic. All patients with ischemia during coitus also demonstrated ischemia during exercise treadmill testing. The average heart rate during coitus was 118 beats/minute, with some patients attaining a heart rate of 185 beats/minute at orgasm. Intercourse in patients with coronary artery disease may provoke increased ventricular ectopic activity that is not necessarily elicited by other stimuli.[149] These electrocardiographic changes and associated symptoms can be abolished with the use of β-blockers.[150] Sexual activity is a likely contributor to the onset of myocardial infarction only 0.9% of the time.[151] Coital death is rare, accounting for 0.6% of sudden death cases.[152] The hemodynamic changes associated with sexual activity may be far greater with an unfamiliar partner, in unfamiliar settings, and after excessive eating and alcohol consumption.

Erectile Dysfunction

PATHOGENESIS

Erection involves the neurologic, psychological, hormonal, arterial, and venous systems. Evidence indicates that more than 80% of the cases of ED are because of organic causes, of which vascular disease is the most common.[153] In most elderly male sexual dysfunction studies, 50% involve vascular problems, and 30% relate to diabetes mellitus.[154]

Neurogenic Disorders

ED can be caused by damage to the brain, spinal cord, cavernous or pudendal nerves, terminal nerve endings, and the receptors. Approximately 95% of patients with upper motor neuron lesions resulting from spinal injury are capable of erection through the reflexogenic mechanism,[155] whereas only 25% of patients with complete lower motor neuron lesions can have erections through the psychogenic mechanism.[155] With incomplete lesions, up to 90% of patients in both groups retain erectile ability. Patients who have a cerebrovascular accident, dementia, epilepsy, Parkinson disease, or a brain tumor most likely experience erectile failure through loss of sexual interest or overinhibition of the spinal erection centers.[156]

Hormonal Disorders

The incidence of ED with a hormonal cause has been estimated to be 5% to 35%, depending on which medical specialty is reporting the finding.[157] The most common hormonal disorder associated with ED in the elderly is diabetes mellitus. Depending on the severity and duration of diabetes, the prevalence of ED ranges from 20% to 85%.[158]

Other hormonal disorders, such as hypothyroidism, hyperthyroidism, Addison disease, and Cushing syndrome, are associated

---

with ED. Patients with hypogonadism caused by pituitary or hypothalamic tumors, antiandrogen therapy, or orchiectomy experience ED. These patients can have a normal erection from visual stimulation, however, indicating that the erectile mechanism is intact.[159]

Vascular Disorders

Atherosclerosis is the leading vascular disease associated with male ED. The age of onset of coronary artery disease parallels the onset of ED, indicating a generalized atherosclerotic etiology for the ED.[160] The degree of arteriolar narrowing and clinical presentation, however, differ from patient to patient. Some patients can have severe coronary artery disease but retain the capability of a full erection. As long as the arterial flow into the penis exceeds the venous outflow, the patient can be potent. Narrowing of the arterial lumen lowers pressure in the cavernous arteries, and poor arterial flow can only partially fill the sinusoidal system. Overall, the partial filling of the sinusoidal system causes inadequate expansion of the sinusoidal wall, resulting in partial compression of the venules. The net effect is a partial erection, difficulty in maintaining an erection, or the most common complaint, early detumescence.

SIGNS AND SYMPTOMS

CASE 109-4

QUESTION 1: F.M., a 66-year-old man, was referred to an urologist because he was experiencing a loss of interest in sexual activity. He describes the inability to maintain a firm erection for the past 6 months in more than 75% of sexual attempts with his sexual partner. Physical examination was unremarkable except for an enlarged prostate gland and evidence of pubic and axillary hair loss. Vital signs were as follows:

Blood pressure, 160/95 mm Hg
Pulse, 88 beats/minute
Respirations, 14 breaths/minute
Temperature, 98.7°F

Current medications include ramipril 5 mg once a day and glipizide 5 mg once daily. F.M.'s medical history is positive for cigarette smoking, hypertension, and diabetes mellitus. Significant laboratory results include the following:

Random blood sugar, 200 mg/dL
SCr, 1.5 mg/dL
BUN, 22 mg/dL
Free testosterone level, 30 pg/mL (normal, 52–280 pg/mL)
Luteinizing hormone (LH), 4 milliunits/mL (normal, 1–8 milliunits/mL)
Follicle-stimulating hormone (FSH) level, 40 milli-international units/mL (normal, 4–25 milli-international units/mL)
Serum prolactin level, 28 ng/mL (normal, <20 ng/mL)

What signs and symptoms does F.M. have that would suggest the need for a complete medical workup for ED?

F.M. presents with the complaint of loss of interest in sexual activity and the inability to maintain a full erection during greater than 75% of sexual encounters with his partner. On physical examination, F.M. is found to have a noticeable loss of pubic and axillary body hair. With long-standing androgen deficiency, there may be loss of hair in the androgen-dependent areas of the body, fine wrinkling of the skin around the mouth and eyes, noticeable loss of muscle mass and strength, altered body-fat distribution, and osteoporosis. In contrast, overt hypogonadism results in a change in the pattern of pubic hair from the male diamond shape to the female-inverted triangle appearance. At this point, it appears that F.M.'s loss of pubic and axillary hair is the result of androgen deficiency, with the cause yet to be determined. The laboratory results for gonadal function coincide with what is expected in an elderly man with ED (see Case 109-4, Question 4).

UROLOGIC WORKUP

CASE 109-4, QUESTION 2: What clinical evaluations and laboratory tests should be included in the medical workup of F.M. to determine the cause of his ED?

A detailed medical and sexual history and thorough physical examination are essential in the evaluation of sexual dysfunction. General medical history and physical examination should consider drug-induced ED (Table 109-6).[161–178]

Although laboratory-based diagnostic procedures are available, sexual function may be best assessed in a naturalistic setting with patient self-report techniques. A psychometrically sound self-reporting tool is the International Index of Erectile Function (IIEF), which addresses the relevant domains of male sexual function (erectile function, orgasmic function, sexual desire, intercourse satisfaction, and overall satisfaction) and has been linguistically validated in 10 languages.[179] A simplified version, the IIEF-5, is a five-item questionnaire that is also popular.[180]

F.M.'s endocrine status should include assessment of his diabetes, thyroid function tests, and a serum lipid profile. Neuropathy and atherosclerosis are common findings among male patients with diabetes mellitus, and both are potential causes of ED. Patients experiencing hypothyroidism may have decreased libido, and hypothyroidism is associated with hyperprolactinemia, which can result in an inhibition in the release of testosterone. Elevated serum lipids (e.g., total cholesterol, triglycerides) may be associated with significant vascular damage that could contribute to erectile dysfunction. Diabetes mellitus is best evaluated with hemoglobin-A_{1c} and fasting blood glucose tests.[181]

The serum concentrations of free testosterone, prolactin, and LH should be evaluated. Testosterone, as with all other hormones secreted into the plasma, is available to tissues only in the free form (i.e., unbound to serum proteins, particularly the sex hormone-binding globulin). Only 1% to 2% of testosterone is free and physiologically active; therefore, measurement of the unbound serum testosterone provides the best estimate of biologically available testosterone. Low testosterone serum concentrations are associated with primary and secondary hypogonadism. Primary hypogonadism is associated with testicular disease (e.g., Leydig cell tumors), whereas secondary hypogonadism is the result of pituitary or hypothalamic disease.

The serum prolactin concentration should be determined because a high serum concentration of prolactin inhibits release of testosterone from the testes. Therefore, a low serum testosterone concentration may be caused by hyperprolactinemia. Hyperprolactinemia may be caused by prolactin adenomas, diabetes mellitus, or drug therapy (e.g., neuroleptics, metoclopramide).

LH stimulates testicular steroidogenesis and secretion of testosterone. LH increases the conversion of cholesterol to pregnenolone, a precursor of testosterone. FSH is required for spermatogenesis in early puberty, but is not a required gonadotropin for the maintenance of spermatogenesis in adult men. Normal testicular function depends on stimulation by the gonadotropin LH, which is secreted by the anterior pituitary gland. Consequently, a low normal serum concentration of LH is associated with secondary hypogonadism.

In patients with symptoms of prostatic disease, expressed prostatic secretions (EPS) should be examined because prostate inflammation has been associated with ejaculatory dysfunction. During prostatic inflammation, the EPS contains leukocytes and macrophages, and microscopic examination of the EPS can determine the degree of prostate inflammation. The presence of greater than 20 white blood cells per high-powered field in the EPS is abnormal and indicative of prostatitis. Only about 5% of prostatitis can be attributed to a bacterial infection; the remaining 95% is caused by unknown etiologies.

Table 109-6

Common Drug-Induced Alterations in Sexual Response

Drug Categories	Clinical Considerations
Antihypertensives	
Diuretic thiazides	Temporal association with sexual dysfunction. Reported incidence varies between 0% and 32%[161–164]; however, impotence generally is not considered common. Mechanism believed to be a "steal syndrome" whereby blood is routed from erectile tissues to skeletal muscle.[165]
Spironolactone	Associated with ↓ libido, impotence, and gynecomastia. Mechanism may be hormone related. Incidence is dose related and reported to be 5%–67%[165] and much more commonly encountered than with the thiazides. May be owing to antiandrogen effects of drug.
Sympatholytics	
Methyldopa	Central action mediated causing vasodilation resulting in erectile dysfunction. Reported incidence: 10%.[146,165] Also ↓ libido.
Clonidine	Induces erectile dysfunction. Mechanism similar to methyldopa and other central α_2-agonists. Incidence reported to be 4%–70% and dose related.[166–168] Also ↓ libido.
Guanabenz, guanfacine	Incidence and mechanism believed to be similar to other central α_2-agonists.
Nonselective β-Blockers	
Propranolol	Associated with erectile dysfunction and ↓ libido. Mechanism believed to be caused by ↓ vascular resistance and central effects. Erectile dysfunction reported to begin at doses of 120 mg/day. Incidence may be as high as 100% at higher dosages.[146,169,170]
Selective β-Blockers	
Atenolol, metoprolol, pindolol, timolol	Incidence of erectile dysfunction is significantly less than nonselective β-blockers.[171]
α-Blockers	
Doxazosin, prazosin, terazosin	Associated with erectile dysfunction and priapism.[146,167] Reported incidence: 0.6%–4%.[146] Mechanism is local α_1-blockade resulting in vasodilation. Erectile dysfunction and priapism appear to be unique to the nonspecific α_1-antagonists.
Phenoxybenzamine	Associated with priapism, retrograde ejaculation, and inhibited emissions during erection. Effects are dose related.[172,173]
Direct Vasodilators	
Hydralazine	Associated with erectile dysfunction. Mechanism is vascular smooth muscle relaxation. Incidence not reported.[172]
Calcium-Channel Blockers	

Nifedipine	Associated with erectile dysfunction. Mechanism believed to be vasodilation and possibly muscle relaxation. Reported incidence: <2%.[174]
Diltiazem, verapamil	Similar to nifedipine. Reported incidence: <1%.
Antiarrhythmics	
Class 1A Disopyramide	Associated with erectile dysfunction in patients treated for ventricular arrhythmias. Incidence not reported. Mechanism believed to be caused by strong anticholinergic effect.[165,172]
Anticonvulsants	
Carbamazepine, phenytoin	May be associated with sexual dysfunction through decreasing DHEA, which is a precursor to testosterone, estrogen, and pheromones.[19]
Antidepressants	
Selective serotonin reuptake inhibitors	Drugs with prominent serotonin agonist effects commonly cause delayed ejaculation and anorgasmia. The reported incidence for delayed ejaculation among men is 2% to 12%; for anorgasmia among women users, the incidence appears to be <3%. This adverse effect is directly dose related.[19]
Tricyclic antidepressants, monoamine oxidase inhibitors	Associated with impairment of sexual performance in both male and female: ↓ libido, anorgasmia, retrograde ejaculation, erectile dysfunction. Mechanism believed to be caused by anticholinergic and serotonergic effects. Incidence not reported; several case studies in the literature.[165]
Trazodone	Associated with priapism in men and ↑ libido in women. Mechanism similar to TCA. Incidence not reported but believed to be dose related.[165] (Note: The literature reports that overall there is less sexual dysfunction with desipramine than with other antidepressants.)

Antipsychotics	
Phenothiazines	Frequently associated with sexual dysfunction. Commonly, ↓ libido is reported. Mechanism is owing to hyperprolactinemia secondary to central dopamine antagonism. Thioridazine is the most often reported offender. Erectile and ejaculatory pain are very common with this drug class; the α-antagonism and anticholinergic effects are responsible. Priapism is common with this drug group, owing to the peripheral α-blockade property. Incidence for all sexual dysfunctions with this drug class: approximately 50% of users.[165]
Anxiolytics	
Short-acting barbiturates	Biphasic effect. At low doses, libido ↑, similar to ethanol, and at higher doses, CNS depression causes ↓ libido and performance.[165]
Benzodiazepines	Biphasic effect. At low doses, ↑ libido, whereas at higher dosages, CNS depression causes performance failure. Some reports of anorgasmia (men and women) and ejaculatory failure.[165]
Substances of Abuse	
Alcohol	Alcohol is thought to impair sexual function through its chronic effects on the nervous system. Short-term use of alcohol can induce erectile dysfunction through its sedative effects. More than 600 mL/week of alcohol increases the

	probability of erectile dysfunction.[175] At low doses, it actually may enhance libido. Sexual dysfunction is dose related and caused by CNS depressant effects.[146,165]
Cocaine	Biphasic effect. At low doses, there is enhanced sexual desire (similar to amphetamines) and possibly performance. At higher dosages, there may be arousal dysfunction, ejaculatory dysfunction, and anorgasmia. Freebasing has been associated with spontaneous orgasm. Continued use (on a run) causes significant loss of sexual interest and performance ability. Chronic use associated with hyperprolactinemia resulting in ↓ libido.[165]
Hallucinogens	Biphasic effect for most drugs in this category. At low doses, libido is enhanced; at higher doses, libido is severely ↓. No reports on chronic use.[165]
Marijuana	Biphasic effect similar to ethanol. With chronic use there is a ↓ in libido. Mechanism may be owing to ↓ testosterone. Incidence not reported.[165]
Opioids	Associated with sexual dysfunction: erection lubrication, orgasm, and ejaculation. Chronic use associated with ↓ libido. Mechanism may be owing to α-antagonism, alterations in testosterone, and the intoxicating effects. Incidence not reported.[146,176,177]
Miscellaneous	
Amyl nitrate	Associated with intense and prolonged orgasms in both men and women. Impotence has been reported in some cases owing to vasodilation.[165]
Cimetidine, ranitidine	Associated with ↓ libido and erectile dysfunction. Mechanism owing to antiandrogen qualities and drug-induced elevation of prolactin. May be dose related.[146,178]
Metoclopramide	Associated with ↓ libido and erectile dysfunction. Mechanism is through CNS dopamine antagonism, resulting in hyperprolactinemia. Incidence not reported.[146]

CNS, central nervous system; DHEA, dehydroepiandrosterone; TCA, tricyclic antidepressants.

Ideally, assessment of ED should include urologic, endocrinologic, psychiatric, and neurologic evaluations as close together as possible. The chief complaint of ED must be identified carefully and described because medical intervention is indicated if it occurs for a 6-month period and in greater than 50% of attempts.[144] A detailed history should determine whether ED varies with partners, sexual settings, position, and masturbation, and whether morning and nocturnal erections are impaired.

RELATIONSHIP OF MEDICAL HISTORY AND ERECTILE DYSFUNCTION

CASE 109-4, QUESTION 3: What is the relationship among hypertension, cigarette smoking, diabetes mellitus, and F.M.'s ED?

Hypertension

In the Massachusetts Male Aging Study (MMAS), heart disease with hypertension and low serum high-density lipoprotein correlated with ED.[136] The hemodynamics of erection can be impaired in patients with myocardial infarction, coronary artery bypass surgery, cerebrovascular accidents, and peripheral vascular disease.[182–185] In several studies of impotent men, the number of abnormal penile vascular findings significantly increased when the history included hypertension and cigarette smoking. Control of blood pressure among hypertensive male patients does not necessarily improve

---

erectile function, and antihypertensive medications can have a significant effect on ED and sexual performances (Table 109-6).[186–188]

Cigarette Smoking

The prevalence of cigarette smoking among men with ED is higher than in the general population.[189–191] When the relation between cigarette smoking and erectile physiology was studied in 314 men with ED,[192] smoking was noted to further compromise penile physiology in men experiencing difficulty maintaining erections long enough for satisfactory intercourse. Several investigators report lower penile blood pressure indices, penile arterial insufficiency, and abnormal blood perfusion associated with cigarette smoking.[189,193] Clearly, smoking cessation may benefit men with existing ED.

Diabetes Mellitus

Diabetes mellitus has been associated with ED. In the MMAS, male patients with diabetes mellitus were 3 times more likely to have ED than patients without diabetes.[136] Other investigators using exclusively diabetic populations have found a prevalence of ED as high as 75% among subjects.[194,195] The onset of ED in the diabetic patient occurs at an earlier age when compared with the general population. In a few cases, it may be the presenting symptom of diabetes mellitus, and in most cases, ED follows within 10 years of the diagnosis, regardless of insulin dependence status.[196,197] Researchers disagree as to the exact contribution of diabetes mellitus to ED, but most of the literature supports an atherosclerotic etiology.[198,199] Other possible causes also include autonomic neuropathy and gonadal dysfunction.[198]

GONADAL FUNCTION IN ERECTILE DYSFUNCTION

CASE 109-4, QUESTION 4: What is the significance of the gonadal function results for F.M.?

Gonadotropins

Abnormalities of primary or secondary hypogonadism must be ruled out, particularly in patients with a decreased libido with or without ED. The results of F.M.'s gonadal function tests are relatively normal for an aged male. Testosterone serum levels decline with aging as a result of hypothalamic–pituitary changes or Leydig cell dysfunction. The understanding of changes that take place in the hypothalamic–pituitary level with advancing age is in a state of flux. For some time, most investigators focused on the increased serum concentration of male gonadotropins (LH, FSH), believing that all elderly men had some degree of primary hypogonadism.[200] Other studies have shown, however, that LH levels in elderly men are lower than the median of those in younger patients.[174] These findings show that LH levels do not increase in response to the decrease in testosterone serum concentrations in the aged male, indicating a defect in the hypothalamic–pituitary axis, leading to secondary hypogonadism.[201] Secondary hypogonadism results when there is a dysregulation of pituitary LH release, resulting in low serum testosterone levels.[156]

Testicular Size and Aging

Testicular size decreases with age; however, the testicular degeneration is sporadic, thereby allowing most elderly men to maintain a normal or slightly decreased sperm output.[200] Overall, spermatogenesis decreases and is accompanied by an increase in serum concentration of FSH. FSH elevation correlates well with a decline in the number of Sertoli cells that secrete inhibin. Inhibin normally decreases FSH.[202]

Testosterone

As a result of primary or secondary hypogonadism in the elderly male, available testosterone declines. Approximately 60% to 75% of circulating serum testosterone is bound to a β-globulin known as sex hormone-binding globulin or testosterone-binding globulin. Approximately 20% to 40% of testosterone is bound to serum albumin, and 1% to 2% is unbound, or free. The unbound portion of testosterone is the only active portion of the total serum testosterone concentration. Testosterone serum concentrations are 20% higher in the morning than in the evening, and this should be taken into consideration when evaluating laboratory results. In virtually all cases of ED, the serum concentration of testosterone should be measured in the morning.

Testosterone production is regulated by feedback with the hypothalamus and pituitary. The hypothalamus produces gonadotropin-releasing hormone (GnRH) in response to low testosterone levels. GnRH induces the pituitary to secrete LH and FSH, which in turn stimulates the Leydig cells of the testes to secrete testosterone. Less than 10% of cases of ED studied are caused strictly by hypogonadism.[138,203] The role of testosterone in ED is complex. After testosterone production decreases, libido eventually declines and precedes the decrease in frequency of erections.[204] Men given antiandrogens maintain their erectile capacity but have a decreased libido.[205] On the other hand, high dosages of androgens given to hypogonadal men increase both the frequency of erections and libido.[206] It would seem reasonable to postulate that at physiologic levels, testosterone modulates the cognitive processes associated with sexual arousal more than it contributes to erectile capability.

Endocrine Disorders

Many endocrine disorders can result in ED. Patients with prolactinomas commonly have ED, but prolactinomas account for less than 1% of ED cases.[169] Prolactin inhibits the release of testosterone, resulting in secondary hypogonadism. Hyperprolactinemia may be more prevalent in diabetic patients.[207] In the elderly, however, hyperprolactinemia often is secondary to the use of medications. F.M.'s serum prolactin level is elevated, most likely because of his diabetes mellitus.

In summary, aged men have a decrease in testosterone because of defects in testicular and hypothalamic–pituitary function. Secondary hypogonadism in elderly men is common, and the point at which this becomes pathologic has not yet been established. Correspondingly, the use of hormonal therapy to treat physiologic secondary hypogonadism is extremely controversial. Therefore, the gonadal function tests for F.M. are normal for his age and do not provide an explanation for his ED.

MEDICATIONS THAT CAUSE ERECTILE DYSFUNCTION

CASE 109-4, QUESTION 5: Is it likely that a medication is causing F.M.'s ED?

Several general statements can be made regarding sexual function and medications. Drugs that affect libido generally have a central mode of action. For example, medications that block central dopamine transmission can decrease libido, and opiates have an antiandrogen effect.[176] Drugs that alter hemodynamics may interfere with erection. Excessive sympathetic tone is thought to cause the "steal syndrome," which increases blood flow to muscles, drawing blood away from the erectile tissue.[165] Drugs that block the peripheral sympathetic system can cause retrograde ejaculation or no ejaculation at all. Numerous drugs have been associated with altered sexual function (Table 109-6).[208]

Few studies exist in the literature solely devoted to drug-induced ED or sexual dysfunction.[187,188] A few studies and review articles, however, list medications as one of many potential causes for ED.[19,136,156,169,209]

Most studies documenting drug-induced ED have been subjective and based on case reports, uncontrolled studies, and clinical impressions. The MMAS reported that ED was statistically correlated with antihypertensive, vasodilator, cardiac, and hypoglycemic drugs. The probability of moderate as well as complete ED was particularly high for vasodilator drugs.[136] Although the MMAS is one of the most well-designed studies to date, the medications reported are not considered to be the universe of all medications associated with ED. Diagnosis of drug-induced sexual dysfunction should be restricted to a reproducible dose-related effect that disappears on discontinuation of the drug.[146] A much larger survey of a controlled study in a clinical population would be required to establish any suspect medication as causative, rather than temporal.

F.M.'s sexual dysfunction (e.g., loss of interest in sexual activity and ED) is not caused by his current drug regimen, ramipril, and glipizide. Although the MMAS[136] reported a correlation between the use of antihypertensives and hypoglycemic drugs with ED, clinicians must look at the individual drugs themselves and the conditions for which they are prescribed. Sexual dysfunction is not likely to occur with ramipril, or any of the other angiotensin-converting enzyme inhibitors, or with the hypoglycemic agent glyburide. Although ramipril is an antihypertensive, its pharmacologic effects do not contribute to a decline in libido or cause ED (an advantage that angiotensin-converting enzyme inhibitors have compared with other antihypertensive medications). Similarly, the pharmacologic action of glipizide does not contribute to F.M.'s decreased libido or ED. In most sexual dysfunction cases, it is less likely that the medication is the direct cause of the problem; rather, it is the medical condition for which the drugs were prescribed. The ability of a drug to induce sexual dysfunction simply is an extension of its pharmacologic actions. As a general rule, drugs that manipulate the sympathetic or the parasympathetic system, both centrally and peripherally, are associated with sexual dysfunction.

CASE 109-4, QUESTION 6: What factors most likely are contributing to F.M.'s ED?

F.M. is a patient with hypertension and diabetes who smokes cigarettes. Those three factors are more likely to be the cause of F.M.'s sexual dysfunction than are his medications. Diabetes mellitus is the most common hormonal disorder associated with ED in the elderly population.[195] The continued loss of interest in sexual activity experienced by F.M. most likely is the result of having experienced ED during past and present sexual events.

F.M.'s subjective and objective findings are common among elderly men. His sexual dysfunction is caused by atherosclerosis and possible neuropathy secondary to diabetes mellitus. Because cigarette smoking is no doubt contributing to F.M.'s ED, cessation should be encouraged; some improvement can be expected.[165] There is no need to alter F.M.'s drug regimen.

MANAGEMENT

CASE 109-4, QUESTION 7: What are the primary therapeutic considerations for F.M.?

Essentially, there are three levels to the management of ED. Level 1 includes lifestyle and drug therapy modifications. Specifically, the patient should be instructed to modify smoking and alcohol use. The patient's drug regimen should be checked periodically to ensure that drugs associated with ED are not being prescribed. If necessary, psychosocial counseling should be provided. After careful consideration, oral medications for management of ED should be instituted. If level 1 therapies have failed or are not acceptable to the patient, then level 2 therapy is instituted. These interventions include a vacuum constriction device to elicit an erection, intracavernosal injections, or transurethral inserts. Level 3 management involves placement of a penile prosthesis.

PHARMACOTHERAPY

Any therapy directed at male sexual dysfunction must include the elimination of drugs causing adverse sexual effects. Drug therapy is directed primarily toward treatment of ED and includes hormonal therapy, bromocriptine, prostaglandin E_1, sildenafil, tadalafil, vardenafil, avanafil, and apomorphine.

Phosphodiesterase-5 inhibitors

CASE 109-4, QUESTION 8: Would phosphodiesterase-5 inhibitor therapy be appropriate for F.M.? What are its side effects and contraindications? Does it interact with other drugs?

F.M. has diabetes mellitus and atherosclerosis and therefore is a candidate for treatment with a phosphodiesterase-5 (PDE-5) inhibitor.[210] These agents are orally active and selective inhibitors of cyclic guanosine monophosphate-specific PDE-5, the predominant phosphodiesterase isoenzyme metabolizing cyclic guanosine monophosphate in the corpus cavernosum. They facilitate an erection in response to sexual stimulation by enhancing the nitric oxide-induced relaxation of corpus cavernosal smooth muscle. The results of double-blind, placebo-controlled clinical trials in men with ED of various causes have demonstrated that PDE-5 inhibitors significantly improve erectile function and the rate of successful sexual intercourse, with therapeutic outcomes approaching those of normal men of the same age.[211–213]

F.M. should be counseled on the adverse effects of PDE-5 inhibitors. The vasodilating action of PDE-5 inhibitors affects both the arteries and the veins, so the most common side effects are headache and facial flushing.[214] PDE-5 inhibitors cause a small decrease in both systolic and diastolic blood pressures, but clinically significant hypotension is rare. Studies of PDE-5 inhibitors and nitrates taken together show much greater drops in blood pressure. For that reason, PDE-5 inhibitors are contraindicated in patients taking long-acting nitrates or short-acting nitrate-containing medications.[143] In phase II/III studies before US Food and Drug Administration (FDA) approval, more than 3,700 patients received sildenafil and almost 2,000 received placebo in double-blind and open-label studies. Approximately 25% of patients had hypertension and were taking antihypertensive medications, and 17% were diabetic. In these studies, the incidence of serious cardiovascular adverse effects was similar in the double-blind sildenafil group, the double-blind placebo group, and the open-label group. Twenty-eight patients had experienced a myocardial infarction. When adjusted for patient-years of exposure, no significant differences were seen in the myocardial infarction rates between the sildenafil and the placebo group, and no deaths were attributed to sildenafil.[215,216] In an analysis of 67 double-blind, placebo-controlled trials of sildenafil, the overall frequency of death was comparable between the sildenafil-treated patients (13 of 8,691; 0.15%) and placebo group (7 of 6,602; 0.11%).[217] Nevertheless, several deaths caused by myocardial infarction or arrhythmia have been associated with the use of sildenafil.[218] Deaths associated with sildenafil (and presumably other PDE-5 inhibitors) are most likely caused by increased cardiac workload in patients with unstable angina.[219]

Transient visual anomalies (mostly blue-green color-tinged objects, increased sensitivity to light, and blurred vision) have been reported in patients taking PDE-5 inhibitors, especially at higher dosages. These visual effects appear to be related to the weaker inhibiting action of PDE-5 inhibitors on the enzyme phosphodiesterase-6, which regulates signal transduction pathways in the retinal photoreceptors. In patients with inherited disorders of retinal phosphodiesterase-6, such as retinitis pigmentosa, PDE-5 inhibitors should be administered with extreme caution. In 2005, the FDA recommended that all PDE-5 inhibitors include a precaution in their labeling regarding the risk of nonarteritic anterior ischemic optic neuropathy as a cause of decreased vision including permanent vision loss. There have been only a handful of reports of nonarteritic anterior ischemic optic neuropathy in postmarketing surveillance, and most patients had underlying risk factors.[220] Clinicians should advise patients to discontinue the use of all PDE-5 inhibitors and seek medical attention in the event of sudden vision loss in one or both eyes.

The vasodilator actions of nitrates are profoundly amplified with concomitant use of PDE-5 inhibitors. This interaction likely applies to all nitrates and nitric oxide donors, regardless of their predominant hemodynamic site of action. They also may potentiate the inhaled form of nitrate, such as amyl nitrite, and therefore are contraindicated in patients using this product. Dietary sources of nitrates, nitrites, and L-arginine (the substrate from which nitric oxide is synthesized) do not contribute to the circulating levels of nitric oxide in humans and, therefore, are unlikely to interact with PDE-5 inhibitors. The anesthetic agent, nitrous oxide, is eliminated unchanged from the body, mostly via the lungs, within minutes of inhalation. It does not form nitric oxide in the human body and does not itself activate guanylate cyclase. As such, no contraindication exists to its use after administration of PDE-5 inhibitors. The concomitant use of nitrates and the PDE-5 inhibitors is contraindicated although some differences in the nitrate-free period do exist based on the pharmacokinetic profile of the PDE-5 inhibitor. After 24 hours, the administration of nitrates can once again be considered in patients using vardenafil and sildenafil; however, this should be extended to 48 hours in patients using tadalafil and can be shortened to 12 hours with avanafil.

CASE 109-4, QUESTION 9: Which PDE-5 inhibitor should be recommended for F.M.?

Sildenafil

The typical dose of sildenafil is 50 mg orally, taken 1 hour before sexual activity. However, it may be taken anywhere from 4 hours to 30 minutes before sexual activity. The maximal recommended dosing frequency is once per day. The following factors are associated with increased plasma levels of sildenafil: age older than 65 years (40% increase in area under the curve), hepatic impairment (e.g., cirrhosis, 80% increase), severe renal impairment (creatinine clearance <30 mL/minute, 100% increase), and concomitant use of potent CYP3A4 inhibitors (e.g., erythromycin, ketoconazole, itraconazole, 200% increase). Because higher plasma levels may increase both the efficacy and the incidence of adverse events, a starting dose of 25 mg should be considered in these patients. The dose may be increased to 100 mg. Because F.M. is older than 65 years of age, he should be started on 25-mg tablets of sildenafil. The dose may be increased under strict supervision.

Sildenafil is metabolized by both the CYP2C9 pathway and the CYP3A4 pathway. Thus, inhibitors of the CYP3A4 isoenzyme, such as erythromycin or cimetidine, may lead to competitive inhibition of its metabolism; however, CYP3A4 is a high-capacity pathway. The effects of erythromycin or cimetidine on the half-life and physiologic effects of sildenafil are not known, but clinicians should be warned about the potential interaction.

Inadequate physical sexual stimulation while using any of the PDE-5 inhibitors can lead to treatment failure. Adequate sexual stimulation is needed to trigger the events leading to erection.[221] PDE-5 inhibitors cannot initiate an erection; they can only assist in the process. Some patients may need several attempts at sexual stimulation before they are successful with intercourse.

Tadalafil

Similar to sildenafil, tadalafil is a selective inhibitor of PDE-5. Tadalafil has several times more affinity for PDE-5 than sildenafil.[222] Tadalafil and vardenafil, however, have minimal or no effect on visual disturbance (impairment of blue-green color discrimination), which is a well-recognized side effect of sildenafil.[223] Tadalafil's extended half-life of 17.5 hours relative to sildenafil most likely precludes its use in patients with angina or hypertension. Tadalafil is metabolized by the hepatic CYP3A4 isozyme. Food has no effect on the oral absorption of tadalafil in contrast to sildenafil (bioavailability decreased by 29%). Tadalafil may be advantageous in a subset of patients, based on its shorter onset of action (16 minutes) and 24-hour duration of action.[224] Specifically, patients with psychogenic or neurogenic ED and those with stable cardiovascular systems may prefer tadalafil because it offers the potential for multiple sessions of intercourse with a single daily dose.

Vardenafil

Vardenafil is the third FDA-approved oral PDE-5 inhibitor for treatment of ED. The warnings regarding the use of nitrates while taking vardenafil are similar to the warnings for sildenafil. Patients using vardenafil may experience headache, flushing, or rhinitis; the incidence of these side effects is dose related.[225] Vardenafil is metabolized by the hepatic CYP3A4 isozyme and has a reported half-life of 5 hours.[226] Thus, drugs known to inhibit the CYP3A4 isozyme have the potential to prolong its half-life. Vardenafil 10 mg does not impair the ability of patients with stable coronary artery disease to exercise at levels equivalent to or greater than that attained during sexual intercourse.[227]

Avanafil

Avanafil is a new PDE-5 inhibitor with enhanced PDE-5 selectivity which may translate to fewer side effects due to less selectivity for non-PDE-5 isoenzymes, found in the heart, retina, and skeletal muscle. The starting dose is 50 mg and should be taken 30 minutes before sexual activity whereas the 100- to 200-mg doses can be taken 15 minutes before. It has a similar half-life to sildenafil and vardenafil and is rapidly absorbed following administration. Side effects and contraindications for avanafil are similar to the other PDE-5 inhibitors.[228]

F.M. has hypertension that most likely would be affected by tadalafil; therefore, extreme caution is advised. Perhaps, the shorter-acting sildenafil, vardenafil, or avanafil would be the PDE-5 inhibitor drug of choice for F.M.

Testosterone

CASE 109-4, QUESTION 10: Should F.M. be treated with testosterone?

Primary hypogonadism with severely deficient serum levels of bioavailable testosterone is the only appropriate indication for the use of androgen hormone therapy.[169] The goal of androgen-replacement therapy is to restore potency and libido by maintaining normal serum levels of testosterone.[229] Testosterone has no benefit in the treatment of eugonadal or mildly hypogonadal elderly men and actually may enhance the growth of undiagnosed adenocarcinoma of the prostate or cause further ED.[143] In eugonadal men, testosterone enhances the rigidity of the erection, but does not change the penile circumference.[230] F.M. would not be a candidate for testosterone therapy.

CASE 109-4, QUESTION 11: Which type of patient would benefit from testosterone therapy?

Unless testosterone deficiency is severe, (free testosterone serum levels less than 7 to 8 pg/mL) testosterone replacement therapy will not improve the success rate of intercourse.[231] Testosterone replacement in patients with primary hypogonadism generally restores libido and potency. In some patients with secondary hypogonadism caused by disorders of the hypothalamus or pituitary, GnRH analogs can be administered to differentiate between hypothalamic and pituitary abnormalities and to correct testosterone deficiency.[229] Libido and potency then are restored.

CASE 109-4, QUESTION 12: How should testosterone be used as a treatment for ED?

Testosterone-replacement therapy is available in several formulations, including gels, transdermal patches, and intramuscular injection. Because of poor drug bioavailability, oral testosterone-replacement therapy is less effective than parenteral testosterone in achieving normal serum testosterone levels. Oral administration also is associated with a higher incidence of hepatotoxicity and adverse serum lipid effects.[143,174] A long-acting testosterone intramuscular formulation, such as the enanthate or cypionate ester, is still considered the regimen of choice for the treatment of primary hypogonadism. A dose of 50 to 400 mg should be administered intramuscularly every 2 to 4 weeks. Side effects of testosterone therapy include early gynecomastia, increases in hematocrit (sometimes to the point of polycythemia), and fluid retention that may worsen hypertension or heart failure.

Results of several studies have demonstrated that serum testosterone levels are normalized while using transdermal testosterone applications.[175,232–234] The system normalizes DHT to testosterone ratios and reduces LH levels toward the normal range. The transdermal testosterone is well tolerated, with application site reactions such as pruritus, burn-like blisters, and erythema being the most commonly reported event. The adhesive side of the patch should be applied to a clean, dry area of the skin on the back, abdomen, upper arms, or thighs. The patient should be instructed to avoid application over bony prominences or on a part of the body that may be subject to prolonged pressure during sleep or sitting (e.g., the deltoid region of the upper arm, the greater trochanter of the femur, and the ischial tuberosity); do not apply to the scrotum. The sites of application should be rotated, with an interval of 7 days between applications to the same site. The area selected should not be oily, damaged, or irritated.

Topical testosterone gel should be applied once daily in the morning to clean, dry skin. Depending on the specific product, it can be applied to the upper arms, shoulders, thighs, or abdomen. A topical solution for application to the axilla is also available. The dose can be as high as 100 mg/24 hours. After the gel or solution has dried on the site of application, it should be protected with clothing to prevent transfer to a nonuser. The patient should wash his hands after application.

Commonly reported adverse effects in chronic users include acne, edema, gynecomastia, and dermatologic reactions to injections or transdermal applications of testosterone. The most serious risk of prolonged testosterone use is prostate carcinoma, although the association between high concentrations of testosterone and the risk of prostate carcinoma is controversial.[235–237] Three studies suggest that testosterone-replacement therapy is relatively safe in hypogonadism.[238–240] Baseline assessment of the prostate should be done before starting testosterone-replacement therapy. This should consist of a TRUS, digital palpation of the prostate gland, and analysis of the PSA, hemoglobin, and hematocrit levels.

Bromocriptine

CASE 109-4, QUESTION 13: Because F.M.'s prolactin serum concentration is 28 ng/mL, should bromocriptine be prescribed to decrease his hyperprolactinemia and treat his ED?

Hyperprolactinemia may be treated with the ergot alkaloid bromocriptine, which works as a dopamine agonist to inhibit prolactin secretion. Even with normalization of prolactin levels, approximately 50% of elderly male patients are unable to achieve erectile function and desire.[174,229] Bromocriptine therapy may be initiated with twice-daily 1.25-mg doses taken with meals to minimize gastrointestinal upset. Thereafter, doses may be increased weekly, at a rate of no more than 2.5 mg/day. Adverse events associated with bromocriptine are nausea, dizziness, drowsiness, hypotension, and cerebrovascular accidents.[143,229] For those who fail bromocriptine, cabergoline is a reasonable alternative given once or twice a week with good efficacy and a lower incidence of nausea.[241]

F.M. is not a candidate for treatment with bromocriptine because he does not have secondary hypogonadism, and his ED probably is secondary to atherosclerosis associated with his hypertension, diabetes, and cigarette smoking. Furthermore, the elevation of F.M.'s serum prolactin concentration is not significant enough to warrant drug therapy. Medication-induced hyperprolactinemia is usually associated with prolactin levels ranging from 25 to 100 µg/L, but metoclopramide, risperidone, and phenothiazines can lead to prolactin levels exceeding 200 µg/L by way of dopamine antagonism.[241] Verapamil can cause hyperprolactinemia presumably by blocking hypothalamic dopamine, and opiates and cocaine can induce it through the µ-receptor.[241] Usually prolactin will normalize 3 days following discontinuation of the offending medication, however this patient is not on any medications that can induce hyperprolactinemia. Because the response rate to bromocriptine in elderly men is 50% (or less), the risk of adverse reactions (e.g., dyskinesia, dizziness, hallucinations, dystonia, confusion, cerebrovascular accidents) outweighs the benefit of this dopamine agonist therapy.

CASE 109-4, QUESTION 14: What other drug therapy is available for F.M.?

Before the advent of the PDE-5 inhibitors, intracavernosal and intraurethral prostaglandin E_1 (alprostadil) administration was the only nonsurgical option for ED. Alprostadil causes direct vascular smooth muscle relaxation allowing blood flow and entrapment in penis. Less invasive than intracavernosal injections, alprostadil intraurethral pellet is inserted, as semisolid gel form, through the urethral opening of the penis 5 to 10 minutes before sex and works for up to one hour. However, it is less effective and not recommended with pregnant partners.[242] Intracavernosal injections are given at the base of the penis 10 to 20 minutes before sex and were effective in 87 percent of cases in one clinical trial.[243] Phentolamine, papaverine, and vasoactive intestinal peptide are also available for intracavernosal injection, but are not FDA-approved. Adverse events from intracavernosal therapies include priapism, pain at the injection site, and penile fibrosis after long-term use. Topical alprostadil cream has also shown efficacy in 74% of patients but is not currently available in the US.[244]

Osteoporosis

R. Rebecca Couris, Suzanne Dinsmore, and Mary-Kathleen Grams

CORE PRINCIPLES

		CHAPTER CASES
1	Osteoporosis is a condition of low bone mass and deterioration of bone tissue leading to bone fragility and potentially fracture with many preventable and inherent risk factors.	**Case 110-1 (Question 1)**
2	Prevention and treatment of osteoporosis focus on modifying preventable risk, providing adequate dietary supplementation of calcium and vitamin D, increasing bone mineral density, and reducing fracture rates.	**Case 110-1 (Questions 1–3), Case 110-2 (Question 3)**
3	Pharmacologic therapy is reserved for those patients with a hip or vertebral fracture, individuals with a T-score less than or equal to −2.5 at the femoral neck or spine once secondary causes have been excluded, and individuals with low bone mass with a 10-year probability of greater than or equal to 3% risk of hip fracture or greater than or equal to 20% risk of major osteoporotic fracture.	**Case 110-2 (Questions 1–3)**
4	Initial therapy with oral bisphosphonates is recommended unless patients are unable to take or have relative contraindications to oral bisphosphonate therapy.	**Case 110-2 (Question 6,7)**
5	Estrogen/progesterone therapy, selective estrogen receptor modulators, parathyroid hormone, denosumab, and calcitonin are alternative therapies for prevention and/or treatment of postmenopausal osteoporosis.	**Case 110-2 (Questions 4,6,8), Case 110-3 (Questions 3,4)**
6	Duration of treatment with antiresorptive and/or anabolic therapy has remained controversial, secondary to concerns for oversuppression of bone turnover markers and the potential for the development of osteosarcomas, respectively.	**Case 110-2 (Question 6)**
7	Prevention and treatment of osteoporosis secondary to prolonged glucocorticoid therapy should be incorporated into a patient's treatment plan with considerations for dosage and duration of glucocorticoid therapy, the patient's individual risk factors, sex, and age.	**Case 110-4 (Questions 1–4)**
8	Pharmacologic therapies to be considered for osteoporosis treatment in men include oral and intravenous bisphosphonates and parathyroid hormone.	**Case 110-5 (Questions 1–6)**

INCIDENCE, PREVALENCE, AND EPIDEMIOLOGY

Osteoporosis is a well-recognized disorder of reduced bone strength leading to an increased risk of fractures. It is the most common bone disease in humans, characterized by low bone mass and a deterioration of bone tissue.[1]

Osteoporosis is considered a silent disease and can progress without symptoms until a fracture occurs.[1] Fractures and their complications make osteoporosis a major public health concern.[2] Fractures of the spine, hip, and wrist are the most common and may be followed by a complete recovery, considerable pain and disability, or death.[1] Consequences of an osteoporosis fracture are physical, financial, and psychological. The considerable morbidity and mortality from these fractures create a heavy economic burden.

Osteoporosis can be classified as primary or secondary. Primary osteoporosis is the deterioration of bone mass that is not associated with other chronic conditions and is associated with natural aging and decreased gonadal function.[3] Both men and women experience osteoporosis. Age-related bone loss begins in the sixth decade of life. Bone loss is accelerated in women in the late perimenopausal period and first postmenopausal years.[4] Conditions that contribute to primary osteoporosis are prolonged periods of inadequate calcium intake, sedentary lifestyle, and tobacco and alcohol abuse. Secondary osteoporosis is the deterioration of bone mass that is associated with chronic conditions or from the use of various medications.[3,5] Secondary causes of osteoporosis are listed in Table 110-1 and include nutritional deficiencies, endocrine disorders such as hyperparathyroidism and diabetes mellitus, malignancies, gastrointestinal diseases, renal failure, connective tissue diseases, and medications, which include anticonvulsant therapy, long-term glucocorticoid therapy, or long-term proton pump inhibitors.

Table 110-1

Risk Factors Associated with the Development of Osteoporosis

↑Age Female gender Caucasian or Asian Family history Small stature Low weight	Predisposing medical problems (e.g., chronic liver disease, chronic renal failure, hyperthyroidism, primary hyperparathyroidism, Cushing syndrome, diabetes mellitus, anorexia nervosa, gastrointestinal resection, malabsorption, vitamin D deficiency, irritable bowel disease, chronic obstructive pulmonary disease, spinal cord injury, Parkinson disease, and human immunodeficiency virus)
Early menopause or oophorectomy Sedentary lifestyle	Drugs (e.g., corticosteroids, long-term anticonvulsant therapy [phenytoin or phenobarbital], aromatase inhibitors, gonadotropin-

↓Mobility Low calcium intake Excessive alcohol intake Cigarette smoking High Caffeine intake	releasing hormone [GnRH] analogs, depot medroxyprogesterone, rosiglitazone, cyclosporine, tacrolimus, antiretroviral therapy, long-term heparin, warfarin, loop diuretics, excessive levothyroxine therapy, proton pump inhibitors, H_2 receptor antagonists, excessive use of aluminum-containing antacids)

The standard method of identifying osteoporosis is the measurement of bone mineral density (BMD) at either the femur neck region of the proximal femur (hip) or the lumbar spine.[2,6] The World Health Organization (WHO) uses a defined criteria to diagnose osteoporosis that has been widely accepted.[7] When measured by dual-energy X-ray absorptiometry (DXA), a bone mineral density that lies 2.5 standard deviations or more below the average value for young healthy women, a T-score of less than −2.5 SD, is considered osteoporosis and an effective method to identify patients at increased risk for fracture. As the T-score decreases, the risk for fracture increases. A T-score between −2.5 and −1 is defined as osteopenia, but is better referred to as low bone mass or low bone density. A T-score greater than or equal to −1 is considered normal. The National Osteoporosis Foundation (NOF) clinician guidelines include this measurement of BMD in the diagnosis of osteoporosis, but also states that the occurrence of adulthood hip or vertebral fracture in the absence of major trauma can be considered osteoporosis without the measurement of BMD.[1]

Although the fracture rate is lower than in osteoporosis, the majority of fractures occur in patients with low bone mass. The prevalence of low bone mass is higher than osteoporosis, and therefore, it is important to monitor for clinical risk factors to predict the risk of fracture.

Osteoporosis is a global concern estimated to affect more than 200 million people worldwide.[8] The prevalence of osteoporosis and the risk of fracture increase with age and vary by race and ethnicity. The risk of hip fracture is greatest in Northern Europe, Australia, and North America.[9] According to data from the United States National Health and Nutrition Examination Survey (NHANES), 2005 to 2008, 9% of adults aged 50 years and over had osteoporosis, as defined above, at either the femoral neck or lumbar spine.[10] Forty-nine percent had low bone mass at either the femur neck or lumbar spine and 48% had normal bone mass at both sites. In 2010, using data from NHANES 2005 to 2010 and the 2010 US Census, it was estimated that 10.3% or 10.2 million adults in the same age range had osteoporosis and 43.9% or 43.4 million adults had low bone mass.[11] Almost 80% of the affected population are women. Osteoporosis at either the femur neck or lumbar spine ranged from 7% to 35% in women and 3% to 10% in men. Prevalence increased with each decade after the age of 50 years in women, but not until the age of 80 years in men.[10] The prevalence of low bone mass at either the femur neck or lumbar spine in adults aged 50 years and over ranged from 54% to 67% in women and 32% to 60% in men. The prevalence of low bone mass in women increased with age until age 70 years and then remained stable. In men, the prevalence of low bone mass did not increase with age until aged 70 years and increased progressively thereafter.

The National Health and Nutrition Examination Survey, 2005 to 2008, provides a separate estimate of osteoporosis and low bone mass by race and ethnicity in three different groups.[10] The number of individuals with osteoporosis or low bone mass was highest among non-Hispanic white women and men. The prevalence or rate, however, was highest among Mexican Americans compared to non-Hispanic white persons and non-Hispanic black persons. Non-Hispanic black persons had the lowest rate of either osteoporosis or low bone mass at the femur neck or lumbar spine.[10,11]

Approximately 50% of Caucasian women and 20% of men will sustain an osteoporosis-related fracture in their lifetime.[1] The risk of fracture is highest in Caucasian women, followed by Asian, African American, and Hispanic women.[9] The clinical impact of osteoporosis is reflected in the impact of these fractures. More than 1.5 million fractures per year occur in the United States that are attributed to osteoporosis.[12] Estimated costs range from 14 to 20 billion dollars each year and include more than 432,000 hospital admissions, 180,000 nursing home admissions, and almost 2.5 million medical office visits.[1,12] Hip fractures account for almost three-fourths of the total cost of osteoporosis-related care, yet represent only 14% of the incident fractures. Hip fractures have a profound impact on the quality of life and a considerable associated mortality. The mortality during the first year after hip fracture is as high as 36% with a higher mortality in men than women.[1] There is a 2.5-fold increased risk of future fractures relative to persons of the same sex and similar age without fractures. In addition, hip fractures result in a multitude of complications for the elderly, including prolonged hospitalization, decreased independent living, depression, fear of future falls, and lifelong disability. An estimated 20% require long-term nursing home placement and approximately 60% are unable to regain their prefracture level of independence. Vertebral fractures may be painless or result in pain that usually lasts less than 3 months. The initiating injury may be as minor as a cough or turning over in bed. The risk of additional vertebral fractures is high. Vertebral collapse or deformity can result in loss of height, kyphosis, abdominal protuberance, or decreased pulmonary function as the abdominal cavity is shortened, chronic back pain, decreased mobility, or mortality.

The rates of osteoporosis and low bone mass have recently declined, but the total numbers of men and women with osteoporosis and low bone mass remain high.[11] The total number of 53.6 million adults over the age of 50 years with osteoporosis or low bone mass could potentially increase by 30% in the year 2030 based on the trends from 2005 to 2010. The impact of osteoporosis on the healthcare system, rising healthcare costs, in an aging population is potentially staggering.

Etiology

Eighty percent of bone that makes up the adult human skeleton is cortical bone, a dense compact bone.[13] Twenty percent is trabecular bone which is less dense than cortical bone and often referred to as spongy or cancellous bone. Cortical bone forms the outer shell as a protector of the marrow space and trabecular bone forms the interior structures in the bone marrow compartment, forming in a honeycombed fashion. Depending on location, bone consists of varied ratios of cortical to cancellous bone leading to differences in hardness and porosity.

The bones of the skeleton help to support and protect the body and undergo cycles of modeling (reshaping) and remodeling (renewal) to remove older bone and to replace it with stronger newly formed bone.[13] In young healthy bone, a balance between osteoblast and osteoclast activity results in a continuous remodeling process. Osteoclasts resorb old bone by increasing enzymes that dissolve bone proteins and mineral, and osteoblasts help reform bony surfaces and fill bony cavities by synthesizing a bony matrix that is made up of collagen and other proteins.[13,14] Bone minerals deposit into the bony matrix and calcify strengthening newly formed bone. When the rate of resorption or removal exceeds the rate of replacement, the resulting bone loss decreases bone strength and increases the risk of fracture.[14]

Bone mass peaks between ages 18 and 25 and begins to gradually decrease beginning at approximately age 30.[15] This slow, age-related bone loss phase leads to a 20% to 30% loss of cortical bone and a loss of 20% to 30% of cancellous bone in both men and women over a lifetime.[16]

During menopause, women undergo an additional phase of bone mineral density (BMD) loss. Unlike the slow age-related phase, this phase is rapid and leads to a loss of 20% to 30% of cancellous and 5% to 10% of cortical bone due to the decline in 17β-estradiol concentrations. Early cancellous bone loss in conjunction with postmenopausal decreases in cortical and cancellous bone may lead to increased vertebral and distal forearm fractures, which may be seen early after menopause.[14,17,18]

In addition, women may have an increased risk for osteoporosis because throughout life they have 30% less bone mass than men of similar age.[14]

Hormone-related, accelerated bone loss can also occur after surgical oophorectomy.

In males, androgens and estrogens play a role in the growth and development of bone.[19,20] Serum testosterone concentrations have been evaluated in many studies and its effects on bone metabolism have been controversial. Data suggest that testosterone has a direct beneficial effect on bone, but to a lesser extent than estrogen, and decreases in bioavailable estrogen due to age-related changes may be responsible for bone loss in older men.[20]

Other hormones regulated by the hypothalamic–pituitary–gonadal axis (e.g., progesterone, follicle-stimulating hormone, inhibins, oxytocin, and prolactin) have been studied for their effects on the skeletal system.[21]

Pathophysiology

Bone remodeling in humans occurs constantly, replacing the adult human skeleton approximately every decade.[22] This is a complex process that involves a balance of local and systemic regulators to form discrete skeletal foci or bone remodeling units.[15]

The receptor activator of nuclear factor-κB ligand (RANKL) and osteoprotegerin are local regulators that determine the formation, activation, and resorption of osteoclasts in remodeling.[13,23]

Osteoblast-derived RANKL binds to the osteoclast RANK receptor and facilitates osteoclast differentiation and resorptive activity. The B cells produce a decoy receptor osteoprotegerin (OPG) that competitively antagonizes RANKL by binding to it and preventing osteoclast stimulation. This process begins with bone resorption that is initiated by osteoclasts excavating lacuna found on the surface of cancellous bone, or it occurs when cavities are formed in cortical bone (Fig. 110-1).[13,18,23]

Figure 110-1 The bone remodeling cycle at the cellular level.

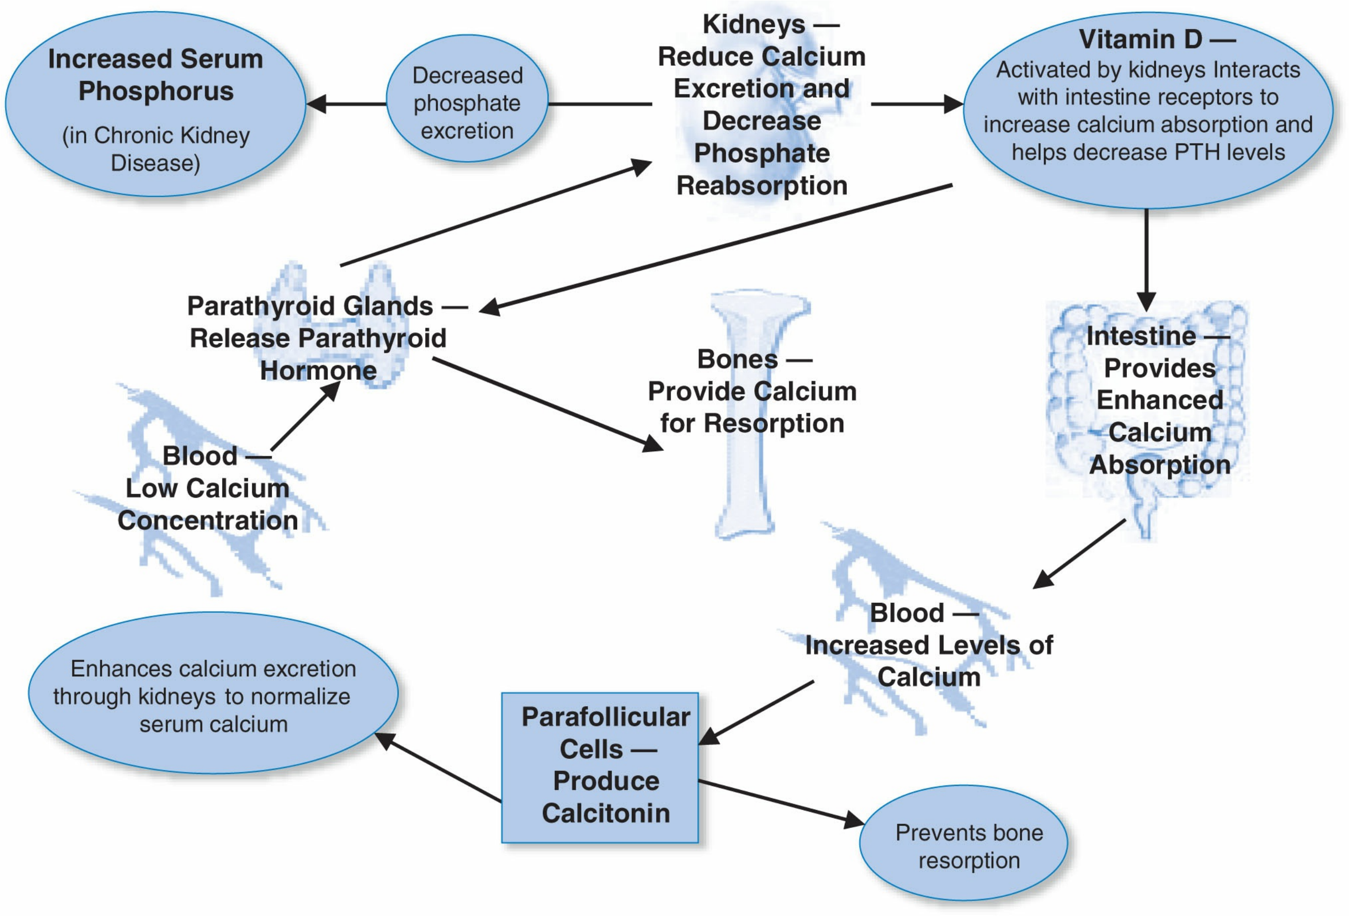
Enzymes, specifically transforming growth factor-β (TGF-β), produced in this process dissolve bone mineral and proteins serving as a chemoattractant for osteoblast precursors to the sites where resorption has occurred.[23] Osteocytes, cells in the bones, have growth factors that display direct and indirect effects on bone turnover. This occurs as collagen fills in bone cavities, which then are calcified.[13]

Calcium and vitamin D are important nutrients required for bone growth. Parathyroid hormone (PTH), glucocorticoid hormones, calcitonin, estrogen, and testosterone are all factors involved in bone remodeling.[18] Parathyroid hormone and glucocorticoid hormones have been associated with bone resorption, whereas calcitonin, estrogen, and testosterone have been associated with bone formation.

Dietary calcium is absorbed in the gastrointestinal tract. The kidneys reabsorb calcium in the tubular system, and the skeletal system serves as a reservoir for calcium. Calcium is primarily regulated by the actions of PTH, vitamin D, and calcitonin. The parathyroid gland releases PTH in response to low serum calcium levels, which in turn facilitates the mobilization of calcium and phosphate from bone and stimulates reabsorption of calcium through the tubular system in the kidneys.[15] Vitamin D aids in intestinal absorption of calcium, phosphorus, and magnesium. Increases in vitamin D levels decrease PTH levels. Vitamin D also increases bone resorption to prevent symptomatic hypocalcemia. Calcitonin is released in response to high serum calcium levels. Calcitonin decreases intestinal absorption of calcium and phosphorus, enhances calcium excretion in the kidneys, and prevents bone resorption (Fig. 110-2).

Overview of Drug Therapy

Osteoporosis is a condition of low bone mass and deterioration of bone tissue with a high-risk factor for fracture. Prevention, identification, and treatment of osteoporosis should all be incorporated into primary health care. Preventive measures to reduce fracture risk include adequate intake of daily calcium and vitamin D. Lifestyle modifications that are universally recommended are weight-bearing exercise, reduced alcohol consumption, and smoking cessation. Fall prevention strategies are also universal suggestions. These recommendations apply to both men and women. Pharmacologic treatment should be considered in patients with low-trauma hip or vertebral fracture, patients with a T-score of ≤ -2.5, and patients with low bone mass who are at increased risk for fracture. Medications include selective estrogen receptor modulators (SERMs; e.g., raloxifene) and calcitonin in women, bisphosphonates (e.g., alendronate), RANKL inhibitors (e.g., denosumab), and parathyroid hormone for both men and women. Testosterone therapy is recommended for men at high risk for fracture with low testosterone levels (<200 ng/dL or 6.9 nmol/L) who cannot tolerate the approved pharmacologic agents for osteoporosis.[24]



Increased Serum Phosphorus
(in Chronic Kidney Disease)
Decreased phosphate excretion
Kidneys — Reduce Calcium Excretion and Decrease Phosphate Reabsorption
Vitamin D — Activated by kidneys Interacts with intestine receptors to increase calcium absorption and helps decrease PTH levels
Parathyroid Glands — Release Parathyroid Hormone
Bones — Provide Calcium for Resorption
Intestine — Provides Enhanced Calcium Absorption
Blood — Low Calcium Concentration
Blood — Increased Levels of Calcium
Enhances calcium excretion through kidneys to normalize serum calcium
Parafollicular Cells — Produce Calcitonin
Prevents bone resorption

Figure 110-2 Pathway for calcium homeostasis with involvement from parathyroid hormone, vitamin D, and calcitonin.

Risk Factors

CASE 110-1

QUESTION 1: T.J., a 28-year-old, thin Caucasian woman, is worried about developing osteoporosis. Her 75-year-old maternal grandmother has osteoporosis and recently her postmenopausal mother (age 53) was told that she was at increased risk for osteoporosis. T.J. is 5 feet 2 inches tall, weighs 108 pounds, and is in good health. She jogs and occasionally does aerobic exercise. Her diet typically consists of cereal for breakfast, a sandwich for lunch, and meat with vegetables for dinner. Her only milk consumption consists of 1 cup of skim milk on her cereal. She occasionally has a dairy product for lunch or dinner. T.J. takes no medications, vitamins, or calcium supplements routinely. She occasionally takes a medication for headache or menstrual cramps. She does not smoke and occasionally drinks alcohol. Does T.J. have an increased risk for developing osteoporosis?

Table 110-1 lists risk factors associated with the development of osteoporosis. T.J. has several risk factors that could increase her risk for osteoporosis. She is a white woman of small stature and low weight (body mass index; BMI = 19.8 kg/m^2), has a positive family history, and has a low calcium intake.

Prevalence of osteoporosis worldwide varies with gender, race, and ethnicity.[9] In the United States, Mexican American women have the highest prevalence of low bone mass and osteoporosis, but non-Hispanic white women are at greatest risk for osteoporosis.[9,11,25] When prevalence is adjusted for risk factors such as age, body mass index, previous fracture, current smoking, alcohol intake, and glucocorticoid use, more non-Hispanic white women meet the NOF criteria for osteoporosis treatment compared to non-Hispanic black or Mexican American women.

LOW BODY MASS

T.J. has a small stature, and a BMI just under 20 kg/m^2 and on the low side of normal (range 18.5–24.99 kg/m^2). Low body mass index (BMI less than 20) is an established independent risk factor for osteoporosis and fracture.[26] In a meta-analysis of 12 cohorts including 60,000 men and women, a BMI of 20 kg/m^2 was associated with almost twice the risk of hip fracture compared to a BMI of 25 kg/m^2.[27] A BMI of 30 kg/m^2 was associated with a 17% reduction in the risk of hip fracture compared to 25 kg/m^2. Nevertheless, obesity should not be considered a protective factor. When adjusted for BMD, there was still a 42% increase in hip fracture in patients with a BMI of 20 kg/m^2, but no difference in the patients with a BMI of 30 kg/m^2.

FAMILY HISTORY AND GENETIC FACTORS

Osteoporosis is a multifactorial disorder that results from the effects of genetic and environmental factors. A family history of osteoporotic fracture is believed to be an underlying genetic predisposition.[7] Small stature or height is inherited. Smaller bone size can influence the risk of fracture, as bigger bones may be more resistant to breaking. The significance of heredity as a risk factor for osteoporosis has been studied. Certain disease states are genetic and have an associated risk of osteoporosis (e.g., celiac disease—a disorder associated with malabsorption). Genetic factors associated with osteoporosis may be related to peak bone mass, polymorphisms in the vitamin D receptor, genes associated with estrogen deficiency or estrogen resistance, bone morphogenetic proteins, signaling pathways, and various other bone-related proteins and receptors.[7,28,29] Women with a positive family history of osteoporosis or osteoporotic fracture typically have lower BMD than those with a negative family history.[30]

MOBILITY AND PHYSICAL ACTIVITY

Bone mass is dependent on physical activity.[7] Prolonged immobility of a limb or prolonged bed rest can result in a loss of skeletal tissue and bone mass. A number of studies have looked at the effect of exercise on bone mass. Cochrane Database published a meta-analysis of randomized controlled trials that included different types of exercise interventions in the prevention and treatment of osteoporosis in postmenopausal women.[31] The effect of all exercise types versus control was a small; there was significant improvement in BMD at the spine and trochanter, but not at the femoral neck or total hip and there was no difference in risk of fracture. Significant effects of low force weight-bearing exercise, such as walking or Tai Chi, were found at the spine and wrist. A significant effect on BMD from high force weight-bearing exercise, such as jogging, jumping, running, dancing, and vibration platform, was found at the hip. Significant effects of non-weight-bearing exercise, such as progressive resistive strengthening, were seen at the spine and the neck of the femur. Combinations of exercise types had a significant effect on BMD at the neck of the femur, spine, and trochanter and reduced the risk of fractures. BMD at the hip, however, favored control. Limitations reported by the authors include small sample size, loss of follow-up, lack of reported exercise characteristics, and heterogeneity. Though the evidence for exercise has limitations and the lasting value of exercise when stopped is not known, there is good evidence that physical activity is associated with improved health, reduced mortality, and should be encouraged.[7] The NOF recommends a combination of regular weight-bearing exercise and muscle-strengthening exercise to increase strength and reduce the risk of falls and fractures.[1] These include walking, jogging, Tai Chi, stair climbing, dancing, tennis, weight training, and other resistive exercises. The Institute for Clinical Systems Improvement (ICSI) guidelines also recommend a combination of exercise to maintain and improve bone health; impact exercise such as jogging, brisk walking, stair climbing; strengthening exercise with weights; and balance training such as Tai Chi or dancing.[26] Exercise can decrease the risk of falls by about 25%.

CIGARETTE SMOKING AND ALCOHOL INGESTION

Although T.J. does not smoke and only occasionally ingests alcohol, it is important to include questions concerning cigarette and alcohol use when obtaining a medical history from a person at risk for osteoporosis. Women and men who smoke have an increased risk for fractures, including hip fractures, compared with nonsmokers.[7] Smoking impairs the absorption of dietary and supplemental calcium, lowers body weight, influences estrogen metabolism, and may be directly toxic to bone cells.[22,26]

Excessive alcohol use by both women and men is associated with decreased BMD. Moderate alcohol consumption has been associated with increased BMD in postmenopausal women;[32] however, conflicting evidence exists. The effect of alcohol on bone is dose dependent; consuming more than two alcoholic drinks daily significantly increases the fracture risk.[7] The proposed mechanism may be a direct effect of alcohol on osteoblasts, or it may be secondary to nutritional compromise that could result in impaired calcium and vitamin D intake with subsequent decrease in bone formation. The effect on bone formation has been seen even at no more than one drink per day for women and two drinks per day for men.[26] It is recommended that alcohol be limited to this amount to protect bone health and reduce the risk of falls.

Table 110-2

Dietary Reference Intakes for Calcium and Vitamin D[33]

Life Stage Group	RDA Calcium	RDA Vitamin D
Males		
19–50 years	1,000 mg	600 IU (15 mcg)
51–70 years	1,000 mg	600 IU (15 mcg)
>70 years	1,200 mg	600 IU (15 mcg)
Females (Nonpregnant)		
19–50 years	1,000 mg	600 IU (15 mcg)
51–70 years	1,200 mg	600 IU (15 mcg)[a]
>70 years	1,200 mg	800 IU (20 mcg)[a]

[a] NOF recommends vitamin D 800 to 1,000 IU in patients ≥ 50 years.

IU, International Unit; RDA, Recommended Dietary Allowance.

DIETARY INTAKE

Dietary calcium and vitamin D are critical to bone health and needed to strengthen bones and increase bone mass. Peak bone mass is achieved in early adulthood and afterward bone constantly undergoes remodeling.[33] Maintaining normal bone mass reduces the risk of osteoporosis and fracture. Women and men need adequate calcium and vitamin D intake to achieve and help maintain optimal bone mass. The Institute of Medicine of the National Academies published recommendations for both calcium and vitamin D intake that would promote bone maintenance along with a neutral calcium balance based on age.[33] For men and nonpregnant women 19 to 50 years of age, intake of 1,000 mg of elemental calcium per day and 600 international units (IU) of vitamin D per day is recommended (Table 110-2). The National Institutes of Health (NIH) base their recommendations on the same published report.[34] The National Osteoporosis Foundation (NOF) has similar recommendations for calcium and, however, differs in their recommendations for vitamin D intake.[1] Vitamin D 800 to 1,000 international units (IU) per day is recommended for individuals 50 years of age and older.

Calcium is best ingested from the diet. Significant sources of calcium include dairy products, tofu, and canned fish (Table 110-3). Calcium absorption from foods is approximately 30%, but will vary depending on the food.[33] Calcium absorption also decreases with age. Absorption from dairy products or fortified juice is about 30%, but for certain green vegetables such as broccoli and kale, the absorption can be twice as high. Oxalate or oxalic acid-containing foods can impair calcium absorption. Kale and broccoli are foods low in oxalate as are mustard or turnip greens.[22] Examples of foods that contain high levels of oxalic acid are spinach, sweet potatoes, beans, or collard greens. Even if high in calcium, oxalate impairs the absorption of calcium. Some foods high in fiber can interfere with calcium absorption; thus, intake of a variety of foods with calcium is recommended. Alcohol, caffeine from coffee or tea, a low protein diet, a high intake of sodium, and excess dietary phosphorous, all negatively affect calcium balance.[22,33]

Vitamin D is considered a nutrient and a regulatory hormone. It is a fat-soluble vitamin that is found naturally in very few foods, but is added to certain foods and is available in supplement form. Vitamin D is a nutrient that can be synthesized in the skin through the action of sunlight, but exposure to sunlight should be limited due to the risk of skin cancers.[33] Sunlight may also not produce enough vitamin D due to differences in skin pigmentation, latitude, or use of sunscreen. Vitamin D regulates calcium and phosphate, which make it important in the development and maintenance of bone health.

Table 110-3

Calcium Content of Selected Foods

Food	Serving Size	Calcium (mg)
Dairy		
Milk, dry nonfat	1 cup	350–450
Yogurt, low fat	1 cup	345
Milk, skim	1 cup	300
Milk, whole	1 cup	250–350
Cheese, cheddar	1 oz.	211
Cheese, cottage	1 cup	211
Cheese, American	1 oz.	195
Cheese, Swiss	1 oz.	270
Ice cream or ice milk	1/2 cup	50–150
Fish		
Sardines, in oil	8 med	354
Salmon, canned (pink)	3 oz.	167
Fruits and Vegetables		
Calcium-fortified juices	1 cup	100–350
Spinach, fresh cooked	1/2 cup	245
Broccoli, cooked	1 cup	100
Collards, turnip greens	1/2 cup	175
Soybeans, cooked	1 cup	131
Tofu	1 cup	75
Kale	1/2 cup	50–150

It directly stimulates calcium and phosphate absorption from the intestinal tract and, with the help of parathyroid hormone (PTH), can mobilize calcium from bone or stimulate calcium reabsorption at the renal distal tubule (see also Chapter 28, Chronic Kidney Diseases). Vitamin D that is found in the diet or that is synthesized from the sun must be converted to its active form, calcitriol. Two major forms of vitamin D are available. Vitamin D_3, cholecalciferol, is synthesized in the skin of humans from 7-dehydrocholesterol, is synthesized commercially, and can also be found in fatty fish, beef liver, egg yolks, and cheese. Vitamin D_2, ergocalciferol, is plant-based and largely synthesized commercially. Both forms can be found in dietary supplements or fortified foods. Cholecalciferol and ergocalciferol are inactive until they are converted to active vitamin D first by the liver to 25-hydroxyvitamin D (25OHD) and then by the kidneys to 1,25-dihydroxyvitamin D, calcitriol. The serum level of 25OHD is considered the marker for adequate intake. The National Osteoporosis Foundation recommends vitamin D intake to maintain serum 25OHD levels > 30 ng/mL (75 nmol/L).[1] Aging, chronic renal insufficiency, intestinal disease, malabsorption, very dark skin, obesity, certain medications, and reduced sun exposure are associated with reduce serum levels of vitamin D.

When vitamin D is taken in conjunction with calcium in postmenopausal women, the risk of fracture and bone loss is slightly reduced; however, the same effect from vitamin D alone is not established.[26,35,36] The combination of vitamin D and calcium results in small increases in BMD of the spine, the total body, femoral neck, and total hip.

There are few adverse effects from vitamin D supplementation. Vitamin D_3 combined with calcium can increase the chance of forming kidney stones and supplementation with the active form of vitamin D can increase the risks of hypercalcemia.

Table 110-4

Calcium Content in Various Supplements

Salt	Percent Calcium
Calcium carbonate	40
Tricalcium phosphate (calcium phosphate, tribasic)	39
Dibasic calcium phosphate dehydrate	23
Calcium citrate	21
Calcium lactate	13
Calcium gluconate	9

T.J. is typical of the average American and has a diet low in calcium. If the calcium or vitamin D in her diet does not achieve the recommendations, supplements should be added. (Table 110-4; see Case 110-1, Questions 2, 3)

OTHER POTENTIAL RISKS

Various medications and medical conditions that have been associated with the development of secondary osteoporosis are listed in Table 110-1.

Prevention

PREMENOPAUSAL WOMEN

CASE 110-1, QUESTION 2: Although T.J. is premenopausal, what recommendations could be made to decrease her future risk of developing osteoporosis?

Universal recommendations for the prevention of osteoporosis are adequate intake of daily calcium and vitamin D, weight-bearing and strengthening exercise, reduced alcohol consumption, and smoking cessation. T.J.'s course of action should be to maximize her peak bone mass and prevent or decrease bone loss. Her diet should consist of adequate calcium of 1,000 mg and adequate vitamin D of 600 IU. T.J. should continue to exercise, developing a lifelong exercise program, and continue to refrain from smoking. T.J. should also maintain her BMI between 20 and 25 kg/m^2.

Exercise

T.J. should be encouraged to participate regularly in weight-bearing and strengthening exercises such as jogging, walking, running, biking, tennis, or weight lifting and to continue appropriate exercise for her age throughout life. Physical activity has numerous benefits in addition to promoting bone health. Exercise enhances overall health and well-being, helps to control blood pressure, and lowers risk factors for cardiovascular disease, colon cancer, and type 2 diabetes.[22] Young women such as T.J. should be made aware that it is important to maintain regular menstrual periods. Amenorrhea due to strenuous exercise or extremely low body weight can increase the long-term risk of osteoporosis and fractures.

Dietary Intake

T.J. should eat a well-balanced diet rich in fruits and vegetables, low-fat dairy products, whole grains, fish, and nuts. This will provide calcium as well as other nutrients needed for bone health. She should ensure her diet contains 1,000 mg of elemental calcium and 600 IU vitamin D, optimally from dietary sources.[22] Dairy products are the major source of dietary calcium in the United States. Low-fat or nonfat versions have the full amount of calcium. Fortified juices or fortified cereals are also good sources of calcium. Although nondairy sources may contain lower amounts of calcium, they can be an important source for men or women with dietary preferences, those who cannot tolerate dairy, or who have food allergies (Table 110-3). The ingestion of foods rich in phytates and oxalates (e.g., cereal grains, legumes, and nuts) may decrease calcium absorption.

If T.J. cannot meet her daily calcium requirement from dietary sources, she can use a calcium supplement. Table 110-4 lists the percentage of elemental calcium available from selected calcium salts. (see Case 110-1, Question 3, for further information on calcium supplements.)

Vitamin D is found in few foods naturally (e.g., beef liver, egg yolk, salmon, tuna), but can be found in fortified juice or milk. It is difficult to quantify the amount of vitamin D obtained from sunlight. Genetic factors, skin pigment, latitude, and the use of sunscreen are all factors that affect sun exposure.[33] T.J. should be able to obtain adequate vitamin D intake from her diet. She could also add a supplement to her diet to achieve 600 IU of vitamin D daily.

Other bone-related nutrients include magnesium, phosphorous, vitamin K, and protein. Magnesium affects the concentration of parathyroid hormone, is involved in the formation of bone, and is widely available in foods and fortified cereals.[37] Low dietary intake of magnesium has been associated with lower bone mineral density, but not an increase in the incidence of hip fracture or total fractures.[38] Total daily magnesium intake was estimated in 73,684 postmenopausal women enrolled in the Women's Health Initiative Observational Study. Women who consumed magnesium in the highest quintile had a 3% higher total hip BMD and a 2% higher whole-body BMD than those in the lowest quintile. The incidence of hip fracture or total fracture was not statistically different across quintiles of magnesium intake. Calcium as well as phosphorous is stored in the bone. A complex balance of both is necessary for bone strength.[22] Low dietary intake of phosphorous as well as excessive intake has adverse effects on bone. Vitamin K is also important to maintain healthy bone. Patients who are on long-term vitamin K antagonists or who have a diet low in vitamin K are at increased risk for fracture and osteoporosis, but this risk is controversial.[39] Currently, there is no strong evidence and no recommendations for supplementation.[39–41] Isoflavones are a class of phytoestrogens found in soybeans and red clover, have estrogen-like activity, and have been shown to increase bone density. There is conflicting and insufficient information on phytoestrogens to support the use of isoflavones for osteoporosis prevention.[22] Soy, however, is a good source of protein, which is also important for bone health. Calcium absorption is decreased in diets that are low in protein.

Smoking and Alcohol

Smoking cessation should be encouraged in men or women who smoke. Rates of bone loss are greater in smokers than for nonsmokers and calcium absorption may be decreased.[26] T.J. occasionally drinks alcohol and should be educated on the risk of alcohol and decreased bone mineral density. Recommended alcohol intake should be limited to no more than one drink per day for women and two drinks per day for men.

CASE 110-1, QUESTION 3: If T.J. needs a calcium supplement, which calcium salt should be recommended?

The amount of elemental calcium in supplements varies. Two common forms of calcium supplements are calcium carbonate and calcium citrate.[33,37] The cost of calcium carbonate tends to be lower and it contains the highest percentage of elemental calcium (40%), allowing fewer tablets per day to meet daily calcium requirements. Calcium absorption from supplements depends on the total amount of elemental calcium consumed at one time. The percentage of calcium absorbed decreases as the dose increases. Maximal absorption occurs at doses ≤ 500 mg at one time.[37] If T.J. needs a calcium supplement, calcium carbonate is a reasonable choice. She should be advised to take it in divided doses up to 500 mg/dose to maximize absorption. Calcium carbonate absorption is dependent on stomach acid and should be taken with food. Calcium citrate contains less elemental calcium, 21%, is less dependent on stomach acid for absorption, and can be taken with or without food. Calcium citrate is beneficial in patients with achlorhydria, inflammatory bowel disease, or in patients taking proton pump inhibitors or histamine 2 receptor blockers. Supplements should be taken with plenty of fluids. Calcium can compete or interfere with the absorption of iron, zinc, and magnesium. Significant drug interactions can also occur, such as impaired absorption of medications including tetracyclines, thyroid products, and quinolones (Table 110-5). T.J. should be informed that the most common adverse effects of calcium are constipation, GI irritation, bloating, and flatulence. Caution should be used in patients with renal insufficiency, hypoparathyroid disease, hypercalcemia, and a history of kidney stones. If T.J. or any family member has a history of urinary stones, her clinician should be aware of supplementation. T.J. should drink plenty of water throughout the day and take calcium carbonate with food to ensure absorption or switch to calcium citrate.

Table 110-5

Drug Interactions

Examples of Drug–Calcium Supplement Interactions[a]	
Allopurinol	Protease inhibitors
Bisphosphonate derivatives	Tetracycline derivatives
Calcium-channel blockers	Protease inhibitors
Certain cephalosporin antibiotics	Quinidine
Corticosteroids (oral)	Quinolone antibiotics
HMG-CoA reductase inhibitors	Sucralfate
Iron salts	Thiazide diuretics
Itraconazole, ketoconazole	Thyroid products

Magnesium salts	Tetracycline derivatives
Multivitamins/fluoride (with ADE)	Vitamin D analogs
Multivitamins/minerals (with ADEK, folate, iron)	Zinc

POSTMENOPAUSAL WOMEN

CASE 110-2

QUESTION 1: T.J.'s mother, M.J., is a 53-year-old Caucasian woman, who is also of small stature and low weight. She occasionally walks in the evenings. She currently is taking a calcium supplement to maintain her total calcium intake (dietary plus supplementation) of about 1 g/day. She takes omeprazole (over-the-counter) for her gastroesophageal reflux disease (GERD) and occasional acetaminophen for headaches. M.J. was a cigarette smoker but stopped in her late twenties and rarely drinks alcohol. She is in good health with no gynecologic surgery or major diseases. M.J. has a strong family history of breast cancer. Her last menstrual period was 6 months ago, but she began experiencing menstrual irregularity 2 years ago. M.J. has been experiencing some menopausal symptoms (hot flushes), but states that they are mild and occur only at night. M.J., worried about developing osteoporosis, decided to make an appointment with her gynecologist to discuss preventive measures. A dual-energy X-ray absorptiometry (DXA) measurement of her spine was administered, which noted her T-score to be −2.0 and a Z-score of −1.0.

In addition to the DXA, what other information should be obtained to determine whether M.J. is at risk for developing osteoporosis or has already developed osteoporosis?

In addition to M.J.'s DXA, a detailed medical history including medication history (prescription and over-the-counter medications), diet, social history (smoking, alcohol), and a physical examination, which includes height, are needed along with a risk factor analysis. Diagnostic tests are indicated when there are multiple risk factors present.[1] The goals of a comprehensive evaluation are to identify modifiable risk factors, rule out potential causes of osteoporosis, and to treat if indicated.

From her history and risk factor analysis, it is determined that M.J. shares similar risk factors for osteoporosis with her daughter. In addition, she is early in the postmenopausal phase, has GERD, and was a previous smoker. M.J. has no loss of height, does not complain of back pain, and does not have signs of kyphosis, all of which may be signs of osteoporosis. As part of the aging process, women may lose 1 to 1.5 inches in height due to degenerative arthritis and shrinking of intervertebral discs.[1] It is important to monitor height as a loss of height may indicate that the patient has a vertebral fracture.

Biochemical markers of bone turnover are not needed for M.J. at this time (e.g., alkaline phosphatase, calcium levels, phosphorus levels, bone-specific alkaline phosphatase, osteocalcin, cross-linked C-terminal telopeptide, and N-telopeptide). They are not used to diagnose osteoporosis but may be used to evaluate drug therapy.[1]

The North American Menopause Society (NAMS) recommends a BMD measurement in women such as M.J. who are older than 50 years of age if one or more risk factors for fracture are present.[32] These risk factors include weight <127 pounds or BMI <21 kg/m^2, fracture other than skull, facial bone, ankle, finger or toe after menopause, first-degree relative with a history of hip fracture, smoking, rheumatoid arthritis, or alcohol consumption of two drinks per day (1 drink = 12 oz of beer, 4 oz of wine, or 1 oz of liquor).[1]

NAMS also recommends BMD testing in postmenopausal women with bone loss due to medical conditions such as hyperparathyroidism, medications such as steroids, postmenopausal women who have had a fragility fracture, and all women over the age of 65.[32] The NOF recommends BMD testing for women age 65 years and older; men age 70 years and older; menopausal women or women in menopausal transition who are younger than age 65 and at increased risk of osteoporosis or who suffered a low impact fracture; nonmenopausal women over age 50 and men ages 50 to 70 who have suffered a low impact fracture or who are at risk for fracture; and adults with a condition or who take medication that is associated with low bone mass.[1] Along with evidence-based recommendations, insurance reimbursement plays a role in BMD testing.

Bone mineral density refers to the amount or weight of bone mass per area and is measured in g/cm^2. BMD is reported as T-score (Table 110.6) and also as Z-score.[26] As T-score is a comparison of BMD to what is expected in a young healthy adult population of the same gender, Z-score is a comparison of BMD to what is expected in a healthy adult population of a similar age, gender, and ethnicity.

T-Score

$$\text{([measured BMD} - \text{young adult population mean BMD]/ young adult population SD)} \qquad \text{(Eq. 110-1)}$$

Z-Score

$$\text{([measured BMD} - \text{age-matched population mean BMD]/ age-matched population SD)} \qquad \text{(Eq. 110-2)}$$

Dual-energy X-ray absorptiometry (DXA) is a two-dimensional X-ray considered the standard for measuring BMD to diagnose or assess therapy.[4] Central DXA of hip, spine, and femoral neck remain the preferred measurement for definitive diagnosis (Table 110-6).[2]

Other methods can be used for screening but should not be used for diagnosis or to follow a patient's response to therapy.[7,26]

For postmenopausal women who are not receiving medications for osteoporosis prevention, a DXA may be useful no more frequently than every 2 to 5 years because the rate of bone loss is approximately 1% to 1.5% per year.[32] T-score values are supported by both the NAMS and NOF for diagnosis. The International Society for Clinical Densitometry (ISCD) recommends using Z-scores when screening low BMD in children, premenopausal women, and men less than age 50. A Z-score of −2.0 or less is below the expected range and a Z-score greater than −2.0 is considered within range.[43]

Table 110-6

Definitions of Bone Mineral Density[42]

Classification	T-Score
Normal	≥ −1.0 SD
Osteopenia (Low bone mass)	−2.5 to −1.0 SD
Osteoporosis	< −2.5 SD

It has been estimated that for every one point decrease in SD from the mean T-score, a 10% to 15% change may occur in BMD. The magnitude of this change can be translated into a 1.5-fold to 3-fold change in risk for fractures (Table 110-7).[32]

The World Health Organization along with several leading osteoporosis organizations developed the WHO Fracture Risk Assessment tool (FRAX) that can be used alone or with BMD to identify fracture risk.[44] FRAX is a computerized-based algorithm created for different populations available online at http://www.shef.ac.uk/FRAX. The FRAX algorithm incorporates ethnicity as well as clinical risk factors (e.g., age, smoking, physical inactivity, height, weight, prior fracture, parental history of hip fracture, long-term use of glucocorticoids, and comorbid conditions that have been associated with decreases in BMD) to calculate 10-year fracture risk. FRAX has been validated in 11 different cohorts and is a valuable tool that provides information on absolute risk instead of relative risk by taking into account the impact of risk factors on fracture and death. As with many tools, there are some limitations to FRAX. The algorithm excludes certain variables such as vitamin D deficiency, bone turnover markers, and falls. It does not take into account multiple fractures and may underestimate risk.

FRAX should not replace clinical judgment for treatment and is intended to be used in postmenopausal women and men over age 50. It has not been validated in patients who have been on or who are receiving medication therapy for osteoporosis.[1,45]

CASE 110-2, QUESTION 2: Based on the information that you have obtained, does M.J. have osteoporosis or is she at risk for developing osteoporosis?

M.J. is 62 inches tall and weighs 50 kg. She has a T-score of −2.0 (DXA measurement of the spine) and a Z-score of −1.0. Using the FRAX risk assessment tool for the US population (http://www.shef.ac.uk/FRAX) without a T-score of the femoral neck, M.J.'s 10-year probability of a hip fracture is 0.5% and her 10-year probability of a major osteoporosis-related fracture is 5.1%. M.J's T-score is consistent with osteopenia or low bone mass.

Table 110-7

Techniques for Measuring Bone Mineral Density

Technique	Abbreviation	Measurement Sites
Dual-energy X-ray absorptiometry	DXA	Hip, spine, total body
Peripheral dual-energy X-ray absorptiometry	PDXA	Forearm, fingers, heel
Peripheral quantitative computed tomography	PQTC	Forearm, tibia
Quantitative ultrasound	QUS	Heel, tibia, patella
Quantitative computed tomography	QCT	Spine, hip
Single-energy X-ray absorptiometry	SXA	Heel

M.J.'s risks include low bone mass, low body mass, a family history of osteoporosis, history of smoking, and medication that increases the risk of osteoporosis.

CASE 110-2, QUESTION 3: What preventive measures would help decrease M.J.'s likelihood of developing osteoporosis?

Exercise

M.J. goes for walks occasionally and should begin a consistent exercise program appropriate for her age and physical condition. Postmenopausal women who incorporated aerobic and weight-bearing exercise showed some improvements in BMD and reduced the risk of fractures as compared to those who did not exercise.[31] Weight-bearing exercise and resistance training may improve strength, muscle mass, flexibility, balance, and decrease M.J.'s risk for falls.[26] (Also see Case 110-1, Question 2).

Dietary Intake

Similar to T.J., it is important for M.J. to have a well-balanced diet rich in fruits and vegetables, low-fat dairy products, whole grains, fish, and nuts to provide adequate calcium and nutrients needed for bone health.

The recommended daily allowance of calcium for women ages 51 to 70 is 1,200 mg per day.[33] M.J's total calcium intake from diet and supplementation is about 1,000 mg/day and should be increased so that she incorporates 1,200 mg/day of calcium in her diet. She can do this by choosing calcium-containing foods (Table 110-3) and by taking a supplement if she cannot get adequate calcium from her diet (Table 110-4).

It is important for M.J. to have adequate vitamin D intake in her diet. The recommended daily allowance of vitamin D for women between 51 and 70 age is 600 IU/day, and for women over age 70, the recommended daily allowance is 800 IU/day. The NOF recommends 800 to 1,000 IU/day for men and women over age 50.[1]

Expert consensus opinion has made recommendations for serum 25(OH) vitamin D levels for bone health.[33] Levels less than 20 ng/mL (50 nmol/L) suggest insufficiency, whereas levels of 29 to 32 ng/mL (70 to 80 nmol/L) suggest adequate stores. There is currently limited evidence to attempt to achieve serum 25(OH) vitamin D levels above 60 ng/mL (150 nmol/L). (For further information, see Case 105-1, Question 2.) A serum 25(OH) vitamin D level should be drawn and M.J. should receive a vitamin D supplement to achieve a serum 25 (OH) vitamin D level of 30 ng/mL (75 nmol/L) if the level is found to be insufficient.

Although calcium and vitamin D are important for bone health, they should not be used instead of drug therapy to treat osteoporosis, but used as part of an overall plan to help improve bone health.

Pharmacologic Prevention

ESTROGEN/PROGESTIN THERAPY

CASE 110-2, QUESTION 4: Because a rapid rate of bone loss is seen during menopause when estrogen decreases, should estrogen therapy (ET) or estrogen + progesterone therapy (EPT) be considered for M.J.?

An estimated 10% to 15% of a woman’s bone mass is estrogen dependent.[46]

Estrogens are important in bone formation, resorption, and maintaining bone mass while menopause is associated with a decrease in estrogen and an increase in bone loss.[15,21]

The National Osteoporosis Risk Assessment Study and the Million Women Study, both large observational studies by design, found that EPT or ET provided significant relative risk reductions in fracture.[47,48] These results were confirmed by the Women’s Health Initiative (WHI) with both the EPT and ET arms, showing significant risk reductions in hip, vertebral, and total fractures compared with placebo.[49,50]

Previously, ET or EPT would have been considered first-line treatment for the prevention of osteoporosis in a postmenopausal woman such as M.J., who has an intact uterus and is at risk for osteoporosis based on risk factors and T-score. In the Women’s Health Initiative (WHI), conjugated equine estrogen (CEE) alone and CEE with medroxyprogesterone (CEE+MPA) were shown to decrease the risk of hip, vertebral, and total fractures in postmenopausal women; however, the intervention phases were ended early because coronary heart disease (CHD), stroke, deep vein thrombosis (DVT), pulmonary embolism (PE), and breast cancer were significantly increased in the CEE + MPA group and rates of stroke were significantly increased in women on CEE alone (also see Chapter 51, The Transition Through Menopause).[49,50] The findings from the WHI do not support the use of ET or EPT for the prevention of osteoporosis. Since the publication of the Heart and Estrogen/Progestin Replacement Study (HERS) I and HERS II and the NIH Women's Health Initiative (WHI), healthcare providers are less likely to prescribe ET or EPT for the sole purpose of osteoporosis prevention or to continue its use after a women no longer needs EPT or ET for postmenopausal symptoms such as hot flushes.[51–53]

EPT is approved for the prevention of osteoporosis in postmenopausal women with a uterus and ET is approved for postmenopausal women without a uterus.[32] When prescribed for osteoporosis prevention, ET and EPT should be used at the lowest effective doses and the shortest duration indicated. Longer therapy should only be prescribed in women who have failed other osteoporosis therapies, or when other osteoporosis therapies are contraindicated and when it can be determined that the benefits outweigh the risks. M.J. does not have bothersome symptoms of menopause; therefore, ET or EPT would not be appropriate at this time.

Contraindications to Estrogen Use

CASE 110-2, QUESTION 5: If M.J. developed bothersome symptoms of menopause, would ET or EPT be appropriate to treat symptoms and prevent osteoporosis?

Contraindications to EPT or ET include pregnancy; active or history of deep vein thrombosis or pulmonary embolism; active or recent (e.g., within the past year) arterial thromboembolic disease (e.g., stroke, myocardial infarction); undiagnosed abnormal genital bleeding; known, suspected, history of breast cancer; known or suspected estrogen-dependent neoplasia; liver dysfunction or disease; or known hypersensitivity to the product or any of its ingredients.[54] In addition, EPT and ET should be used with caution in those with a history of asthma, diabetes mellitus, migraine, epilepsy, systemic lupus erythematous, porphyria, and hepatic hemangiomas. Patients on EPT or ET are at increased risk for cancer, including endometrial (if not on EPT), breast (for EPT), and ovarian cancer as well as increased cardiovascular events, thromboembolic disease, stroke, gallbladder disease, and dementia (also see Chapter 51, The Transition Through Menopause).

M.J. stated that she has a strong family history of breast cancer, and starting EPT or ET would not be the treatment of choice for the prevention of osteoporosis.

BISPHOSPHONATES

CASE 110-2, QUESTION 6: Should a bisphosphonate be considered for the prevention of osteoporosis in postmenopausal women such as M.J.?

NAMS recommends adding osteoporosis drug therapy in postmenopausal women who have had a vertebral or hip fracture, in postmenopausal women with a BMD of −2.5 or worse at the lumbar spine, femoral neck, or total hip, and in postmenopausal women with a T-score of −1.0 to −2.5 who have a 10-year fracture risk of 20% (spine, hip, shoulder, wrist) or risk of 3% (hip) calculated using FRAX.[32] Bisphosphonates, analogs of pyrophosphate, are considered first-line therapy for the prevention and treatment of osteoporosis in postmenopausal women. Alendronate (excluding effervescent tablets), ibandronate, risedronate-immediate release, and zoledronic acid are indicated for osteoporosis prophylaxis in postmenopausal women like M.J, whereas other agents are indicated for osteoporosis treatment and prevention (see Table 110-8).[55]

Alendronate, ibandronate, risedronate, pamidronate, and zoledronic acid are aminobisphosphonates with a greater selectivity for the antiresorptive surfaces of the bone due to changes in the nitrogen-containing side chain of the compounds.

Bisphosphonates have high affinities for bone hydroxyapatite and can be incorporated into bone. They concentrate in mineral tissue and interfere with the osteoclast-mediated bone resorption to cause osteoclast apoptosis, decreased bone turnover, resulting in decreased fracture rates in postmenopausal women who are at risk for osteoporosis.[56]

Because of their incorporation into bone, bisphosphonates have long half-lives, estimated to be 1 to 10 years. Unlike etidronate (a nonaminobisphosphonate), aminobisphosphonates do not inhibit bone mineralization, which could lead to osteomalacia.

Bisphosphonates-Bone Mineral Density Efficacy in Postmenopausal Women

Alendronate

In a Cochrane review that included randomized controlled trials (RCTs) of alendronate for the primary and secondary prevention of osteoporotic fractures in postmenopausal women taken for at least 1 year, alendronate was compared to placebo with or without calcium and vitamin D.[57] Trials were considered primary prevention trials if the women had an average T-score within 2 SD of the mean, or if the prevalence of vertebral fracture was less than 20% at baseline. Secondary prevention trials were defined as women having a bone density at least 2 SD below peak bone mass or a previous vertebral compression fracture or age greater than 62 years. Clinically, important improvements were seen with vertebral fractures although not statistically significant for primary prevention. In secondary prevention studies, alendronate 10 mg daily led to clinically and statistically significant reductions in hip, wrist, vertebral, and nonvertebral fractures.

Table 110-8

Medications Approved for Prevention and Treatment in Postmenopausal Osteoporosis

Class	Medication	Prevention	Treatment
Bisphosphonates	Alendronate	5 mg PO daily 35 mg PO weekly	10 mg PO daily 70 mg PO weekly
	Alendronate/cholecalciferol		70 mg/2,800 IU PO weekly 70 mg/5,600 IU PO weekly
	Ibandronate	2.5 mg PO daily 150 mg PO monthly	2.5 mg PO daily 150 mg PO monthly
	Risedronate	5 mg PO daily 35 mg PO weekly 75 mg PO 2 consecutive days each month 150 mg PO monthly	5 mg PO daily 35 mg PO weekly 35 mg DR*-PO weekly 75 mg PO 2 consecutive days each month 150 mg PO monthly
	Zoledronic acid	5 mg IV every other year	5 mg IV yearly
Selective estrogen receptor modulators (SERMs)	Raloxifene	60 mg PO daily	60 mg PO daily
Polypeptide hormone	Calcitonin	Not indicated	100 IU IM or SC once daily, every other day, or 3 times per week 100 IU intranasally in one nostril daily
Monoclonal antibody	Denosumab	Not indicated	60 mg SC every 6 months
Parathyroid hormone	Teriparatide	Not indicated	20 mg SC once daily
Estrogen	Conjugated estrogen	When other treatments are not appropriate (without uterus)	Not indicated
	Estrogen + progestin	When other treatments are not appropriate (with uterus)	Not indicated
	Conjugated estrogen + bazedoxifene	0.45 mg/20 mg PO daily	Not indicated

Source: Facts & Comparisons eAnswers. http://online.factsandcomparisons.com/index.aspx. Accessed June 18, 2015.

A 2-year multicenter study of postmenopausal women age 45 to 59 was conducted to compare the efficacy and tolerability of alendronate to EPT.[58] Women were randomized to receive placebo, alendronate 2.5 mg/day or alendronate 5 mg/day, or open-label EPT, unless contraindicated decreases in BMD of the lumbar spine were noted in the placebo group, whereas 2% and 2.7% increases were seen in the alendronate 2.5 and 5 mg/day groups, respectively, after the first year. Forty percent of women who were in the placebo group lost 2% of bone mineral density at the hip as compared to only 10% in the alendronate 2.5 mg and 6% in the alendronate 5-mg groups. Hip BMD increased at 2 years by 1.9% (EPT) and 1.3% (alendronate 5 mg) in the United States cohort. In the European cohort, women on EPT had significantly greater increases in total body BMD as compared to those on alendronate 5 mg/day. Alendronate 2.5 and 5 mg/day were well tolerated with adverse effects similar to placebo. The adverse effects of EPT could not be directly compared to alendronate because the EPT arm was open label. Alendronate and EPT both increase BMD, therefore decreasing the acceleration of bone loss in postmenopausal women without osteoporosis. Alendronate is an effective alternative to EPT without the well-known side effects.

Ibandronate

In a double-blind, placebo-controlled phase II/III study, oral ibandronate 2.5 mg/day in early postmenopausal women without osteoporosis resulted in significantly increased BMD in the lumbar spine (1.9%) as compared to placebo (−1.9%) and total hip (1.2%) as compared to placebo (−0.6%) after 2 years.[59] Oral ibandronate 2.5 mg/day significantly reduced biochemical turnover markers.

MOBILE, a randomized controlled, noninferiority study, included 1,609 postmenopausal women ages 55 to 80 with osteoporosis and compared daily ibandronate (2.5 mg/day) to three different monthly regimens; ibandronate 50 mg given on 2 consecutive days/month, 100 and 150 mg once monthly.[60] All monthly regimens were at least as effective as daily ibandronate after 1 year. At 2 years, the mean increase in BMD of the lumbar spine seen in the ibandronate 50 mg on 2 consecutive days/month was (5.3%), ibandronate 100 mg/month (5.3%), and ibandronate 150 mg/month (6.4%) as compared to ibandronate 2.5 mg taken daily (4.8%). Increases were seen in the total hip, trochanter, and femoral neck with ibandronate 150 mg/month being the most significant.

In a 5-year long-term extension (MOBILE LTE), increases in BMD that were achieved during the MOBILE study were maintained, and further increases were seen in lumbar spine BMD.[61] Minor changes were seen in the femoral neck and trochanter. Overall adverse effects of monthly ibandronate were similar to daily ibandronate. Benefits in BMD changes and decreases in bone turnover markers were greatest for ibandronate 150 mg/month.

Ibandronate has also been studied as an intravenous (IV) formulation of 3 mg administered every 3 months.[62] One-year results from the dosing intravenous administration (DIVA) study improved BMD in the lumbar spine (4.5% vs. 3.5%) and the total hip (2.1% vs. 1.5%) to a similar if not greater degree than daily oral tablets.

Risedronate

In a double-blind, placebo-controlled study, early postmenopausal women age 40 to 61 with normal BMD for age, received 2 years of risedronate treatment or placebo.[63] Women who received risedronate 5 mg/day for 2 years had BMD increases of 1.4% from baseline in the lumbar spine as compared to a 4.3% loss in the placebo group. There was an increase of 2.6% at the femoral trochanter at 2 years and 1.3% at the femoral neck at 9 months with risedronate 5 mg/day as compared to a decrease of 2.4% at the femoral neck and 2.8% at the trochanter with placebo.

In a study of postmenopausal women who were at least 50 years of age, were postmenopausal for 5 or more years, and had osteoporosis, 75 mg of risedronate on 2 consecutive days a month (2CDM) was as safe and effective as risedronate 5 mg/day for 12 months.[64] At 2 years, lumbar spine BMD increases of 4.2% in the 2CDM and 4.3% 5 mg/day were observed.[65] There were no statistically significant differences in BMD changes of lumbar spine, proximal femur, and bone turnover markers. Adverse effects in both groups were similar.

In a study that compared risedronate 5 mg/day and 150 mg/month in postmenopausal women with osteoporosis, similar increases in lumbar spine BMD from baseline were observed (3.4% and 3.5%, respectively) after 1 year and no difference in the new incidence of vertebral fractures.[66] There were similar changes in biochemical bone turnover markers. Adverse effects were similar, with a higher incidence of constipation in the 5 mg/daily group and diarrhea in the 150 mg/monthly group.

Zoledronic Acid

Zoledronic acid is an intravenous bisphosphonate that was initially approved for osteoporosis treatment and later received FDA approval for osteoporosis prevention in postmenopausal women.[1,32]

In a 2-year study of zoledronic acid for the prevention of bone loss in postmenopausal women with low bone mass, 581 women were randomized to receive zoledronic acid 5 mg IV at baseline and 12 months (2 × 5 mg), zoledronic acid 5 mg IV at baseline only and placebo at 12 months, or placebo at baseline and at 12 months.[67] At 2 years, BMD was significantly increased in the lumbar spine in the (2 × 5 mg; 5.18%), (5 mg 4.42%) as compared to placebo (−1.32%). At 2 years, BMD also increased at the proximal femur sites (2 × 5 mg; total hip 2.91%, femoral neck 2.2%, trochanter 4.83%) (5 mg; total hip 2.28%, femoral neck 1.64%, trochanter 4.16%).

Zoledronic acid infusion for osteoporosis prophylaxis is administered every other year as compared to yearly when treating osteoporosis.

Oral bisphosphonates are first-line and most commonly prescribed medications for the prevention and treatment of osteoporosis. The decision to start medication therapy for the prevention of osteoporosis prevention in postmenopausal women should involve both the patient and physician. A BMD of the femoral neck may help to better determine a more accurate FRAX 10-year risk score. M.J. has multiple risk factors for osteoporosis but pharmacologic therapy is not indicated at this time.

Length of Treatment

The incorporation of bisphosphonates into bone results in a reservoir of available drug that is slowly released over time.[68,69] The peak effect of reducing bone turnover markers occurs in 3 to 6 months and continues for months to years with discontinuation. Approval studies in the United States were for 3 to 4 years; however, extension studies suggest longer efficacy.[61,69–72]

No consensus is currently available on how long to continue bisphosphonate therapy. In the Fracture Intervention Trial Long-term Extension (FLEX) of the original Fracture Intervention Trial (FIT), the effects of continuing alendronate were compared to the effects of stopping alendronate after 5 years of treatment.[69] Statistically significant bone loss occurred (2% to 3% more than those who took alendronate for 10 years) when women were switched to placebo after 5 years of alendronate therapy; however, BMD remained well above FIT baseline. A gradual rise was seen in biochemical markers of bone turnover and there were no significant differences seen in clinical or nonvertebral fractures. There was a slightly higher risk of clinically detected vertebral

---

fractures, in the placebo group (women who had discontinued alendronate therapy after 5 years) compared to the groups who continued alendronate, suggesting that women at high risk for vertebral fracture or with T-scores less than −3.5 may benefit from continued bisphosphonate therapy.

The long-term effects of risedronate 5 mg/daily on bone were studied in women with osteoporosis who were in the Vertebral Efficacy With Risedronate Therapy-North American (VERT-NA) study who took risedronate for up to 5 years.[73] In biopsies of the iliac crest that were taken at 3 and 5 years, changes in bone mineral and collagen were preserved in the risedronate groups as compared to maturation that was observed with placebo. The FLEX and VERT-NA studies suggest that women with good response to bisphosphonate therapy who are not at high risk for fracture may be able to take a “drug holiday” (e.g., 1-year off therapy) after 3 to 5 years of treatment.[74] Women who are able to reach a T-score of greater than −2.5 may be able to discontinue therapy for several years.

The length of therapy should be a decision made based on the benefits of therapy, adverse effects, and safety of bisphosphonates (see Contraindications and Adverse Effects below).[68] In a NAMS Practice Pearl, the authors describe a guide to bisphosphonate drug holidays according to fracture risk.[68] Low risk—discontinue; mild risk—treat for 3 to 5 years then consider a drug holiday; moderate risk—treat for 5 to 10 years then consider a 3- to 5-year drug holiday; and high risk—treat for 10 years then consider a drug holiday for 1 to 2 years. For high-risk patients on drug holiday, treat with a nonbisphosphonate such as raloxifene or teriparatide.

CASE 110-2, QUESTION 7: What are the potential adverse effects of bisphosphonates?

Adverse Effects

Common adverse effects associated with the use of oral bisphosphonates include gastrointestinal symptoms, such as acid regurgitation, dysphagia, abdominal distension, gastritis, nausea, dyspepsia, flatulence, diarrhea, and constipation.[75] Less common esophageal adverse effects, such as esophagitis, esophageal ulcers, and erosions, have occurred and have rarely been followed by esophageal stricture or perforation.[75,76] The risk of severe esophageal adverse effects is reported to be increased in patients who do not take bisphosphonates with 6 to 8 ounces of water, do not remain upright after taking bisphosphonates, or in those who develop esophageal irritation and continue to take bisphosphonates (see Dosing section). A medication guide will address issues that are specific to bisphosphonates and are intended to help patients better understand treatment, adverse effects, and adherence.[77] In addition, hypocalcemia, musculoskeletal pain, headaches and rash have been noted.

Both intravenous (IV) and oral bisphosphonates are associated with osteonecrosis of the jaw (ONJ), a serious but rare adverse event.[78,79] It was first reported in a series of cancer patients receiving IV bisphosphonates. Risk factors for osteonecrosis of the jaw include the diagnosis or previous history of cancer; invasive dental procedures; concurrent use of chemotherapy, corticosteroids, or angiogenesis inhibitors; poor oral hygiene; preexisting dental disease or infection; and anemia and coagulopathy. The risk of ONJ increases at higher doses and with duration of exposure.

Bisphosphonates are associated with atypical fractures of the femoral shaft.[26,78] A warning is included in the manufacturers' information for all bisphosphonate drugs that are indicated for the prevention or treatment osteoporosis. A safety review of oral bisphosphonates and atypical subtrochanteric femur fractures by the FDA is also ongoing.[80] A clear connection has not been found. The mechanism of action is not clear; however, bone is normally subject to microdamage with every day stresses and this initiates bone remodeling.[81] Antiresorptive agents may oversuppress bone turnover causing microdamage to accumulate which may lead to brittle bone and an increased risk of fracture. Lee et al.[81] conducted a meta-analysis that included nine observational studies and one randomized controlled trial, a total of 658,497 patients. The results were statistically significant for increased risk of subtrochanteric or diaphyseal fracture with bisphosphonate use (adjusted odds ratios

[AOR] = 1.99, 95% confidence intervals [CI] = 1.28–3.10), subtrochanteric fractures AOR = 2.71 (95% CI = 1.86–3.95), and diaphyseal fractures AOR = 2.06 (95% CI = 1.70–2.50). The analysis was limited by the multiple study designs, varying lengths of follow-up, and different patient populations leading to a high heterogeneity. The pooled results of combined subtrochanteric or diaphyseal fracture and subtrochanteric fracture results had significant heterogeneity (84.3% and 83.6%, respectively). The results for diaphyseal fracture had moderate heterogeneity (29.7%). The overall risk is low compared to osteoporotic fracture. In a nested case–control study of 52,595 women 68 years and over who took at least 5 years of bisphosphonate therapy, the subtrochanteric or femoral shaft fracture occurred in 71 (0.13%) during the subsequent year and 117 (0.22%) within 2 years.[82] The results were similar to the meta-analysis. Compared with no use or transient use, the use of bisphosphonates for 5 years or longer was associated with a significantly increased risk of atypical hip or femur fracture (odds ratio [OR] = 2.74; 95% CI, 1.25–6.02). Duration less than 5 years was not associated with increased risk of fracture.

Additional adverse effects reported with zoledronic aced are pyrexia, headache, pain in extremity, flu-like illness, and eye inflammation.[78]

Currently, there is not enough evidence to hold bisphosphonate therapy in patients who should be treated for osteoporosis or osteoporosis prevention; however, if a patient has prodromal pain in the thigh or leg or has suffered an atypical fracture while on bisphosphonate therapy, it would be reasonable to discontinue therapy and evaluate.[76]

Dosing

Alendronate is approved for the prevention of osteoporosis in doses of 5 mg PO daily and 35 mg PO weekly. Alendronate is also available with cholecalciferol in a 70 mg/2,800 IU and 70 mg/5,600 IU PO weekly tablet. Ibandronate is approved at 2.5 mg PO daily and 150 mg PO monthly. Risedronate is approved at 5 mg PO daily, 35 mg PO weekly, and 75 mg PO on 2 consecutive days each month and 150 mg PO monthly. The delayed-release formulation of risedronate is not indicated for the prevention postmenopausal osteoporosis. Zoledronic acid is indicated at 5 mg IV every 2 years over no less than 15 minutes.[83] Selecting the appropriate dosing option may improve adherence to therapy.

Oral bisphosphonates are poorly absorbed and after an overnight fast when taken with water approximately 50% will be absorbed through the gut and 50% will be excreted in urine. Patients should be instructed to take most bisphosphonates with 6 to 8 ounces of water early in the morning on arising and at least 30 minutes (60 minutes for ibandronate) before ingesting food, beverage, or other medications. Risedronate is also available as a 35-mg delayed-release tablet that should be taken once weekly after breakfast. Patients should not lie down, but should stay fully upright for at least 30 minutes (60 minutes for ibandronate) after ingesting an oral bisphosphonate to prevent esophageal irritation or ulceration and to ensure appropriate bioavailability. With all bisphosphonates, patients should ingest adequate calcium and vitamin D, but should not take the calcium or vitamin D at the same time as the oral bisphosphonates because they may decrease the absorption of bisphosphonates.

A diagnosis of GERD, as seen in M.J., may preclude the use of oral bisphosphonate therapy for prevention of osteoporosis

due to gastric irritation. Zoledronic acid for prevention of osteoporosis is an alternative. Using the information available for M.J. (T-score of −2.0 at lumbar spine, Z-score −1.0, estimated 10-year probability of hip fracture 0.5%, and estimated 10-year probability of major osteoporosis-related fracture 5.1%), therapy is not indicated at this time.

The current guidelines from the NOF and NAMS recommend pharmacologic therapy be reserved for those patients with a hip or vertebral fracture, individuals with a T-score of −2.5 or less at the femoral neck or spine once secondary causes have been excluded, and individuals with low bone mass with a 10-year probability of at least 3% risk of hip fracture or at least 20% risk of major osteoporotic fracture.[1,32] At this time, M.J. should maintain adequate intake of calcium and vitamin D, as well as implement an exercise program and continue to avoid risk factors for osteoporosis.

Contraindications and Precautions

Hypocalcemia should be corrected before beginning therapy and all patients on bisphosphonates should receive adequate calcium and vitamin D through diet and/or supplements. Patients on loop diuretics should be monitored for hypocalcemia. Patients receiving zoledronic acid should be appropriately hydrated, the infusion given over no less than 15 minutes, then followed by a 10 mL of normal saline flush.[78] To reduce the incidence of acute-phase reaction symptoms, acetaminophen may be given postinfusion.

Although no dosage adjustments are recommended for patients with mild renal insufficiency, alendronate and zoledronic acid are not recommended in patients with creatinine clearance less than 35 mL/minute and ibandronate and risedronate are not recommended in patients with creatinine clearance <30 mL/minute.

CASE 110-2, QUESTION 8: Should a SERM such as raloxifene, be considered for the prevention of osteoporosis in M.J.?

Selective Estrogen Receptor Modulators (SERMs)

Raloxifene

Raloxifene is a benzothiophene second-generation selective estrogen receptor modulator with both agonist and antagonist action on select estrogen target tissues.[84,85] Raloxifene binds to estrogen receptors (ER) resulting in estrogen agonist effect in bone and lipid metabolism and estrogen antagonist effect in breast and endometrial tissue.[85] Tamoxifen is also a SERM, but differs from raloxifene in that it has agonistic effects on endometrial tissue and raloxifene does not. Tamoxifen is indicated for the prophylaxis and treatment of breast cancer and is not indicated for postmenopausal osteoporosis prevention. Raloxifene's agonist activity on bone tissue is believed to effect osteoclastogenesis, leading to a reduction in bone resorption and a decreased rate of bone turnover, increasing BMD.[85,86] In a study of 601 postmenopausal women age 45 to 60 with normal to low bone mineral density, patients were randomized to receive raloxifene 30, 60, 150 mg, or placebo daily for 2 years.[86] Significant increases in BMD of the lumbar spine (1.6%, placebo −0.8%), hip (1.6%, −0.8%), femoral neck (1.2%, placebo −1.3%), and total body (1.4%, placebo −0.6%) were observed, along with decreases in bone turnover markers, serum concentrations of total cholesterol, and LDL. No significant differences were observed in endometrial thickness.

Jolly et al. conducted a 2-year extension study of two 3-year prospective, randomized, double-blind, placebo-controlled trials of raloxifene for the prevention of postmenopausal osteoporosis.[87] The study included 328 women from the initial 1,145 core study age 45 to 60. After 5 years of therapy with raloxifene 60 mg daily, bone turnover markers decreased, BMD of the lumbar spine increased (2.8%), and total hip BMD (2.6%) as compared to placebo. In women with osteopenia of the lumbar spine, 2.5% developed osteoporosis in the lumbar spine as compared to 18.5% of those who took placebo. There were significant reductions in total cholesterol and LDL, but not HDL or triglycerides. No significant endometrial differences were reported as compared to placebo. Women with osteopenia who took raloxifene 60 mg daily for 5 years were 87% less likely to progress to osteoporosis at the lumbar spine then those on placebo. Women with normal BMD were 77% less likely to progress to osteopenia after 5 years of raloxifene 60 mg daily. There was a statistically significant increase in the incidence of hot flashes (raloxifene 28.8%; placebo 16.8%).

The Efficacy of Fosamax versus Evista Comparison Trial (EFFECT) was a randomized, double-blind clinical trial including 487 postmenopausal women with low bone density of the spine or hip (T-score $\leq$ 2.0). Efficacy and tolerability of alendronate were compared to raloxifene.[88] Patients were randomly assigned to either alendronate 70 mg weekly and daily placebo identical to raloxifene or raloxifene 60 mg daily and weekly placebo identical to alendronate for 12 months. After 1 year, increases in BMD were greater for alendronate than raloxifene in the lumbar spine (4.8% vs. 2.2%, respectively; $p < 0.001$) and total hip (2.3% vs. 0.8%, respectively; $p < 0.001$). Tolerability and GI effects were similar in both groups; however, significantly higher reports of vasomotor symptoms came from the raloxifene group.

In other clinical trials, women who took raloxifene had an increased risk of deep vein thrombosis (DVT) and pulmonary embolism (PE).[89]

A paradox still exists regarding how raloxifene can decrease vertebral fractures by up to 41% while increasing BMD by only 2% to 3%, rates that are lower than those noted for ET, EPT, or alendronate.[90] In addition, raloxifene has not been observed to have a significant effect on hip fractures when compared to other agents. The antifracture effect of raloxifene on vertebral fractures may occur secondary to normalization of the high turnover rate of cancellous bone, which then prevents further disruption of bone microarchitecture.[91] This may occur through raloxifene binding at estrogen β-receptor sites that are predominantly in cancellous bone, whereas α-receptors are predominantly in cortical bone. Thus, bone type and estrogen receptors are different in the hips compared with vertebrae. In addition, a less potent antiresorptive agent, such as raloxifene, may help prevent vertebral fractures but not hip fractures because the threshold for preventing osteoclast activity in cancellous bone (which is predominant in vertebrae) may be lower than in cortical bone (which predominates in hips). For these reasons, it may require a more potent antiresorptive agent to increase BMD in the hips.

Raloxifene might be considered for osteoporosis prevention in a woman such as M.J., even with her strong family history of breast cancer. This latter recommendation is based on results from the MORE trial.[90] A 76% decrease was noted in risk for invasive breast cancer in postmenopausal women with osteoporosis (mean age, 66.5 years) who received raloxifene for 3 years. A total of 7,705 women were assigned to raloxifene groups (60 mg twice daily or 60 mg daily) or a placebo group. Of those enrolled in either raloxifene group (n = 5,129), only 13 cases of breast cancer were reported versus 27 that occurred in the 2,576 women in the placebo group. Postmenopausal women over 50 with low bone mass such as M.J. are candidates for osteoporosis prevention therapy if they have a 10-year hip fracture probability of 3% or greater or a 10-year major osteoporosis-related fracture probability of 20% or greater based on the WHO FRAX.[45]

Raloxifene 60 mg PO daily is indicated for the prevention of osteoporosis in postmenopausal women.[89]

Dosing and Pharmacokinetics

Raloxifene 60 mg once daily can be taken without regard for food.[89] Raloxifene is approximately 60% absorbed and undergoes extensive glucuronide conjugation, resulting in a 2% absolute bioavailability. Some circulating raloxifene glucuronide conjugates are converted back to the parent compound. Raloxifene and its monoglucuronide conjugates are highly protein-bound.

Raloxifene is primarily excreted in feces, with less than 0.2% excreted unchanged and less than 6% eliminated in urine as glucuronide conjugates. There appear to be no differences in pharmacokinetics based on age or sex. Raloxifene has a mean half-life of 27.7 hours after a single dose and 32.5 hours after multiple doses.

Adverse Effects

Adverse effects of raloxifene include an increased risk for venous thromboembolic disease, flu syndrome, headache, hot flashes, nausea, diarrhea, flatulence, gastroenteritis, leg cramps, peripheral edema, arthralgia, neuralgia, sinusitis, bronchitis, rash, sweating, and conjunctivitis.[89]

Contraindications and Potential Drug Interactions

Raloxifene carries a boxed warning and is contraindicated in patients with active venous thromboembolism or a past history of venous thromboembolism due to increased risk.[87] Raloxifene is contraindicated in women who are pregnant, plan to become pregnant, and those nursing. Raloxifene should be used with caution during periods of prolonged immobilization, in patients with a history or risk of stroke, moderate or severe renal impairment, and in patients with hepatic impairment. The coadministration of cholestyramine may decrease the absorption of raloxifene and should be avoided. Prothrombin time should be monitored when starting or discontinuing raloxifene in patients taking warfarin. Raloxifene is over 95% bound to plasma proteins and may affect highly protein-bound medications.

Bazedoxifene is a third-generation SERM and is available only in a combination product with conjugated estrogen.[92] It is indicated for the treatment of moderate-to-severe vasomotor symptoms associated with menopause, such as hot flashes, and the prevention of postmenopausal osteoporosis in women with an intact uterus. Due to the boxed warnings (endometrial cancer, cardiovascular disorders, and probable dementia) and adverse events associated with estrogen, its use is limited to the shortest duration possible. The manufacturer suggests that nonestrogen agents be considered when using the medication for the sole purpose of osteoporosis prevention (see section on ET).

Treatment

CASE 110-3

QUESTION 1: T.J.'s 75-year-old grandmother, M.B., was diagnosed with osteoporosis 5 years ago when she broke her distal forearm. At that time, it was noticed that she had mild kyphosis. M.B has lost 1.5 inches in height (current height 5 feet and weight 100 pounds) and still has mild kyphosis. She denies severe back pain but occasionally uses acetaminophen or ibuprofen for mild back pain. A recent bone scan revealed significantly decreased vertebral and forearm bone mass. M.B. had her last menstrual period before her hysterectomy was performed 25 years ago. She took CEE 0.625 mg daily up until about 8 years ago when it was discontinued by her primary care physician. M.B. has hypertension for which she receives hydrochlorothiazide 25 mg daily and enalapril 10 mg daily. She was prescribed alendronate 70 mg once weekly, but admits she was not good at filling it regularly as it was expensive and eventually stopped taking it. M.B. does take calcium carbonate 1,200 mg/day in divided doses with meals and Vitamin D 1,000 IU daily, both of which were started after experiencing a fracture 5 years ago. M.B. does not smoke cigarettes, drink alcohol, or take any other nonprescription medications.

Does M.B. exhibit any clinical signs of osteoporosis?

There are few clinical signs of osteoporosis. It is usually asymptomatic until a fracture occurs. M.B. exhibits a loss of 1.5 inches in height and mild kyphosis. She also has mild back pain. There are other causes of kyphosis, but M.B. may exhibit kyphosis due to compression fractures associated with osteoporosis. (see Case 110-2, Question 1, for further information about osteoporosis clinical signs and symptoms.)

CASE 110-3, QUESTION 2: What changes, if any, should be made to MB's treatment plan?

A treatment plan for M.B. should be aimed at preventing further bone loss and minimizing falls, which could lead to fractures. It is important for M.B. to continue calcium and vitamin D in her diet and maximize her physical function by incorporating exercise in her treatment plan. M.B has experienced a previous fracture and likely vertebral compression due to osteoporosis. She is at a higher risk for a subsequent fracture. The benefits of pharmacologic treatment using a different medication or reinitiating alendronate should be discussed with MB, along with counseling on adherence.

RECURRENT FRACTURE RISK

Vertebral fractures are a common consequence of osteoporosis and associated with a decreased health-related quality of life (HRQOL).[93,94] They can occur without symptoms and may go unrecognized at the time of the fracture. The risk of an additional vertebral fracture within a year of the incident fracture is 5 times higher compared to postmenopausal women with no previous vertebral fracture.[93,95] The physical symptoms resulting from vertebral fractures become more evident with each recurrence.[93] They are associated with loss of height, pain, decreased mobility, and mortality. The risk of recurrent fracture is also high at other sites such as the hip and wrist. A large, random cohort of almost 40,000 U.S. Medicare beneficiaries, who were not enrolled in a prescription benefit plan, were evaluated for the occurrence of a second fracture or death using data from 1999 to 2006.[96] Those who experienced a second fracture and subsequently died were only counted in the second fracture category, although a time to event analysis was performed including the risk of second fracture with death. The 5-year risk of second fracture and the 5-year risk of death increased with age.

For persons ages 65 to 74 years: the 5-year rate of death after a hip or clinical vertebral fracture was highest in patients with dementia (64.7%; 61.8%, respectively) and chronic kidney disease (76.7%; 65.2%); the rate of death after a wrist fracture was highest in patients with dementia (56%) and heart failure (33.3%), and with chronic kidney disease only slightly lower (31.6%); the 5-year rate of death was highest after hip fracture in all patients (38.1%) than for clinical vertebral fracture (29.3%) or wrist fracture (13.1%); the 5-year rate of death among men was higher than women after all incident fractures such as hip fracture (48.7% vs. 33.1%), clinical vertebral fracture (38.5% vs. 25.3%), and wrist fracture (17.3% vs. 12.3%); and the 5-year rate of second fracture was higher in women than in men such as hip fracture (27.2% vs. 17.7%), clinical vertebral fracture (37.4% vs. 24.5%), and wrist fracture (21.1% vs. 17.6%). With each decade over the age of 65, there was greater than a 20% higher risk of death than the previous decade (e.g., after hip fracture, the 5-year risk of death was 38.1% for ages 65–74, 49% for ages 75–84, and 63.7% for ages 85 and older). The increase was not as large for a second fracture. In the majority of subcategories, the 5-year risk of death or subsequent fracture was greater than 20%. Patients' ages 65–74 without comorbidity and who experienced a wrist fracture had less than 20% risk of death or subsequent fracture.

DIETARY INTAKE

Calcium and vitamin D supplementation in combination can improve bone density as well as prevent incident fractures in postmenopausal women with osteoporosis.[35,36] It is difficult, however, to find evidence to support the benefit of supplements for treatment of secondary prevention of fracture in older patients diagnosed with osteoporosis. In a small randomized controlled of patients with a previous low-energy fracture, calcium 1,200 mg plus vitamin D 1,400 IU per day significantly increased BMD of the lumbar spine compared to baseline after 1 year, whereas BMD of the lumbar spine decreased compared to baseline in the placebo group.[97] When stratified for age, the effect of treatment in lumbar spine in patients was greater in patients aged <70 years than those aged >70 years ($p < 0.05$). BMD in the lumbar spine increased in the group aged <70 years and decreased in the age group aged >70 years. No significant changes were shown for BMD of the hip. Patients who were older in this trial had a higher rate of previous hip fracture and demonstrated poorer physical performance, which is a limitation in the applicability of the subgroup analysis. A large randomized controlled trial of 5,292 women ≥70 years of age who experienced a low-trauma osteoporotic fracture were randomly assigned 800 IU daily oral vitamin D_3, 1,000 mg calcium, oral vitamin D_3 (800 IU/day) combined with calcium (1,000 mg/day), or placebo and followed between 24 and 62 months.[98] No statistically different results were found between the intervention groups in the incidence of all fractures, radiographically confirmed fractures, hip fractures, other types of fracture; death; time to fracture or death; or falls. Although well designed, there were very few measurements of baseline concentration of 25OHD, no reports of BMD, and patients in this trial reported only moderate adherence.

Sufficient dietary calcium and vitamin D is a universal recommendation for elderly patients with osteoporosis. Maintaining serum 25OHD levels above 30 ng/mL (75 nmol/L) is an important goal as low levels of vitamin D are associated with an increased risk of falling.[1,99,100] The dietary goal for all patients with osteoporosis is to eat a well-balanced diet rich in fruits and vegetables, low-fat dairy products, whole grains, fish, and nuts. She should try to maintain her BMI between 20 and 25 kg/m^2. In patients like M.B., it is important to ensure vitamin D levels are adequate and dietary intake of calcium is at least 1,200 mg/day. If M.B. does not achieve this from her diet, the supplements she is currently taking would be recommended. Intestinal absorption of calcium carbonate is dependent on stomach acid. There is some controversy on whether gastric acid secretion is decreased with aging and if patients who are older should take calcium citrate instead of calcium carbonate.[101,102] Calcium carbonate supplements are the form most often associated with constipation, which can be problematic as gastric motility is decreased with aging.[101,102] Calcium citrate should be used over calcium carbonate in patients with achlorhydria, a condition common in the elderly, and in those patients who complain of constipation. M.B. should continue taking her calcium carbonate in divided doses with meals. If there is a question of absorption due to lower gastric acid or complaints of constipation, M.B. could switch calcium products to calcium citrate. (see Case 115-1, Questions 2 and 3, further discuss calcium requirements, supplementation, and product selection and the use of vitamin D).

EXERCISE AND FALL PREVENTION

Falls are common among older adults and the leading cause of fractures and injury, both fatal and nonfatal.[103] One in three adults over the age of 65 years falls each year. Fall-related fractures occur more often among older women than men, although men are more likely to die from fall-related fractures than women. Pain and disability are common results of falling as well as developing a fear of falling again. Those aged 75 and older are 5 times more likely to be admitted to a long-term care facility than those between the ages of 65 and 75 years. Fall prevention that includes exercise training is an important nonpharmacologic treatment for older patients with osteoporosis. In a meta-analysis of 17 randomized controlled trials of various fall prevention programs in community dwelling patients over 60 years of age, exercise significantly reduced the rate of falls, including falls resulting in injuries or fractures.[104] A reduction of about 37% for all injurious falls was found, along with a reduction of 43% for severe injurious falls, and 61% for falls resulting in fractures.

M.B. should include a regular weight-bearing and strengthening exercise routine that is appropriate for her age and physical condition. Exercise helps maintain bone mass, function, and agility. Older patients should be screened at least once per year for fall risk to determine whether there are any underlying factors or medical conditions associated with the risk of falls.[105] Any patient who presents to a clinician after a fall should have a risk assessment as well. Patients at higher risk of falling include those with deficits in gait and balance, foot problems, impairment of vision, cardiovascular disease, postural hypotension, and vitamin D deficiency. Removal of contributing factors and treating underlying medical conditions with the fewest medications possible can reduce the risk of falling. Pharmacists have an important role in optimizing medication therapy to decrease CNS effects or adverse effects affecting cognition and blood pressure. The prevention of falls also includes maintaining a safe environment, reducing tripping hazards, adding handrails inside and outside the tub or shower and next to the toilet, and improving the lighting in the home.[103,105]

PHARMACOTHERAPY

Pharmacologic treatment is indicated in patients who have experienced a hip or vertebral fracture, in those with T-scores < -2.5 at the femoral neck, total hip, or lumbar spine, and in postmenopausal women and men age 50 and older with low bone mass and high risk of fracture.[1] Agents approved for treatment of osteoporosis include bisphosphonates (alendronate, risedronate, ibandronate, and zoledronic acid), calcitonin, denosumab, estrogen, raloxifene, and teriparatide. Drug therapy decisions in a patient with osteoporosis or risk of fracture should be based on the patient's medical history, patient preferences, and a balance of the risks and benefits of a medication. The goal of pharmacotherapy is to reduce the rate of fractures with the least amount of adverse effects. Head-to-head trials are often the best evidence for comparison, but this evidence is not always available. Osteoporosis diagnosis and evaluation of bone health are based on bone mineral density assessment, which is used to estimate fracture risk. When searching for the best therapy, it is important to be mindful that the basis of treatment is the reduction of fractures. Trials reporting BMD alone may not be sufficient to predict the effect on fractures.

CASE 110-3, QUESTION 3: What medications might be considered for the treatment of osteoporosis in MB?

ESTROGEN

As discussed in Case 110-2, conjugated estrogen therapy has positive effects on BMD and fracture rates, but is no longer recommended for the treatment of osteoporosis. M.B. may have benefitted from years of using estrogen therapy, preserving BMD, but the benefit of estrogen therapy on BMD only occurs while taking it. Bone loss is accelerated once hormone therapy is stopped; thus, M.B. and her physician should discuss whether she would benefit from another drug for treatment of her osteoporosis.

SELECTIVE ESTROGEN RECEPTOR MODULATORS

Raloxifene is an estrogenic agent that reduces the risk of vertebral fracture.[89] The recommended dose is 60 mg (tablet) orally once daily. It is the only SERM approved in the United States that is indicated for the treatment and prevention of osteoporosis in postmenopausal women.

In a randomized controlled trial including almost 7,000 postmenopausal women, raloxifene 60 mg or 120 mg daily for 3 years increased BMD in the femoral neck (2.1% and 2.4%, respectively) and spine (2.6% and 2.7%, respectively) compared to placebo ($p < 0.001$ for all comparisons).[106] Women ages 31 to 80 were included with or without a previous vertebral fracture. The incidence of new vertebral fracture was 10.1% for placebo, 6.6% for raloxifene 60 mg/day, and 5.4% for raloxifene 120 mg/day. Compared to placebo, the risk of new vertebral fracture was 0.7 (95% CI, 0.5–0.8) for raloxifene 60 mg/day and 0.5 (95% CI, 0.4–0.7) for raloxifene 120 mg/day and risk reduction was similar regardless of preexisting fracture. There were no significant differences in total nonvertebral fractures. Serious adverse events included venous thromboembolism 0.3% for placebo and 1.0% for each 60-mg and 120-mg groups (RR 3.1; 95% CI 1.5–6.2). Other common and significantly different adverse effects included influenza-like syndrome, hot flashes, leg cramps, and peripheral edema. Subjects enrolled in this 3-year raloxifene trial above by Ettinger et al.[106] were eligible to participate in a 1-year extension with no raloxifene and then a 4-year continuation which included raloxifene 60 mg daily for the raloxifene group.[107] The primary outcome of the 4-year extension was invasive breast cancer and included roughly 4,000 women from the original trial. Raloxifene reduced the risk of estrogen receptor-positive invasive breast cancer by 84% (RR 0.16; 95% CI 0.09, 0.30). During the 1-year extension with no raloxifene, BMD decreased significantly. It increased as raloxifene was restarted and was maintained. Vertebral fracture risk was maintained 4 years after randomization, but was not measured in the 4-year extension trial. Bone mineral density was measured in US sites only in the 4-year extension trial and included 386 women in the final analysis.[108] After a total of 7 years on raloxifene, BMD in the femoral neck increased 1.9% from baseline and 3% from placebo ($p = 0.30$). BMD in the lumbar spine increased 4.3% from baseline and 2.2% from placebo ($p = 0.045$). The safety of raloxifene after 7 years was similar to 3 years. (see Case 110-2, Question 8, for additional information about raloxifene.)

Bisphosphonates are the major pharmacologic group of medications for the treatment of osteoporosis. A meta-analysis of seven randomized controlled trials, approximately 3,700 participants, comparing raloxifene and alendronate was conducted to determine the efficacy and safety of the two medications in postmenopausal women.[109] The length of the trials was at least 12 months and the majority of trials included were of good quality. The raloxifene dose in each trial was 60 mg daily. The alendronate dose varied and included were two trials at 70 mg each week, four trials at 10 mg daily, and one trial at 5 mg daily. There were no statistical differences found between raloxifene and alendronate in the risk of vertebral fractures, nonvertebral fractures, or total fractures within a follow-up period of 12 to 24 months. There were no significant differences in upper GI disorders, venous thromboembolism, or vasodilation. There was a significantly higher rate of diarrhea found in the alendronate group and significant increase in vasomotor events found in the raloxifene group. In a subgroup analysis, there was a higher risk of upper GI disorders for alendronate compared to raloxifene in patients over 65 years of age and for alendronate administered daily compared to raloxifene.

Raloxifene has a unique benefit and risk profile when compared to other treatments for osteoporosis. Raloxifene decreases the risk of vertebral fractures by 34% to 44% compared to placebo, but no significant differences are found in the risk of total nonvertebral fractures.[110] No differences in the rate of vertebral or nonvertebral fracture risk have been found in head-to-head trials comparing raloxifene and alendronate.[109,110] The safety and efficacy of raloxifene have been studied in a randomized controlled trial up to 7 years. Significant adverse effects include an increase in venous thromboembolism; myalgias, cramps, and limb pain; and hot flashes. The FDA has issued a boxed warning regarding the increased risk of deep vein thrombosis and pulmonary embolism while taking raloxifene and a warning of increased risk of death due to stroke in postmenopausal women with documented coronary heart disease or those at increased risk for coronary events.[89] As with other estrogen therapy, it is necessary to continue raloxifene therapy to maintain increases in BMD.

Bisphosphonates

Bisphosphonates, such as alendronate, risedronate, ibandronate, or zoledronic acid, can be used as an alternative to raloxifene to prevent fractures due to osteoporosis. They have multiple administration options available and may be beneficial in enhancing adherence in certain patients. (see Case 110-2, Question 7 to address the use of aminobisphosphonates in the treatment of postmenopausal osteoporosis: A table of medications and doses can be found in Table 110-8).

Alendronate was the first bisphosphonate approved for the treatment of postmenopausal osteoporosis in 1995 and available as a daily or weekly tablet.[75] Many clinical trials have been published regarding the use of bisphosphonates in the treatment of osteoporosis. In a Cochrane review of 11 randomized controlled trials, approximately 12,000 postmenopausal women who had previous fracture or whose BMD was greater than 2 SD below the mean, alendronate reduced the risk of vertebral fracture (NNT 16), nonvertebral fracture (NNT 50), wrist fracture (NNT 50), and hip fracture (NNT 100).[57] Compared to placebo, alendronate reduces the risk of vertebral fracture by 40% to 64%, nonvertebral fracture, 11% to 49%, and hip fracture, 21% to 55%, over 3 years.[57,110] Alendronate is well tolerated and adverse events reported in clinical trials were similar to placebo. Adverse reactions reported in postmarketing surveillance and outside of clinical trials suggest alendronate is strongly associated with upper gastrointestinal events.[75] Monthly alendronate is slightly better tolerated than daily alendronate, but the risk of gastrointestinal intolerance exists and may lead to development of esophagitis, esophageal ulcers, esophageal stricture or perforation, gastric or duodenal ulcers, and possibly esophageal cancer. Adverse effects are greater in patients who lie down after taking oral bisphosphonates, who fail to swallow the medication with a full glass (6–8 ounces) of water, or who continue to take the medication after developing symptoms suggestive of esophageal irritation.

As similar gastrointestinal events have been reported with other oral bisphosphonates,[76,111] the FDA requires a medication guide to be provided at the time these medications are dispensed.[77] A medication guide will address issues that are specific to bisphosphonates and are intended to help patients better understand treatment, adverse effects, and adherence. (see Case 110-2, Question 7 for additional information on adverse effects)

Risedronate is available as an oral tablet in four different doses: administered daily, weekly, monthly, or 2 consecutive days monthly.[76] Similar to alendronate, risedronate significantly reduces the rate of vertebral, nonvertebral, and hip fracture.[110,112] Most trials used doses of 5 mg daily. Although they were not of high quality, in head-to-head trials comparing different dosing schedules, there were no statistical differences in the dosing regimens.[110] Comparing risedronate to placebo, the reduction in the risk of vertebral fracture ranged from 39% to 69%, even among

---

subgroups with mild-to-severe renal impairment. The reduction in the risk of nonvertebral fracture ranged 19% to 60% and the reduction in the risk of hip fracture from 26% to 40%. Adverse events reported in clinical trials were similar to placebo.

Ibandronate is available as a daily or monthly tablet and a 3-mg quarterly intravenous injection.[111] Compared to placebo, daily oral ibandronate significantly decreases vertebral risk fracture 52% to 62% over 3 years.[110,113] No statistically significant decreases in nonvertebral or hip fracture have been found using ibandronate.[114] However, in a subgroup analysis of two noninferiority trials, higher doses of ibandronate (150 mg once monthly, 3 mg IV quarterly, and 2 mg IV every 2 months) reduced the risk of nonvertebral fracture compared to lower doses of ibandronate HR 0.620 (0.395–0.973).

Alendronate or risedronate would be the oral bisphosphonate treatment of choice due to the reduction of vertebral, nonvertebral, and hip fracture.

Zoledronic acid is available as a 5 mg intravenous infusion given over a 15-minute period once yearly for the treatment of osteoporosis.[78] It significantly reduces the risk of vertebral (NNT 14), nonvertebral (NNT 38), and hip fracture (NNT 98) similarly to that achieved by alendronate or risedronate.[115,116] Zoledronic acid was associated with atrial fibrillation in a large trial of postmenopausal women diagnosed with osteoporosis, but not in a subsequent study of postmenopausal women with recent hip fracture.[78,115] It is less likely to cause gastrointestinal symptoms than oral bisphosphonates; however, it is associated with injection reactions such as fever (18%), myalgia (9%), and flu-like symptoms (8%) that typically resolve within 3 days but can last up to 2 weeks. There is an increased risk of hypocalcemia following an injection compared to placebo. Zoledronic acid is contraindicated in patients with acute renal impairment, patients with creatinine clearance less than 35 mL/minute, and patients with hypocalcemia.

The controversial atrial fibrillation results in the zoledronic acid trials prompted an investigation by the FDA.[79] Following an analysis of clinical trials comparing alendronate, ibandronate, risedronate, and zoledronic acid to placebo, the FDA stated there was no clear association of risk for atrial fibrillation in male and female patients treated with bisphosphonate drugs.

Both intravenous (IV) and oral bisphosphonates are associated with osteonecrosis of the jaw (ONJ) and atypical fractures. (see Case 110-2, Question 7 for additional information on adverse effects)

M.B. has been diagnosed with osteoporosis and her risk of recurrent fracture is high. Bisphosphonates are effective for secondary prevention after a first fracture. Oral alendronate as previously prescribed or oral risedronate would be the bisphosphonate of choice for M.B.

CASE 110-3, QUESTION 4: What other possible alternatives or additive therapies for the treatment of postmenopausal osteoporosis are available for M.B.?

Calcitonin

Calcitonin decreases bone resorption and bone turnover.[32] Synthetic calcitonin made from salmon is 40 to 50 times more potent than human calcitonin.[117] A nasal spray and an injectable formulation are available and indicated for the treatment of osteoporosis in women who have been postmenopausal for at least 5 years.[118,119] Injectable calcitonin is also indicated for the treatment of hypercalcemia and Paget disease. Calcitonin is only recommended for the treatment of osteoporosis when alternatives are not suitable and can be considered third-line treatment.[26,32,118] Fracture reduction has not been shown in quality clinical trials.

Common nasal symptoms from nasal administration include rhinitis, nasal sores, irritation, itching, sinusitis, and epistaxis.[119] Local skin reactions (10%) are common with injectable calcitonin.[118] Nausea with or without vomiting (10%) and flushing (2%–5%) can occur at initiation of therapy, but subsides over time. Other adverse effects include arthralgia, headache, and back pain. More severe adverse effects associated with calcitonin salmon include serious hypersensitivity, hypocalcemia, and malignancy. Injectable calcitonin should be refrigerated when not in use and nasal spray refrigerated until it is opened for use; thereafter, it is stable for 30 days at room temperature. Calcitonin nasal spray should be used in alternate nostrils daily.

Due to calcitonin salmon's weak efficacy, alternative treatments should be used for the treatment of osteoporosis.

Denosumab

Denosumab is a human monoclonal antibody that binds to RANKL, a regulator of bone-resorbing osteoclasts.[23] Denosumab is administered by subcutaneous injection every 6 months and inhibits bone turnover with a rapid onset. Denosumab significantly increases BMD in the lumbar spine, total hip, and at the femoral neck compared to placebo.[120] This effect dissipates quickly and BMD returns to approximately baseline levels within 12 months of discontinuation.

In a large randomized, placebo-controlled, multicenter trial that included 7,868 postmenopausal women with osteoporosis, denosumab 60 mg subcutaneously every 6 months was compared to placebo for a duration of 36 months.[121] Denosumab reduced the primary outcome of new clinical vertebral fracture, 2.3% versus 7.2% (RR 0.32; 95% CI 0.26 to 0.41; $p < 0.001$). Denosumab slightly reduced the cumulative risk of new hip fracture, 0.7% versus 1.2% (HR, 0.60; 95% CI, 0.37 to 0.97; $p = 0.04$), and also reduced the cumulative risk of nonvertebral fracture, 6.5% versus 8.0% (HR 0.80; 95% CI, 0.67 to 0.95; $p = 0.01$). Eczema occurred in 3% of patients receiving denosumab and 1.7% for placebo ($p < 0.001$). A serious skin infection occurred in 12 patients (0.3%) receiving denosumab and only one patient receiving placebo ($p = 0.002$). Other adverse effects were similar in both groups.

In two head-to-head clinical trials comparing denosumab to weekly alendronate, denosumab was associated with greater increases in BMD at the hip, lumbar spine, femoral neck, and radius at 12 months.[122,123] Similar findings have been published comparing denosumab to monthly ibandronate.[124] At 12 months, BMD was significantly higher at the total hip, femoral neck, and lumbar spine in postmenopausal women receiving denosumab than in those receiving ibandronate. Palacios et al. pooled data from two trials comparing denosumab 60 mg subcutaneously every 6 months to either ibandronate or risedronate, 150 mg once monthly for 12 months.[125] Postmenopausal women with low bone mineral density and suboptimal adherence with prior oral bisphosphonate therapy were included in the trials. A treatment satisfaction questionnaire at baseline was compared to 6 and 12 months. Satisfaction improved in all patients, but was significantly higher in the denosumab group ($p < 0.001$). Qualitative measures of effectiveness, side effects, convenience, and overall satisfaction were greater in patients who transitioned to denosumab. The clinical outcome of fracture was not reported and the comparison of fracture risk between denosumab and oral bisphosphonates cannot be made.

Denosumab is approved for the treatment of postmenopausal women with osteoporosis who are at high risk for fracture.[120] Common adverse reactions include back pain, pain in extremity, hypercholesterolemia, musculoskeletal pain, and cystitis. Serious infections including cellulitis can occur when taking denosumab as well as skin rash and eczema. There is a risk of hypocalcemia with treatment.

Adequate supplementation of calcium and vitamin D, at least 1,000 mg of calcium and 400 IU of vitamin D daily, is recommended. Hypocalcemia must be corrected before the initiation of treatment serious hypersensitivity reactions, pancreatitis, osteonecrosis of the jaw (ONJ), and atypical femur fractures have all been reported. Denosumab is available as prefilled syringes that should be stored in the refrigerator at 2°C to 8°C (36°F–46°F). It should be left out and brought to room temperature for administration. It is recommended that a healthcare provider administers denosumab by subcutaneous injection in the upper arm, upper thigh, or abdomen.

Parathyroid Hormone

Endogenous parathyroid hormone (PTH) regulates the level of calcium in the blood.[22] Even a small decrease in calcium will cause secretion of PTH. It acts on the kidneys to conserve calcium and stimulate the production of calcitriol, which increases the absorption of calcium. PTH stimulates bone formation and bone resorption, but also increases the movement of calcium from the bone to the blood. Hyperparathyroidism is uncontrolled overactivity and the continuous secretion of PTH. Excessive PTH causes bone breakdown by osteoclasts and has been shown to contribute to bone loss and bone fragility. A controlled intermittent injection, however, promotes bone formation, increasing BMD and bone size. Teriparatide is a human recombinant fragment of the first 34 amino acids of parathyroid hormone (PTH 1-34), which produce most of its chief biologic effects.[126] It is available as a multidose pen, given as a daily 20 mcg subcutaneous injection, and approved for the treatment of postmenopausal women with osteoporosis who are at high risk for fracture.

Early clinical trials in humans were stopped prematurely because animal data showed increased incidence of osteosarcoma at high doses and long duration.[22,126] A boxed warning for the potential risk of osteosarcoma appears in the manufacturer’s package information and a medication guide is required to be dispensed with teriparatide.

Neer et al.[127] conducted one of the early randomized placebo-controlled trials using teriparatide that was terminated early. The trial enrolled 1,637 postmenopausal women who had been in menopause at least 5 years and sustained at least one moderate or two mild vertebral fractures. Patients were randomized to a daily subcutaneous injection of 20, 40 mcg, or placebo and completed an average of 18 months of therapy. Teriparatide (PTH) 20 and 40 mcg reduced new vertebral fractures by 65% and 69%, respectively, and reduced new nonvertebral fractures by 53% and 54%, respectively. BMD increased significantly in the lumbar spine (9% and 13%) and femoral neck (3% and 6%) for the 20 and 40 mcg doses, but decreased by 2% at the radius in patients taking 40 mcg. Nausea and headache were significant compared to placebo for patients taking the 40 mcg dose, whereas dizziness and leg cramps were significant for patients taking the 20 mcg dose. Hypercalcemia happening at least once during the first 4 to 6 hours after injection occurred in 2% of women in the placebo group, in 11% of women in the 20 mcg group, and 28% of women in the 40 mcg group. The dose of PTH in these patients was decreased by half after the first incidence of hypercalcemia. PTH increased serum calcitriol and serum uric acid, and slightly decreased serum magnesium, but approximately 5 weeks after treatment was terminated, serum calcium, magnesium, and uric acid returned to or approached baseline values.

A meta-analysis of randomized placebo-controlled trials had similar results; PTH decreased vertebral fracture risk by 63% (RR = 0.37; 95% CI: 0.28–0.48) and nonvertebral fracture risk by 38% (RR = 0.62; 95% CI: 0.46–0.82).[128] PTH also reduced the incidence of new and worsening back pain (OR = 0.68, 95% CI: 0.53–0.87). Adverse effects of nausea and hypercalcemia following injection were reported.

A subgroup analysis of the European Study of Forteo (EUROFORS) included 503 patients who received teriparatide in a 2-year, randomized controlled, open-label clinical trial of 868 postmenopausal women with established osteoporosis.[129] Patients were divided into three subgroups based on previous treatment with antiresorptive medications. Changes in BMD were analyzed in patients who were treatment-naïve (n = 84), patients pretreated with antiresorptive medication (AR) who had no evidence of inadequate treatment response (n = 134), and patients pretreated showing an inadequate response to AR treatment (n = 285) at 6, 12, 18, and 24 months. The mean BMD decreased at the total hip and femoral neck in the first 6 months of treatment with teriparatide in patients who were previously treated with AR, but not in patients who were treatment-naïve. There was an increase from baseline of BMD at the femoral neck at 12 months and at the hip by 18 months. At 24 months, changes in BMD were significant in all three subgroups at the lumbar spine, total hip, and femoral neck. Gains in BMD were greatest for treatment-naïve patients. Significant increases in BMD at the lumbar spine, total hip, and femoral neck occurred between 18 and 24 months.

Teriparatide has a unique mechanism of action that makes it attractive to combine with other medications to treat osteoporosis. Teriparatide has been given safely in combination with denosumab for 12 months along with a 12-month extension in a small trial (n = 94) of postmenopausal women.[130,131] At 12 months, all groups had a significant change in BMD, but the combination resulted in greater increases in BMD than with either medication alone. At 24 months, BMD continued to increase, but the increase in hip and femoral neck BMD from teriparatide was significantly higher than in the first year and when compared to the second 12 months of denosumab. Overall increases in BMD at the femoral neck (6.8%), total hip (6.3%), and spine (12.9%) are greater from the combination of teriparatide and denosumab than can be achieved from either drug alone. BMD of the distal radius increased at 24 months, but a decrease in BMD from baseline occurred in the teriparatide group. Medications were well tolerated. Mild hypercalcemia was reported in the first 12 months but did not occur in the second 12 months. Serious adverse effects were reported, but all were judged unrelated to the medications.

Teriparatide in combination with alendronate does not have the same results.[132] The combination of teriparatide and alendronate increased BMD at the radius, but decreased BMD at the lumbar spine, femoral neck, and total hip compared to teriparatide alone. However, the addition of teriparatide to alendronate in women on long-term therapy instead of switching to teriparatide resulted in increased BMD at 18 months compared to teriparatide alone.[133]

When combined with zoledronic acid, BMD in the lumbar spine improved significantly over zoledronic acid alone, but was not different than teriparatide alone.[134] BMD in the total hip was increased in the combination group and significantly different from teriparatide alone, but not different from zoledronic acid alone.

Teriparatide may have a slight benefit in combination with bisphosphonates and more significant effects when combined with denosumab, but more information is needed to determine the effect on fracture risk.

Teriparatide has been used to treat and promote healing of bisphosphonate- or denosumab-induced osteonecrosis of the jaw.[135,136] Weekly administration at different doses is being explored for the prevention of vertebral fractures.[137,138]

Initial administration of teriparatide should be given when the patient can sit or lie down as orthostatic hypotension may occur with the initial doses.[126] Teriparatide pens are stable for up to 28 days, including the first injection. The remaining medication should be discarded after 28 days. Teriparatide should be stored under refrigeration at 2°C to 8°C (36°F–46°F) and injected immediately on removal from refrigeration. After use, the pen should be recapped and protected from light. Safety and efficacy

with teriparatide is limited beyond 2 years and therapy is not recommended for longer than 2 years at this time.

Adverse effects reported include hypercalcemia, leg cramps, nausea, and dizziness. Orthostatic hypotension may occur within 4 hours of administration and spontaneously resolves after a few minutes to hours for the first several doses. Patients should immediately sit or lie down if symptoms occur.

Glucocorticoid-Induced Osteoporosis

CASE 110-4

QUESTION 1: D.J. is a 56-year-old male who was diagnosed with Crohn disease 10 years ago. D.J. has been somewhat stable on methotrexate and sulfasalazine for the past 5 years. D.J. has experienced increased symptoms for the past week, which have been getting progressively worse. D.J. was hospitalized and started on parenteral corticosteroids and discharged on 60 mg/day of prednisone to slowly taper over 3 months. Because this is the third flare of his disease in 2 years, D.J.'s physician was concerned about the risk of osteoporosis. As a member of the healthcare team, you will meet with DJ at his follow-up visit in a few days. During your meeting with D.J., he asks you why men have to worry about osteoporosis. Provide an explanation to D.J., including his risks and outline patient-specific goals for him.

Glucocorticoid therapy, such as prednisone, is a common cause of osteoporosis. The risk of fracture increases at the start of therapy, within 3 to 6 months, and decreases after discontinuation.[139] Fracture risk increases with dose and duration of therapy.

Glucocorticoids contribute to bone loss resulting in osteoporosis by reducing the lifespan of osteoblasts and increasing osteocyte apoptosis.[140] Glucocorticoids reduce bone formation, decreased bone volume, and lead to rapid bone loss.

D.J. is at risk for substantial loss of bone mass due to a high dose of medication for an extended period of time. The goal while he is on glucocorticoid therapy would be to minimize bone loss. D.J. would be a candidate for pharmacologic therapy for the prevention of osteoporosis while taking prednisone. The minimum threshold for risk of osteoporosis according to National Osteoporosis Foundation (NOF) is 5 mg prednisone daily for 3 months.[1]

CASE 110-4, QUESTION 2: What medications are available to prevent osteoporosis in D.J.?

BISPHOSPHONATES

Alendronate, risedronate, and zoledronic acid are FDA-approved for the treatment of glucocorticoid-induced osteoporosis (GIOP). Risedronate and zoledronic acid are approved for the prevention of GIOP. The American College of Rheumatology (ACR) published guidelines for the prevention and treatment of glucocorticoid-induced osteoporosis.[141] For postmenopausal women and men ages 50 years and over, alendronate, risedronate, and zoledronic acid are all recommended in patients receiving glucocorticoid doses of 7.5 mg/day if the duration is at least 3 months.

Bisphosphonates increase BMD and prevent bone loss in patients treated with glucocorticoids.

Alendronate 5- and 10-mg doses for 48 weeks were found to increase BMD in the lumbar spine, femoral neck, and trochanter while it decreased in placebo in patients on long-term glucocorticoids, with no significant difference in fracture rate.[142] At the completed trial, 389 of 560 patients were still receiving daily prednisone 7.5 mg and eligible to continue a 12-month extension.[143] At the end of the 12-month extension, BMD increased at the lumbar spine, femoral neck, and trochanter significantly in the alendronate groups and decreased in the placebo group. Although only a small number of vertebral fractures occurred, the difference was significant for alendronate (0.7%) versus placebo (6.8%; $p = 0.026$). Alendronate at a dose of 70 mg weekly is also more effective than placebo at increasing BMD in patients taking glucocorticoids.[144] Risedronate 5 mg daily for 48 weeks preserved BMD at the lumbar spine while it decreased in placebo in patients who were started on long-term glucocorticoids.[145] No significant difference in fracture rate was found. In a 1-year noninferiority trial of zoledronic acid 5 mg IV, one dose, versus risedronate 5 mg oral daily, BMD was increased in the lumbar spine 4.06% versus 2.71%, respectively ($p < 0.001$).[146] Zoledronic acid was noninferior and superior to risedronate. In a study of men on glucocorticoids for at least 1 year, zoledronic acid had similar results and significantly increased BMD at the lumbar spine and total hip compared to risedronate.

Although daily doses of alendronate and risedronate are approved for the indication of glucocorticoid-induced osteoporosis, weekly doses are more frequently used in clinical practice and significantly reduce the incidence of fracture.[147] Weekly doses also improve adherence. (see Case 110-4, Question 4: Adherence)

PARATHYROID HORMONE

Teriparatide is also approved for the treatment GIOP. A 36-month trial conducted by Saag et al. compared teriparatide 20 mcg subcutaneously daily versus alendronate 10 mg oral daily.[148] The study included 400 men and women, primarily with rheumatologic conditions. Teriparatide increased spinal BMD 7.2% versus 3.4% in the alendronate group after 18 months of therapy. Hip BMD increased 3.8% in the teriparatide group versus 2.4% in the alendronate group. Differences between groups were noted as early as 6 months. At 36 months, teriparatide continued to increase BMD in the spine, hip, and femoral neck to a greater extent than alendronate. There were fewer vertebral fractures in the teriparatide group (1.7%) than in the alendronate group (7.7%; $p = 0.007$). No significant difference in nonvertebral fractures was found between groups. A small ($n = 95$), 18-month trial compared teriparatide 20 mcg subcutaneously daily to risedronate 35 mg weekly in men who were with a minimum of 3 months prior glucocorticoid use (median 6.4 years).[149] Significant increases in BMD from baseline were found for both treatment groups, but a significantly greater increase occurred with teriparatide (16.3% versus 3.8%; $p = 0.004$). No vertebral fractures occurred during the trial. A total of five patients in the risedronate group (10.6%) developed new clinical fractures while no fractures occurred in the teriparatide group ($p = 0.056$).

Denosumab is not approved for the treatment of GIOP, but increases BMD and reduces bone turnover in patients on long-term glucocorticoids.[150,151]

CASE 110-4, QUESTION 3: What recommendations should D.J.'s clinician share with him for preventing osteoporosis?

Adequate dietary calcium and vitamin D are essential. Supplementation is recommended if needed to maintain dietary calcium 1,200 to1,500 mg daily and vitamin D 800 to 1,000 IU daily.[141] Lifestyle changes are encouraged in patients and include smoking cessation, reduced alcohol intake, and regular exercise.

D.J. is a candidate for bisphosphonate therapy. He should receive an oral bisphosphonate such as alendronate 70 mg weekly or risedronate 35 mg weekly while taking prednisone. He should be counseled on the proper administration and adverse effects of bisphosphonates and receive a medication guide with the medication. (see Case 110-2, Question 8).

D.J. should choose 1 day of the week he will remember to take his medication. It should be taken in the morning on an empty stomach with a full glass of water. He should remain upright and not eat or drink anything for at least 30 minutes after taking his dose.

CASE 110-4, QUESTION 4: How does adherence affect prevention or treatment of osteoporosis?

Osteoporosis is a major public health concern, but is an asymptomatic disease until fracture occurs. Although many medications used to treat osteoporosis have the convenience of less frequent dosing, adherence is not optimal.[110] Potential barriers to adherence of osteoporosis medication include dosing frequency, side effects of medications, comorbid conditions, knowledge about osteoporosis, and cost.

Adherence in clinical trials does not typically reflect real-world patients. Of 18 randomized controlled trials that reported rates of adherence, the majority reported over 90%. Of 59 observational studies, adherence was substantially lower: 10 of 13 adherence studies reported rates below 50%; in studies using data from health plans, 35% to 52% of patients had an adherence rate of 80% or above; and in several marketing scans, adherence above 80% ranged from 23% to 49%, and only 33.5% for teriparatide.

In a meta-analysis of bisphosphonate adherence including 15 observational studies (n = 704, 134), the overall risk of fracture was estimated to be 46% higher when low adherence was compared to high adherence.[152] This meta-analysis was limited by heterogeneity and differences in the observational study designs.

A systematic review that included two separate searches of male osteoporosis included 18 studies related to adherence, and 37 studies related to cost.[153] This systematic review also included mostly observational studies and did not pool the data. Over a 1-year period, only 32% to 64% of men were above 80% adherent to medication above. Overall clinical outcomes were worse with nonadherence. The overall cost associated with osteoporotic fractures in men is not as high as in women, but four studies that explored direct and indirect costs found the overall cost per fracture in men is higher than in women.

Oral bisphosphonates are first-line agents for prevention and treatment of osteoporosis. Weekly doses improve adherence compared to daily doses; monthly doses do not improve adherence compared to weekly doses and monthly adherence may be slightly lower.[154–156]

Although the consequence of poor adherence is an estimate, it makes sense that promoting adherence will improve the effect of bisphosphonates, and is important to achieve the results that are reported in clinical trials.

Osteoporosis in Men

CASE 110-5

QUESTION 1: M.B.'s husband, J.B., is 77 years old and presents to his physician for a routine physical examination. J.B's wife has osteoporosis and his daughter has low bone mass. J.B. would like to know whether men develop osteoporosis. Should he be tested for osteoporosis?

The National Osteoporosis Foundation (NOF) estimates that 9.9 million Americans have osteoporosis and that 2 million are men.[92,157]

The prevalence in men increases later in life, with the greatest increase seen at age 80.[10] The age-adjusted prevalence of osteoporosis at either the femoral neck or lumbar spine differs by race (4% non-Hispanic white men; 9% other races) as does the prevalence of low bone mass (24% non-Hispanic black men; 39% non-Hispanic white men). Approximately 80,000 men will break a hip each year and mortality rates after hip fracture are higher in men than in women.[157]

In an Endocrine Society Clinical Practice Guideline for Osteoporosis in Men, Watts et al.[24] suggest BMD testing for all men age 70 and greater, men with a history of fracture after age 50, and in men age 50 to 69 with conditions or disease states such as delayed puberty, alcohol abuse, smoking, hypogonadism, hyperparathyroidism, hyperthyroidism, COPD, and glucocorticoid or GNRH agonists use.

J.B. is over age 70, and should have a DXA of the spine and hip to measure BMD.[24,92,] When a spine or hip BMD is not possible and in men receiving androgen deprivation therapy (ADT) or with hyperparathyroidism, a DXA of the forearm may be measured.

The same WHO criteria that were established for women are used to diagnose osteoporosis in men (T-score < or equal to −2.5).[45]

CASE 110-5, QUESTION 2: J.B. knows that BMD loss in both his wife and daughter has been attributed to a decrease in hormones. Is hormone loss the same cause of osteoporosis in men?

Many risk factors contribute to osteoporosis in men (Table 110-1); however, a decrease in androgen and estrogen production is the primary hormonal contributor to the development of osteoporosis in this population.[158]

Androgens and Estrogens

Androgen production, specifically serum testosterone concentrations, decreases with age. These decreased concentrations are thought to decrease bone formation and increase resorption. Testosterone has been linked to decreases in BMD, whereas dihydrotestosterone has not been linked.[159] Despite testosterone's importance for skeletal health in men, research now suggests that estrogen may play a more important role in skeletal biology. Two genes, estrogen receptor α and aromatase, are required for estrogen effects; ER-α is found on osteoblasts, osteoclasts, and stem cells in bone. Aromatase is present in osteoblasts and stem cells in bone. The absence of these genes results in an inability to convert androgen into estrogen. Replacement of estrogen in aromatase deficiency showed significant increases in bone mass and markers of bone turnover normalized.

CASE 110-5, QUESTION 3: Should J.B. be given supplementation for hypogonadism if his testosterone levels are low?

Hypogonadism may be a major contributor of bone loss in adult men and may increase the risk of fracture.[160] If a complete history and physical activity suggest a specific cause for osteoporosis, it would be appropriate for J.B.'s provider to order more tests including serum testosterone levels and replace testosterone if indicated, along with treatment for osteoporosis.[24]

CASE 110-5, QUESTION 4: If it is determined that J.B. has osteoporosis, should he receive calcium and vitamin D?

All men who are at risk for osteoporosis such as J.B. or who have osteoporosis should receive 1,000 to 1,200 mg of calcium daily through their diet and supplementation if necessary.[24] A 25(OH)D level should be drawn and if indicated, J.B. should receive vitamin D to achieve a level of at least 30 ng/mL.

CASE 110-5, QUESTION 5: What therapies are available to treat osteoporosis in men?

FDA-approved therapies for men include bisphosphonates (alendronate, risedronate, zoledronic acid), parathyroid hormone (teriparatide), and monoclonal antibody (denosumab) (see Table 110-8). In a 2-year double-blind trial, 241 men with osteoporosis were randomized to receive either alendronate 10 mg daily or placebo.[161] One-third of the population had low serum-free testosterone levels. BMD increased by 7.1% versus 1.8% in the lumbar spine, 2.5% versus −0.1% in the femoral neck, and 2% versus 0.4% in total body for alendronate and placebo groups, respectively. The incidence of new vertebral fractures was less in the alendronate group (0.8%) when compared with placebo (7.1%), and a smaller decrease in height was observed in the alendronate group (0.6 mm) as compared to placebo (2.4 mm).

In a 2-year double-blind, placebo-controlled trial, 284 men were randomly assigned in a 2:1 fashion to receive risedronate 35 mg weekly or placebo.[162] All patients received calcium and vitamin D supplementation. Lumbar spine BMD increased 4.5% over placebo in the risedronate group. There were no differences between groups in vertebral and nonvertebral fractures, but bone turnover markers were significantly lower in the risedronate group.

In a multicenter, double-blind, active-controlled, parallel-group study of osteoporosis, 302 men age 25 to 85 were randomly assigned to receive once-yearly zoledronic acid 5-mg IV infusion or oral alendronate 70 mg weekly and followed for 2 years.[163] All patients received calcium and vitamin D supplementation. The results of the study confirmed noninferiority of zoledronic acid to alendronate with similar BMD response and suppression of bone turnover markers. BMD at the lumbar spine increased by 6.1% in the zoledronic acid group versus 6.2% in the alendronate group with other sites showing similar BMD increases between groups.

Orwoll et al. also conducted a multicenter, randomized, double-blind, active-controlled trial in 437 men age 30 to 85 with BMD less than 2 SD lower than the young adult male mean BMD.[164] Patients received teriparatide 20 mcg subcutaneously daily, 40 mcg subcutaneously daily, or placebo with calcium and vitamin D supplementation for a median duration of 11 months. Lumbar spine BMD increases were noted after 3 months with increases of 5.9% in the 20 mcg group and 9.0% in the 40 mcg group by study end. Increases were also seen in bone turnover markers in the 20 and 40 mcg groups. The study was originally planned to be a 2-year study, but it was stopped early after findings of osteosarcomas in rats during routine testing.

In a systematic review and meta-analysis of antiresorptive and anabolic treatments for osteoporosis in men, both classes of drugs increased BMD as compared to placebo in men with osteoporosis.[165] More research is needed on vertebral and nonvertebral fractures as a primary endpoint in studies that include men.

CASE 110-5, QUESTION 6: When is pharmacologic treatment recommended?

Pharmacologic therapy is indicated in men who are diagnosed with osteoporosis; have low bone mass in addition to a 10-year risk of hip fracture ≥ 3% using WHO FRAX; have had a hip or vertebral fracture without a major trauma; and those who are on long-term glucocorticoid therapy >7.5 mg/day.[24]

The Endocrine Society recommends monitoring DXA at the spine and hip every 1 to 2 years to evaluate treatment and bone turnover markers at 3 to 6 months after starting therapy.

J.B. should maintain adequate dietary calcium and vitamin D intake. Supplementation is recommended if needed to maintain dietary calcium 1,200 mg daily and vitamin D 600 IU. Lifestyle changes are encouraged in patients and include smoking cessation, reduced alcohol intake, and regular exercise.

Drug Index

Note: Page number followed by f and t indicates figures and tables respectively

A

Abacavir (ABC), 58t, 1616
  for HIV, 1577t
Abatacept, 881, 883, 896t, 897, 898, 904
Abciximab, 22
  for ACS, 237
Abilify (see Aripiprazole)
Abiraterone, 2095, 2096
Abreva (see Docosanol cream)
Acamprosate, 1898–1899
Acarbose, for type 2 diabetes, 1125, 1126, 1134
ACE inhibitors (see Angiotensin-converting enzyme (ACE) inhibitors)
Acetaldehyde, 1892
Acetaminophen, 44, 49, 1182, 1183, 1185, 1187t, 1191, 1982t
  analgesic syndrome from, 601
  for arthritis, 2228
  for burns, 863
  for dysmenorrhea, 1015
  for end-of-life care, 86
  for HAV, 1665
  hepatitis and, 1672
  for migraine headache, 1237
  neonates and, 2157, 2165, 2166
  for OA, 867, 869
  for PDA, 2181
  PegIFN therapy, 1678
  for postoperative pain management, 1180
  pregnancy and, 79, 942t
  toxicity with, 79–82
Acetazolamide, 564, 581
  cryptococcal disease, 1643
  and hypokalemia, 583t
Acid-related disorders, pharmacotherapy of drugs
  antacids and alginic acid, 482, 484
  bismuth salts, 486
  H_2-receptor antagonists, 484
  misoprostol, 486
  PPI, 484–486
  sucralfate, 486
Acitretin, for psoriasis, 836t, 840
Aclidinium bromide, for COPD, 420t

Acular (see Ketorolac)
Acupressure, 975
Acupuncture, 975
ACV (see Acyclovir (ACV))
Acyclovir (ACV), 744, 1648t, 1650
  administration of, 1650
  adverse effects of, 1334t, 1647, 1647t
  dosing of, 1336t
  for genital herpes, 1529, 1530t
  for herpes encephalitis, 1646–1647
  for herpes labialis, 1650–1651
  for herpes simplex virus, 1167–1168, 1648, 1650
  oral administration, 1647–1648
  pharmacokinetics of, 1653t
  for PHN, 1652, 1654
  renal failure, dosing of drugs, 672–673
  toxicity, 1654–1655
  against varicella infection, 1652
Acyclovir and Hydrocortisone cream (Xerese), 1650
Acyclovir cream (Zovirax), 1650
ADACEL, 1357
Adalimumab, 881, 895, 896t, 904
  for inflammatory bowel disease, 522t
  for PsA, 842–843
  for RA, 882
  for UC, 527–528
Adapalene, 827, 828, 829, 830
Adefovir dipivoxil, 1678
Adenosine, 319–320
Ado-trastuzumab emtansine, 469t
Adrenaclick, 446t
Aerosolized aztreonam, 460
Afatinib, 470t
Aflibercept, 1169
Afrezza, 1084, 1086
Afrin (see Oxymetazoline)
Aggressive insulin therapy, 453
Akynzeo (see Palonosetron; Netupitant)
Alanine aminopeptidase, 1990
Albendazole, 1705t
  for ascariasis, 1703t
  for enterobiasis, 1703t
  for filariasis, 1704t
  for giardiasis, 1704t
  for hookworm, 1704t
  for hydatid cysts, 1705t
  for pinworm, 1708
Albiglutide, 1126–1127
Albumin, 358
  in edema, 573
Albuterol, 392, 689t
  for acute asthma, 388
  for AECOPD, 1408
  anxiety from, 1736t
  for chronic asthma, 395

for COPD, 419, 420t
for end-of-life care, 86
for hyperkalemia, 587t
with ipratropium, 86
muscle cramps and, 172t
nebulization, 389, 586
respiratory acidosis and, 565
Alcaftadine (Lastacaft), 439t, 1165
Alcohol, 1627
and acute gout, 915
AF and, 312t
for BMD, 2271
diabetes and, 1081
GERD and, 505t
heartburn and, 977
HF and, 275
hypertension and, 139
MI and, 210t
muscle cramps and, 172t
for osteoporosis, 2274
pulmonary embolism and, 196–197
for schizophrenia, 1783t
teratogenic effects, 973t
variant angina and, 228
Aldesleukin, 469t, 1994t
Aldosterone antagonists
for ACS, 238t
for HF, 270, 289–290
for hypertension, 140, 148–149t, 157
in left ventricular remodeling, 257
Alectinib, 470t
Alemtuzumab (Campath), 469t, 1231–1232, 1232t, 1983t
monoclonal antibodies, 723
for MS, 1222
Alendronate, 2277–2278, 2277t
androgen deprivation therapy, 2097
dose, 2279
for end-of-life care, 86–87
Alfentanil, 2131t
Alfuzosin, 2256
Alginic acid, 482, 484

Alirocumab, 129–131
Aliskiren, 128, 157t, 605, 609
for hypertension, 140, 158
Allegra (see Fexofenadine)
Allopurinol, 58t, 916, 917t
for HF, 278
weight gain with, 2021
Allylamines, 1624, 1625
Almotriptan, 1238t, 1239

Alocril (see Nedocromil)
Alogliptin, 1127–1128
Alomide (see Lodoxamide)
Alosetron, 536
Aloxi (see Palonosetron)
α-adrenergic agonists, 503t
α-adrenergic blockers, 2242
α-blockers, 157–158
  with β-blockers, 158–159
  for hypertension, 140
Alphagan (see Brimonidine)
α_2-adrenergic agonist, 1878
α_2-agonists
  for ADHD, 1870
  for developmental disorders, 1855–1856
  for hypertension, 159
Alprazolam (Xanax), 1027t, 1271t, 1272, 1737t, 1759
  drug interaction with smoking, 1906t
  for panic disorder, 1748
  for PMDD, 1025
  sedative-hypnotics, 1882
Alprostadil, 2266
Alrex (see Loteprednol)
Alteplase, for STEMI patients, 237
Altretamine, 470t
Aluminum hydroxide, 620t
Aluminum salts, 482, 917t
Amantadine (Symmetrel), 1224, 1250t, 1262, 1649t
  adverse effects, 1647t
  for Akathisia, 1800t
  for influenza, 1655–1656
  for Parkinsonism, 1799
  pharmacokinetics of, 1653t
AmB (see Amphotericin B (AmB))
AmB formulation, 1643
Ambien, 1767t
Ambien CR, 1767t
Ambrisentan, 128, 924
Ameliorate, 1878
Amifostine, 469t, 1973–1974
Amikacin (Amikin), 461t, 1325t
  adverse effects of, 1332t
  for CAPD-associated peritonitis, 1476t
  for CNS infections, 1373t
  for gram-negative aerobes, 1327t
  for MAC, 1619
  pharmacodynamic actions of, 48
  for tuberculosis, 1430t
  for UTI, 1497t
Amikin (see Amikacin)
Amiloride, 543, 580–581
  for hypertension, 148
Aminess, 794t
Aminobenzoates, 852
Aminoglycosides, 455, 460, 635–636, 1720

  adverse effects of, 1332t
  for CNS infections, 1373t
  extended-interval dosing of, 461
  for NEC, 2183
  for neutropenic patients, 1563, 1564
  for pneumonia, 1419
  renal failure, dosing of drugs, 668–670
  for RMSF, 1725
  for sepsis, 2186
  for UTI, 1497t
Aminopenicillin, 423
Aminophylline, 2189
Aminosalicylates
  compounds, 523t
  for inflammatory bowel disease, 520, 523
Aminosyn, 794t
Aminosyn HBC, 794t
Aminosyn II, 794t
Aminosyn-RF, 794t
Amiodarone, 120t, 214
  for ACS, 238t
  adverse effects of, 326
  for AF, 316–317
  antiadrenergic effects of, 326
  for cardiopulmonary arrest, 331
  for HF, 299–300
  and liver toxicity, 326
  and MI, 324
  for SuVT, 324–325
  for tachycardia, 1802
  for ventricular arrhythmias treatment, 248

  dosing, 1335–1340
  toxicities, 1331–1334
Antimotility drugs, 1461
Antimycotic pulse therapy, 1627
Antineoplastics, and lactation, 1003t
Antioxidants, 1265
  as photoprotective agents, 853
Antiplatelet agents, 658
Antipseudomonal β-lactam, 460
Antipseudomonal penicillins, 674
Antipsychotics
  for acute agitation, 1846
  for acute mania, 1844–1845

  for bipolar depression, 1837, 1847
  for critically ill patients, 1208
  and lithium, 1843t
Antipyretics, 1665
Antiretroviral therapy (ART), 996
Antispasmodics, 1185
  for IBS, 535
Antispasticity agents, 1185
Antithymocyte globulin (ATG), 722–723
Antithyroid drugs, teratogenic effects, 973t
Antivirals
  adverse effects of, 1334t
  in febrile neutropenic patient, 1569
  for HBV, 1677
  in immunocompromised patients, 1654–1655
Anzemet (see Dolasetron)
Apidra (see Insulin glulisine)
Apixaban, 1307t
  for prevention of stroke, 317–318
  for stroke prevention, 178
  for warfarin therapy, 200
Apokyn (see Apomorphine)
Apomorphine (Apokyn), 1251t, 1254t, 1262
Apraclonidine (Iopidine), 1152
Apremilast
  for plaque psoriasis, 841
  for PsA, 843
Aprepitant (Emend), 128, 472t, 942t
  for CINV, 471–473, 472t, 474t, 475
  for PONV, 478t
Apriso (see Mesalamine)
Aquacel Ag (see Silver sulfadiazine cream)
AquaDEK chewable tablet, 457t

AquADEK liquid, 457t
Aquaretics, 579–580
Aranesp (see Darbepoetin alfa)
ARBs (see Angiotensin receptor blockers (ARBs))
Arformoterol, 420t
Argatroban, 178
Aripiprazole (Abilify), 1267, 1739, 1797t, 1799t
  for acute agitation, 1846
  for acute mania, 1844–1845, 1845t
  and bipolar depression, 1847
  for bipolar disorder, 1849t
  for developmental disorders, 1857–1858
  for dyslipidemia, 1804
  for hyperprolactinemia, 1803
  for schizophrenia, 1789, 1791t, 1792, 1793, 1793t
Aripiprazole lauroxil, 1795t
Aripiprazole monohydrate, 1795t

Armodafinil, 1777, 1779
ARNI (see Angiotensin receptor-neprilysin inhibitor (ARNI))
Aromatase inhibitor (Letrozole), 959, 960, 1013, 1972
  for endometriosis, 1020
  for polycystic ovary syndrome, 1012t
Arsenic trioxide, 469t
  for AML, 2027
ART (see Antiretroviral therapy (ART))
Artemisinin, 1695
Artesunate, 1696
Arylcycloalkylamines, 1885
Asacol HD (see Mesalamine)
Ascorbic acid (vitamin C), 657–658, 918, 942t, 961
  for anemia, 1931
Asenapine (Saphris), 1797t, 1799t
  for acute mania, 1845t
  for bipolar disorder, 1849t
  for hyperprolactinemia, 1803
  for schizophrenia, 1790, 1791t
Asparaginase (Elspar), 469t, 1982t, 1996, 1996t
  neurotoxicity of, 1985, 1985t
  preparations, 2018

  -carbonic acid system, 611
  hyperkalemia and, 586, 587t
  in metabolic acidosis, 562–563
  for preventing SRMB, 515t
  for salicylate toxicity, 70
  for TCA toxicity, 77–78
BiDil (see Isosorbide dinitrate (BiDil))
Biguanide (Metformin)
  adverse effects of, 1112
  contraindications and precautions of, 1112–1113
  dosage and clinical use of, 1113
  drug interactions, 1113
  efficacy of, 1113
  mechanism of action, 1112–1113
  pharmacokinetics of, 1112
  for polycystic ovary syndrome, 1012t
  for type 2 diabetes, 1140
Bile acid resins
  adverse effects, 127
  clinical pearls, 127
  drug interactions, 127
  efficacy, 127
  mechanism of action, 126, 126f
  pharmacokinetics/pharmacodynamics, 127
  place in therapy, 127
Bilirubin, 30, 30f
  blood chemistry reference values for, 19t
Bimatoprost (Lumigan), 1151

  for ocular hypertension, 1151

Biperiden
  for Akathisia, 1800t
  for Parkinsonism, 1799

Biphosphonates, for hypercalcemia, 589t, 590

Bisacodyl, 2159t
  for end-of-life care, 87

Bismuth salt, 486, 496–497

Bismuth subsalicylate (BSS)
  for gastroenteritis, 2161
  for Helicobacter pylori, 493–494t
  for infectious diarrhea, 1449

Bisoprolol
  in HFrEF, 287–288
  in hypertension, 159t

Bisphosphonates, 2038, 2283–2284, 2286–2287
  and dyspepsia, 487
  GERD and, 503t
  for osteoporosis, 2271
  for prostate cancer, 2096

Bivalirudin, 254
  for ACS, 239t
  for heparin-induced thrombocytopenia, 178
  in patients with HIT, 657

Black cohosh (Cimicifuga racemosa), 1030

Blenoxane (see Bleomycin)

Bleomycin (Blenoxane), 469t, 1978t, 1982t, 1987, 1991t, 1993, 1994t, 1995, 1977, 2040t
  gonadal toxicity of, 1998
  for HL, 2041

Boceprevir, 120t, 128
  for HAV, 1687

Bonine (see Meclizine)

BOOSTRIX, 1357

Borates, 1626

Boric acid, for VVC, 1526

Bortezomib (Velcade), 469t, 2037t, 2038
  neurotoxicity of, 1985t
  peripheral nerve toxicity of, 1986
  plus dexamethasone, 2037t

Bosentan, 924, 942t
  for pulmonary HTN, 266

Bosutinib, 470t

Botulinum toxin A, 1271t, 1272

BranchAmin, 794t

Brentuximab vedotin, 469t

Breo Ellipta (fluticasone furoate/vilanterol), for chronic asthma, 396

Brevibloc (see Esmolol)

Brexpiprazole (Rexulti), 1789, 1791t
  for Akathisia, 1799

Brimonidine (Alphagan), 1152

Brinzolamide (Azopt), 1152

Brisdelle (see Paroxetine mesylate)

Bromocriptine (Parlodel), 1250t, 1254t, 2266
  and lactation, 1000
  for type 2 diabetes, 1131

Bronchodilators, for COPD, 416–417, 423
BSS (see Bismuth subsalicylate (BSS))
Budesonide, 441t
  for allergic rhinitis, 442
  for BPD, 2176
  for chronic asthma, 395, 396–397
  for COPD, 420t
  for inflammatory bowel disease, 521t
Budesonide/formoterol (Symbicort), 396
Bumetanide, 580, 647
  for HF, 277
Bupivacaine, 1177t
Buprenorphine, 1187t
  dosage of, 1199t
  for opioid withdrawal syndrome, 1878, 1879

Bupropion, 1827
  for ADHD, 1871
  for depressive disorders, 1819t, 1820t, 1821t
  for diabetes, 2226t
Bupropion/zonisamide ER, 764
  for bipolar depression, 1837
  and sleep, 1774
  for smoking cessation, 1909
  sustained-release, 1914, 1919, 1920–1922, 1924
BuSpar (see Buspirone)
Buspirone (BuSpar), 1027t, 1738t, 1739, 1740, 1746
  vs. benzodiazepines, 1746
  and elderly, 1739
  for PMDD, 1025
Busulfan (Busulfex, Myleran), 469t, 470t, 1994t, 1996t
Butenafine, 1624t
Butoconazole, 1624t
  for VVC, 1525t
Butyrophenone, 1789t

C

Cabazitaxel (Jevtana), 469t
  peripheral nerve toxicity of, 1986
  for prostate cancer, 2095
Cabozantinib, 470t
Caffeine, 765t, 942t
  for apnea, 2189
  for BPD, 2190
  drug interaction with smoking, 1906t
  and heartburn, 977
  for IDH, 657
  and lithium, 1843t
  and pregnancy, 970
“Caine” anesthetics, 822t
Calamine lotion, 821

Calcijex, 622
Calcimimetics, 622–623
Calcineurin inhibitors, 635–636, 721–722
  for FSGS patients, 628–629
  induced nephrotoxicity, 729
Calcipotriene, for psoriasis, 835t, 837–838
Calcitonin, 2277t, 2284
  for hypercalcemia, 589t, 590
  for osteoporosis, 2271
Calcitriol, 621–622
  for psoriasis, 835t, 838
Calcium, 26–27, 1986
  blood chemistry reference values for, 18t
  and BP, 134
  and children, 2140t
  for endometriosis, 1021
  homeostasis, 586–587
  hypercalcemia, 588–591
  for PMS, 1024
  and pregnancy, 968
  recommended daily allowance, 969
  and respiratory alkalosis, 1672
  role of, 586
Calcium acetate, 620t
Calcium carbonate, 620t
Calcium-channel blockers (CCBs), 171, 211, 918, 993
  for ACS, 239t
  for AF, 314
  in anginal syndromes, 216t
  CAD and, 147
  diabetes and, 155–156
  dihydropyridines, 155
  GERD and, 503t
  hemodynamic and electrophysiologic profile, 223t
  for HF, 271–272
  for hypertension, 140, 155–156, 156t
  for hyperthyroidism, 1057, 1059t
  nondihydropyridines, 155
  in patients with CKD, 617
  for pregestational diabetes, 979
  for PSVT, 320
  for thyroid storm, 1067
  vasospastic and classic exertional angina, 222
Calcium gluconate, 587t
Campath (see Alemtuzumab)
Camphor, 1626, 1627
Canagliflozin, 1129–1130
Canakinumab, 903, 913
Canasa, 523t
Candesartan, 1242
  for HF, 271, 283
  for hypertension, 154t
Candicidin, 1626
Cangrelor, 246–247t
  for ACS, 239t

for thrombotic events reduction, 244
Cannabinoids, 1224
for CINV, 473
Cannabis, 1783, 1783t
Canrenone, 581
Canthaxanthin, 856
Capecitabine (Xeloda), 470t, 1978t, 1991t
Capoten (see Captopril)
Capreomycin, for tuberculosis, 1430t
Caprylic acid, 1626
Capsaicin, 1187t
for neuropathic pain, 1188
for OA, 869
Capsaicin cream, 1182t
for PHN, 1654
Capsaicin patch, 1182t, 1654
Captopril (Capoten), 171, 257, 281–282, 281t, 336t, 2223
for BP, 339
and hyperkalemia, 584–585
in hypertension, 153t
Carba, 822t
Carbachol (Isopto Carbachol), 1152
Carbamazepine (CBZ), 42, 58, 58t, 214, 942t, 1181t, 1187t, 1279t, 1284t, 1743, 1754, 1837, 2261t
for acute mania, 1844–1845
autoinduction of metabolism of, 1282
bioequivalence of generic dosage of, 1282
for bipolar disorder, 1849t
for epilepsy, 57
extended-release forms of, 1282
for HAV, 1688
and hematologic toxicity, 1281
hepatotoxicity with, 1281–1282
initiation and dosage of, 1281
lamotrigine and, 1286–1287
and lithium, 1843t
for nocturnal leg cramps, 173
for ocular emergencies, 1160t
pharmacokinetics of, 1282
for schizophrenia, 1809
for seizures, 1281–1282
teratogenic effects, 973t
valproate and, 1296
Carbapenem
for febrile neutropenia, 1561
for skin and soft tissue infections, 1552
for UTI, 1497t
Carbidopa–levodopa (enteral suspension) (Duopa), for Parkinson's disease, 1250t
Carbidopa–levodopa (CR) (Sinemet CR), for Parkinson's disease, 1250t, 1260
Carbidopa–levodopa (ER) (Rytary), for Parkinson's disease, 1250t, 1260–1261
Carbidopa–levodopa ODT (Parcopa), for Parkinson's disease, 1250t
Carbonyl iron, 1930
Carboplatin (Paraplatin), 469t, 475, 1991t, 2065
for blood progenitor cell rescue, 2005
for NSCLC, 2062t, 2063t, 2064t
for SCLC, 2068t

Carboprost tromethamine, for postpartum hemorrhage, 997–998, 997t
Cardene IV (see Nicardipine)
Cardiac resynchronization therapy (CRT), 272
Carfilzomib, 469t, 2038
Cariprazine (Vraylar), 1797t, 1845
    for acute mania, 1845t
    for schizophrenia, 1789, 1791t
Carisoprodol, 1186t
Carmustine (BiCNU), 469t, 1979t, 1987, 1991, 1991t, 1994t, 1996, 1996t
    and cranial neuropathies, 1987
Carteolol (Ocupress), 1151
Carvedilol, 258
    in HFrEF, 287
    for hypertension, 158–159, 159t
    in peri-infarction period, 253, 258
Caspofungin, 1569, 1624t, 1625, 1632, 1633, 1634, 1640, 1641
    adverse effects of, 1334t
    dosing of, 1336t
    for fungal endocarditis, 1400
    renal failure, dosing of drugs, 675
Catapres (see Clonidine)
Catechol-O-methyltransferase inhibitors (COMT), 1262–1264
    pharmacologic and pharmacokinetic properties of, 1263t
Catecholamines, for septic shock, 371
Cathelicidins, 1626
CBZ (see Carbamazepine (CBZ))
CCBs (see Calcium-channel blockers (CCBs))

Ceclor (see Cefaclor)
Cedax (see Ceftibuten)
Cefaclor (Ceclor), 1325t
    for chronic antimicrobial therapy, 1499t
    for UTI, 1489t
Cefadroxil (Duricef), 1325t
Cefamandole (Mandol), 1325t
Cefazolin (Ancef), 658, 661, 662, 1165, 1325t, 1548
    for aerobic gram-positive cocci, 1326t
    for anaerobes, 1328t
    for CAPD-associated peritonitis, 1476t
    dosing of, 1336t
    for gram-negative aerobes, 1327t
    for PVE, 1392t
    for pyelonephritis, 995
    renal failure, dosing of drugs, 675–676
    for skin and soft tissue infections, 1548
    for surgical procedures, 1345t, 1346, 1348–1349
    for UTI, 1497t
Cefdinir (Omnicef), 1325t
Cefditoren (Spectracef), 1325t
Cefepime (Maxipime), 1325t
    for aerobic gram-positive cocci, 1326t

- for anaerobes, 1328t
- for CAPD-associated peritonitis, 1476t
- for CNS infections, 1373t
- for cystic fibrosis, 461t
- dosing of, 1336t
- for febrile neutropenia, 1561
- for gram-negative aerobes, 1327t
- for gram-negative bacillary meningitis, 1378
- for skin and soft tissue infections, 1550
- for UTI, 1497t

Cefixime (Suprax), 1325t
- for disseminated gonococcal infection, 1514
- for shigellosis, 1456
- for typhoid fever, 1456
- for uncomplicated gonorrhea, 1508

Cefizox (see Ceftizoxime)

Cefonicid (Monocid), 1325t

Ceforanide (Precef), 1325t

Cefotaxime (Claforan), 1325t
- for anaerobes, 1328t
- and biliary pseudolithiasis, 1375
- for CNS infections, 1373t
- for NEC, 2183
- for sepsis, 2186t
- for UTI, 1497t

Cefotetan (Cefotan), 1325t
- for anaerobes, 1328t
- for chorioamnionitis, 996
- for PID, 1512–1513t

Cefoxitin (Mefoxin), 1325t
- for chorioamnionitis, 996
- for PID, 1512–1513t
- for surgical procedures, 1345t
- for UTI, 1497t

Cefpodoxime proxetil (Vantin), 1325t
- for UTI, 1489t

Cefprozil (Cefzil), 1325t

Ceftaroline (Teflaro), 1325t, 1371, 1393
- for aerobic gram-positive cocci, 1326t
- for gram-negative aerobes, 1327t
- for skin and soft tissue infections, 1549
- for UTI, 1497t

Ceftazidime (Fortaz), 462, 661, 663, 671, 1325t
- for anaerobes, 1328t
- for CAPD-associated peritonitis, 1476t
- for cystic fibrosis, 461t
- dosing of, 1336t
- for febrile neutropenia, 1561
- for gram-negative aerobes, 1327t
- for gram-negative bacillary meningitis, 1378
- renal failure, dosing of drugs, 667–668
- for skin and soft tissue infections, 1550
- for UTI, 1497t

Ceftazidime-avibactam, 1327t

Ceftibuten (Cedax), 1325t

Ceftin (Cefuroxime axetil), 1325t
Ceftizoxime (Cefizox), 1325t
  for anaerobes, 1328t
  for CAPD-associated peritonitis, 1476t
Ceftolozane/tazobactam (Zerbaxa), 1325t, 1371, 1401
  for gram-negative aerobes, 1327t
Ceftriaxone (Rocephin), 549, 690, 1325t, 1371, 1376, 1401, 1720, 1723, 2131t
  and aminoglycoside, 1390
  for anorectal gonorrhea, 1511
  and biliary pseudolithiasis, 1375
  for CNS infections, 1373t
  for disseminated gonococcal infection, 1514
  dosing of, 1336t
  for endocarditis, 1390
  for neonatal DGI, 1514
  for skin and soft tissue infections, 1549
  for tularemia, 1723
  for typhoid fever, 1455
  for uncomplicated gonorrhea, 1508t, 1509
  for UTI, 1497t
Cefuroxime (Zinacef), 1325t, 2131t
  for aerobic gram-positive cocci, 1326t
  for gram-negative aerobes, 1327t
  for N. meningitides, 1374
  for UTI, 1497t
Cefuroxime axetil (Ceftin), 1325t, 1720
Cefzil (see Cefprozil)
Celecoxib, 55, 490, 707, 870–871, 870t, 887, 888t
Celexa (see Citalopram)
Central α_2-agonists, for hypertension, 140
Cephalexin (Keflex), 977, 1325t
  for chronic antimicrobial therapy, 1499t
  for pyelonephritis, 977
  for skin and soft tissue infections, 1547
  for UTI, 1489t
Cephalosporins, 662, 685–686, 1372, 1720, 1725
  adverse effects of, 1332t
  for cardiac surgery prophylaxis, 1391–1392
  for chorioamnionitis, 996
  for CNS infections, 1373t
  during pregnancy, 977
  for tularemia, 1725
  for uncomplicated gonorrhea, 1508t, 1509
  for UTI, 1497t
Cephalothin, 661, 662
Ceritinib, 470t
Certolizumab
  for CD, 529
  pegol, 524, 881, 882, 895, 896t
    for inflammatory bowel disease, 522t
Cerubidine (see Daunorubicin)
Cervarix, 1359
Cesamet (see Nabilone)
Cetilistat, 764
Cetirizine (Zyrtec), 433t

  for rhinitis, 437
  and sleep, 1766
Cetuximab (Erbitux), 469t, 1983t, 2064, 2065
  for colon cancer, 2073
Cevimeline, 1974
Chasteberry (Vitex agnus-castus or VAC), 1024
ChEIs (see Cholinesterase inhibitors (ChEIs))
Chemoprophylaxis, for OIs, 1598
Chemotherapy
  acneiform–erythematous rash, 1978
  for acute leukemia, 1997
  for acute myeloid leukemia, 1997
  for acute tubular obstruction, 1992
  for aggressive lymphomas, 2042
  in ALL, 2016, 2017t
  and alopecia, 1976–1977
  for AML, 2026
  and anemia, 1972
  for arrhythmias, 1990
  for autonomic neuropathy, 1987
  for B-cell lymphoma, 2020–2021
  on bone marrow, 1969–1973
  for cardiomyopathy, 1987–1988
  and cardiotoxicity, 1987–1990
  and colony-stimulating factors, 1970–1971
  and cranial nerve toxicity, 1987
  cytotoxic effects, 1970
  dermatologic impacts, 1973–1976
  and diarrhea, 1976
  dosage regimen for intrathecal, 2016t
  dosing in infants and young children, 2007
  and dry skin, 1978
  and esophagitis, 1975
  and esophagus, 1975
  and filgrastim, 1971, 1972
  and GI tract, 1973–1976
  and hand-foot syndrome, 1978
  hematologic effects, 1969–1973
  and hemorrhagic cystitis, 1992–1993
  for HL, 2041
  hypersensitivity reactions, 1980–1984
  and hypertension, 1990
  for indolent NHLs, 2044
  induction combination, 2014–2015
  interaction with radiation therapy, 1978–1979, 1978t

---

  intrathecal prophylaxis, 2015–2016
  irritant and vesicant reactions, 1979–1980
  for large cell lymphomas, 2021
  and life-threatening neutropenia, 1970
  long-term complications, 1997–1999

  for tachycardia, 1801

  for Tardive dyskinesia, 1801
Clozaril (see Clozapine)
Coal tar, 1626
  for psoriasis, 835t, 837
Cobicistat, 914t
Cobimetinib, 470t
Cocaine, 1177t
  CNS stimulants, 1882
  and lactation, 1003t
  for schizophrenia, 1783, 1783t
  teratogenic effects, 973t
Codeine, 59, 677 (see also Opioids)
Coenzyme Q, 304–305
Coenzyme Q10 (CoQ_{10}), 121
  for Parkinson's disease, 1265
Cogentin (see Benztropine)
Colazal (see Balsalazide)
Colchicine, 128, 913, 915
  drug interaction, 914t
Colesevelam, 127, 942t
  for type 2 diabetes, 1130–1131
Colestipol, 127
Colfosceril, 2170
Colistimethate, 463
  for cystic fibrosis, 461t
Colistin, 461t
Colloids, 358–359
Combination vaccines, 1356t
Combined androgen blockade (CAB), 2090
Compazine (see Prochlorperazine)
Conivaptan, 128, 914t
  for hyponatremia, 579
Conjugated equine estrogen (Premarin), 1033t
Conjugated estrogen, 1037
Conjugated pneumococcal vaccine (PCV), 1355
Contrave (see Naltrexone/Bupropion)
ConvaTec (see Silver sulfadiazine cream)
Corlanor (see Ivabradine)
Corlopam (see Fenoldopam)
Corticosteroids, 523, 712t, 713t, 721, 899–900, 928, 942t, 1372, 1627, 1639, 1652, 1995–1996
  for acne, 827
  for acute asthma, 392–393
  for acute gout, 913
  for adult meningitis, 1377
  for AECOPD, 1408
  for anaphylaxis, 687–688, 689t
  antibiotics with, 819
  for bacterial meningitis, 1372
  for brain abscess, 1382
  for cataracts, 1166–1167
  for chronic asthma, 395–397
  for CINV, 471
  for COPD, 417–418, 422–423
  Crohn's disease, 529
  during delivery, 989, 994

  for depressive disorders, 1815t
  for diabetes, 1146
  for drug-induced lupus, 692
  drug interaction with smoking, 1907t
  for FSGS patients, 628
  for hypercalcemia, 589t, 591
  hyperglycemia and, 1146
  for hyperthyroidism, 1059t
  and hypokalemia, 583t
  infection and, 1322
  for inflammatory bowel disease, 521t, 523
  for inflammatory response in CF, 459
  intra-articular, 900, 902–904
  for JIA, 902–904
  management of acute PJP, 1604
  for migraine headache, 1240
  for MS, 1222, 1228
  ophthalmic, 1165–1167, 1166t
  for ophthalmopathy, 1067
  for PMR and GCA, 925
  for PPROM, 994
  for psoriasis, 835t, 836–837
  for RA, 881, 883
  for rhinitis, 442
  for SARS, 1660
  for septic shock, 372–373
  for skin, 813–820, 814–815t, 817t
    adverse drug effects of, 816–818
    contraindications to, 813, 815
    indications for, 813
  for systemic lupus erythematosus, 708
  teratogenic effects, 973t
  therapy for LN, 626
  therapy for Wegener granulomatosis, 628
  tuberculous meningitis and, 1444
  ulcerative colitis, 525–526
Corticotropin, 913
Cosmegen (see Dactinomycin)
Cotrimoxazole, 1720
  for aerobic gram-positive cocci, 1326t
  for gram-negative aerobes, 1327t
COX-1 (see Cyclooxygenase-1 (COX-1))
COX-2 (see Cyclooxygenase-2 (COX-2))
Creatine, 1265
Crinone (see Progesterone vaginal gel)
Crizotinib, 128, 470t, 2006
Crofelemer, for infectious diarrhea, 1449
Cromolyn, 459
  for allergic rhinitis, 434
  for rhinitis, 438–439
Cromolyn sodium (Crolom; Nasalcrom), 439t, 440t
Cromolyn sodium ophthalmic, 1165
Crotamiton, 1705t
CRT (see Cardiac resynchronization therapy (CRT))
Crystalloids

composition and properties of, 353t
for hemorrhagic shock, 355
CSA (see Cyclosporine (CSA))
Cubicin (see Daptomycin)
Cyanocobalamin, 914t (see also Vitamin B_{12})
for pernicious anemia, 1935
CYC (see Cyclophosphamide (CYC))
Cyclobenzaprine, 1186t, 1194t
Cyclooxygenase-1 (COX-1), 490
Cyclooxygenase-2 (COX-2), 694, 870, 870t, 887, 888t, 889, 913
for systemic lupus erythematosus, 706–707
Cyclophosphamide (CYC), 469t, 470t, 626, 709, 712t, 713t, 917t, 924, 1971, 1977, 1979t, 1987, 1994t, 2004, 2005, 2018, 2037t, 2040t, 2042
for ALL, 2017t
for breast cancer, 2052, 2053
for CLL, 2033
and gonadal toxicity, 1997–1998
and hemorrhagic cystitis, 2021
neurotoxicity of, 1985t
for ophthalmopathy, 1067
for rhabdomyosarcoma, 2010–2011
for T-cell lymphomas, 2020t
teratogenic effects, 973t
therapy for Wegener granulomatosis, 627–628
Cycloserine, for tuberculosis, 1430t
Cyclosporine (CSA), 120t, 127, 214, 528, 928, 942t
for acute UC, 524
for inflammatory bowel disease, 521t
for kidney transplantation, 730–733, 737
for ophthalmopathy, 1067

---

in organ transplantation, 721–722, 725, 728
for psoriasis, 836t, 840–841
for RA, 883
therapy for LN, 626
CYP2D6 inhibitor, 1774, 1778
CYP3A4 inhibitor, 1743, 1746
and sleep, 1774
Cyproheptadine, for pruritus, 819
Cyproterone, for acne, 829
Cytarabine, 469t, 1985–1986, 1994t, 1996, 1997, 1998, 2018, 2021, 2026, 2028, 2031
adverse effects of, 2028
for aggressive lymphomas, 2043
for ALL, 2017t
for AML, 2025
gonadal toxicity of, 1998
neurotoxicity of, 1985t
for T-cell lymphomas, 2020t
Cytomegalovirus hyperimmune globulin, 743
Cytovene (see Ganciclovir)

D

D-penicillamine, 881
Dabigatran, 128, 187, 1307t
  for DVT, 189
  for stroke prevention, 178, 317
  for warfarin therapy, 200
Dabrafenib, 470t
Dacarbazine (DTIC), 469t, 1978–1979t, 1991t, 2040t
Daclatasvir, for HAV, 1688
Dacogen (see Decitabine (Dacogen))
Dactinomycin (Cosmegen), 469t, 1978–1979t
  hepatotoxicity of, 2007–2008
  for rhabdomyosarcoma, 2010, 2011
Dalbavancin (Dalvance), 1393
  adverse effects of, 1333t
  for aerobic gram-positive cocci, 1326t
Dalfampridine, 1223
Dalfopristin/Quinupristin (Synercid), 1325t
  adverse effects of, 1333t
Dalteparin, 177t, 188t, 189
  LMWH, 656
Dalvance (see Dalbavancin)
Danaparoid, in patients with HIT, 657
Danazol, 120t
  adverse effects, 1022
  for endometriosis, 1020
  for PMDD, 1027
Dantrolene, 1224
Dapagliflozin, 1129–1130
Dapsone, 1604
Daptacel, 1357
Daptomycin (Cubicin), 1326t, 1393
  adverse effects of, 1333t
  for aerobic gram-positive cocci, 1326t
  for CAPD-associated peritonitis, 1476t
  dosing of, 1337t
  for endocarditis, 1396
  enterococcal endocarditis and, 1399
  MRSA, 1550
  for skin and soft tissue infections, 1549
Darbepoetin alfa (Aranesp), 615–616
  for anemia, 1942
Darifenacin, 2251
Darunavir (DRV), 128, 942t, 1579t
Dasabuvir, for HAV, 1689
Dasatinib (Sprycel), 470t, 914t, 1989, 1990, 2031
Daunorubicin (Cerubidine), 469t, 1977, 1979t, 1981t, 1988, 2028
  for AML, 2025
  and hepatic dysfunction, 1996t
  for T-cell lymphomas, 2020t
dDAVP (see desmopressin)
ddl (see Didanosine (ddI))
Decadron (see Dexamethasone)
Decitabine (Dacogen), 469t
Decongestant

  for allergic rhinitis, 434, 434t
  for rhinitis, 437–438
DEET (see N,N-diethyl-m-toluamide (DEET))
Deferasirox, for vaso-occlusive complications, 1940, 1941
Deferoxamine (DFO)
  in iron toxicity, 73
  for vaso-occlusive complications, 1940, 1941
Defibrillator, role of, 300
Dehydroepiandrosterone sulfate (DHEAS), 826
DEKAs Plus chewable tablet, 457t
DEKAs Plus liquid, 457t
DEKAs Plus softgel capsules, 457t
Delavirdine (DLV), for HIV, 1580t
Δ-9-tetrahydrocannabinol (THC), 1885
Delzicol (see Mesalamine)
Demeclocycline, 579
Demerol (see Meperidine)
Denavir (see Penciclovir cream)
Denileukin diftitox, 469t
Denosumab, 2038, 2277t, 2284–2285
  androgen deprivation therapy, 2097
  for prostate cancer, 2096
Deoxycholate, for sepsis, 2186t
Depacon, 1299
Depo-Provera, 947–948
Depot medroxyprogesterone acetate (DMPA), 1021
Desferal, in iron toxicity, 73
Desiccated thyroid, 1048–1049
Desipramine (see also Antidepressants)
  for depressive disorders, 1819t, 1821t
Desloratadine (Clarinex), 433t
  for rhinitis, 437
Desmopressin (dDAVP), 647
Desogestrel, 936–938t, 945
Desvenlafaxine (Pristiq)
  for depressive disorders, 1819t, 1821t
  for diabetes, 2226t
  for serotonin, 1826
  for vasomotor symptoms, 1036t
Dexamethasone (Decadron), 472t, 475–476, 994, 1639, 2036, 2037t, 2038
  for ALL, 2017t
  for bacterial meningitis, 1372–1373
  for BPD, 2175
  for PCOS, 1013
  for PONV, 478t
  for prostate cancer, 2094
  for T-cell lymphomas, 2020t
Dexedrine (see Dextroamphetamine)
Dexlansoprazole, 483t, 1216t
  PPI, 484, 485
Dexmedetomidine, 1213–1214
  for pediatric intubation, 2200t
Dexmethylphenidate, for ADHD, 1867t
Dexrazoxane, 469t, 1980, 1981t, 1988–1989
Dextran component, 614

Dextroamphetamine (Dexedrine), 468t, 1778
Dextromethorphan, 1224, 1232
  dissociative drug, 1885
  quinidine combination, for agitated behaviors, 2243
Dextrorphan, 1885
Dextrose, 661, 663, 792
DFO (see Deferoxamine (DFO))
DHA (see Dicosohexanoic acid (DHA))
DHAP, for aggressive lymphomas, 2041–2042
DHEAS (see Dehydroepiandrosterone sulfate (DHEAS))
DHT (see Dihydrotestosterone (DHT))
Diazepam, 565, 988, 1186t, 1737t, 1742, 1746, 2131t
  for Akathisia, 1800t
  drug interaction with smoking, 1907t
  febrile seizures and, 1295
  PCP-induced seizures, 1885
  for pediatric intubation, 2199t
  in SE, 1299
  for Tardive dyskinesia, 1801
Dibenzoxazepine, 1789t
Dibenzoylmethanes, 849t, 852
Diclegis, 975
Diclofenac, 55, 870t, 871, 887, 888t, 1187t
Diclofenac gel, 869
Diclofenac patch, 869
Diclofenac topical solution, 869
Dicloxacillin, 645, 1325t
  for skin and soft tissue infections, 1547
Dicosohexanoic acid (DHA), 125–126
Dicyclomine (see Antispasmodics)
Didanosine (ddI), 918t
  for HIV, 1578t
  for HIV in labor, 996
  for HIV-related anemia, 1944
Dienogest, 938t
Diethylcarbamazine, for amebic liver abscess, 1704t
Diethylpropion, 762
Diethylstilbestrol, teratogenic effects, 973t
Dificid (see Fidaxomicin)
Diflucan (see Fluconazole)
Diflunisal, 870t
Digitalis (Digoxin), 128, 214, 484, 665, 914t, 2131t
  for AF, 312–313
  doses of, 291

---

  drug interactions, 293t
  effect on mortality, 290–291
  efficacy of, 290
  for HF, 268, 271

advantages of, 187
dosing for AF and VTE, 179t
drug interactions with, 179t
for management of PE, 191
pharmacokinetic and pharmacodynamics properties of, 178t
for stroke prevention, 194

  for VTE treatment, 194

Direct thrombin inhibitors
  for heparin-induced thrombocytopenia, 178
  injectable, 180t

Direct vasodilators, for hypertension, 140

Dirithromycin (Dynabac), 1325t

Diskus, for chronic asthma, 394, 396

Disopyramide
  for HF, 275
  for tachycardia, 1802

Disulfiram, alcohol withdrawal, 1897, 1898

Diuretics, 580
  acetazolamide, 581
  adverse effects of, 277–278
  and azotemia, 277
  and BNP, 278
  combination therapy of, 279
  for dysmenorrhea, 1015
  for HF, 270
  for hypertension, 140, 147–151
  and hyperuricemia, 278
  and hypokalemia, 150, 278
  hypomagnesemia and, 151, 278
  and hyponatremia, 151, 277–278, 581
  loop, 580
  and metabolic alkalosis/acidosis, 581
  monitoring parameters with, 280t
  for nephrotic edema, 574
  osmotic, 581
  for PMS, 1025
  potassium-sparing, 580–581
  thiazide, 580, 2261t

Divalproex, 1242, 1292, 1849t

Divigel (see Estradiol gel; Estradiol topical emulsion/gel/solution)

DLV (see Delavirdine (DLV))

DMARD, for RA, 891–899

DMPA (see Depot medroxyprogesterone acetate (DMPA))

DOACs (see Direct oral anticoagulants (DOACs))

Dobutamine, 212, 2207t, 2208
  in cardiac failure, 363–364, 363t
  for cardiogenic shock, 363–364
  for HF, 271, 298
  for septic shock, 371–372
  for tachycardia, 365

Docetaxel, 469t, 475, 1978t, 1981t, 1983t, 1990
  and hepatic dysfunction, 1996t
  for NSCLC, 2062t, 2064t
  peripheral nerve toxicity of, 1986
  for prostate cancer, 2094

Docosanol cream (Abreva), 1650

Dofetilide
  for AF, 316–317
  for SuVT, 325
  for tachycardia, 1802
  for WPW, 320

Dolasetron (Anzemet), 472t
  for PONV, 478t
Donepezil
  for Alzheimer's disease, 2238
  for vascular dementia, 2242
Dopamine, 641, 689t, 1224, 2207t, 2208
  for cardiac performance, 362–363, 363t
  for cardiogenic shock, 362–363
  GERD and, 503t
  for HF, 271, 298
  for hyperprolactinemia, 1802
  for mild hypotension, 363–364
  for NVP, 976t
  for septic shock, 371–372
  for Tardive dyskinesia, 1801
Dopamine agonists, 1252–1253, 1261–1262
  adverse effects of, 1255–1256
  dosage of, 1255
  for Parkinson's disease, 1253–1256
Doral (see Quazepam)
Doribax (see Doripenem)
Doripenem (Doribax), 1326t, 1371
  for skin and soft tissue infections, 1550
Dornase alfa, 458–459
Dorzolamide (Trusopt), 1152
Doxazosin, 157t, 2256, 2261t
  for BPH, 2256
  in patients with CKD, 617
Doxepin (Silenor)
  for depressive disorders, 1819t
  for pruritus, 819
  for treatment of insomnia, 1767t
Doxercalciferol, 622
Doxorubicin, 469t, 1977, 1978–1979t, 1978t, 1979, 1981t, 1983t, 1987–1988, 2003, 2005, 2040t, 2042
  for ALL, 2017t
  for breast cancer, 2052, 2053
  and cardiomyopathy, 1987–1988
  cardiotoxicity of, 2007
  gonadal toxicity of, 1998
  for HL, 2041
  for osteosarcoma, 2008
  for rhabdomyosarcoma, 2010, 2011
  for T-cell lymphomas, 2020t
Doxycycline, 927, 942t, 1325t, 1698t, 1720, 1723
  for cellulitis, 645
    for acne, 828, 829
    for COPD, 418
    dosing of, 1337t
    for lymphogranuloma venereum, 1515
    for malaria prophylaxis, 49
    for PID, 1512–1513t
    for skin and soft tissue infections, 1547, 1552
    in UTI, 1501
  for HGA, 1726
  for HME, 1726

for Lyme disease, 1720
for RMSF, 1725
for TBRF, 1723
for tularemia, 1724
Doxylamine, 1776
for NVP, 975, 976t

DPP-4 (see Dipeptidyl peptidase-4 inhibitors (DPP-4))
DPPC (see Dipalmitoylphosphatidylcholine (DPPC))
Dramamine (see Dimenhydrinate)
Dronabinol (Marinol), 472t, 1204
Dronedarone, 120t
for AF, 316–317
for HF, 275
Droperidol (Inapsine), 472t
for NVP, 976–977, 976t
for PONV, 478t
Drospirenone, 937t, 1011, 1012, 1025, 1027
DRV (see Darunavir (DRV))
DTaP (see Diphtheria, tetanus, and acellular pertussis (DTaP))
DTIC (see Dacarbazine (DTIC))
Dulaglutide, 1126–1127, 1139
Dulera (see Mometasone/formoterol)
Duloxetine, 1181t, 1188, 1194t, 1738t, 1754, 2252
for depressive disorders, 1819t, 1820t, 1821t
for diabetes, 1145, 2226t
for OA, 872–873
for serotonin, 1826
for stress incontinence, 2252
Duricef (see Cefadroxil)
Dutasteride, 2257–2258
for BPH, 2257–2258
for prostate cancer, 2099
Dyclonine hydrochloride, 1974
Dymista (see azelastine HCl/fluticasone propionate)
Dynabac (see Dirithromycin)

E

Ecamsule, 849t, 852
Echinacea, 1661
Echinocandins, 1569, 1625, 1629t, 1631, 1632, 1636, 1640, 1643
Echothiophate iodide, 1152–1153
Econazole, 1624t
Ecstasy (see 3,4-methylenedioxymethamphetamine)
Edluar, for treatment of insomnia, 1767t
Edoxaban, 1307t
for prevention of stroke, 178, 317–318
Efavirenz (EFV), 942t
for HIV, 1580t
for HIV in labor, 996
Effexor (see Venlafaxine)

Effexor XR (see Venlafaxine)
EFV (see Efavirenz (EFV))
EGFR inhibitors (see Epidermal growth factor receptor (EGFR) inhibitors)
Eicosopentanoic acid (EPA), 125–126
Elbasvir, for HAV, 1688, 1689
Eldepryl (see Selegiline)
Elestat (see Epinastine)
Elestrin (see Estradiol gel; Estradiol topical emulsion/gel/solution)
Eletriptan, 1238t, 1239
Ellence (see Epirubicin)
Elotuzumab, 469t
Eloxatin (see Oxaliplatin)
Elspar (see Asparaginase)
Eluxadoline (Viberzi), 536
Emadine (see Emedastine)
Emedastine (Emadine), 439t
Emend (see Aprepitant; Fosaprepitant)
Emollients, for psoriasis, 835t
Empagliflozin, 1129–1130
Empiric antibiotics, 661
Empiric antifungal therapy, 1641
Emtricitabine (FTC), 1679
  for HIV, 1577t
Enalaprilat (Vasotec IV), 171, 281–282, 281t, 335t, 2223
  for hypertension, 153t, 344
Encainide, and PVC, 323
Enfuvirtide (T-20) Fuzeon, for HIV, 1580t
Engerix-B, 1355
Enjuvia (see Synthetic conjugated estrogens)
Enoxaparin, 177t, 188t, 189, 251, 252, 677–678
  for ACS, 240t
  LMWH, 656
  and UFH, 254
Ensulizole, 849t
Entacapone, 1250t, 1251t, 1263–1264
  adverse effects of, 1264
  dose of, 1264
  pharmacologic and pharmacokinetic properties of, 1263t
Entecavir, 1680
  for HBV, 1678
Entocort EC, 523
Entresto (see Sacubitril/valsartan)
Enzalutamide, for prostate cancer, 2095
EPA (see Eicosopentanoic acid (EPA))
Epanova, 126
Ephedrine, in treatment of IDH, 657
Epidermal growth factor receptor (EGFR) inhibitors, 1978
Epinastine (Elestat), 439t
Epinephrine, 445, 446t, 2207t, 2208
  for anaphylaxis, 687–688, 689t
  for cardiogenic shock, 363t, 364
  for cardiopulmonary arrest, 330–331
  dose of, 330
  for septic shock, 371
EpiPen 2-Pak, 446t

EpiPen Jr 2-Pak, 446t
Epipodophyllotoxins, 1981t
Epirubicin (Ellence), 469t, 1978–1979t, 1988
  and hepatic dysfunction, 1996t
Eplerenone, 543
  for hypertension, 140, 157
  side effects of, 257
Epoetin alfa, 615
  for anemia, 1942
Epoprostenol, 924
Epoxy resin, 822t
Eprosartan mesylate, for hypertension, 154t
EPT therapy (see Estrogen/progestogen (EPT) therapy)
Eptifibatide, for ACS, 237
Erbitux (see Cetuximab)
Ergocalciferol, 621
Ergot alkaloids
  adverse effects of, 1239–1240
  for migraine headache, 1239
Ergotamine, and lactation, 1003t
Eribulin, 469t
Erlotinib (Tarceva), 470t, 2064–2066
  drug interaction with smoking, 1906t
Ertapenem (Invanz), 1326t
  dosing of, 1337t
  for gram-negative aerobes, 1327t
  for UTI, 1497t
Erythrocin (see Erythromycin)
Erythromycin, 120t, 128, 828, 830, 942t, 1325t, 1371, 2163, 2163t
  for acne, 828, 830
  adverse effects of, 1332t
  for aerobic gram-positive cocci, 1326t
  and breast milk, 1001
  for BV, 995
  for Campylobacter infection, 1459
  and dyspepsia, 487
  for GBS infection, 995
  for RMSF, 1725
  for skin and soft tissue infections, 1547
  for TBRF, 1722
Erythropoietic therapy, for anemia, 1942
Escitalopram (Lexapro), 1027t, 1036t, 1738, 1738t, 1748
  for depressive disorders, 1819t, 1820t, 1821t
  for diabetes, 2226t
  for panic disorder, 1748
  for PTSD, 1754
  for SAD, 1752
  for vasomotor symptoms, 1036t
ESHAP, for aggressive lymphomas, 2041–2042
Eslicarbazepine, 1279t, 1281
  for seizures, 1286t
Esmolol (Brevibloc), 335t
  for hypertension, 346
Esomeprazole, 228, 483t, 484, 485, 502, 1216t, 2163t
  for end-of-life care, 95

for preventing SRMB, 515t
Estazolam, 1737t, 1767t
Esterified estrogen (Menest), 1033t
Estrace (see Estradiol cream)
Estradiol acetate tablet (Femtrace), 1033t
Estradiol acetate vaginal ring (Femring), 1033t
Estradiol cream (Estrace), 1033t, 2218
Estradiol gel (Divigel; Elestrin; Estrogel), 1033t
Estradiol hemihydrate tablets (Vagifem and Vagifem LD), 1033t
Estradiol hemihydrate tablets (Vagifem), 1033t
Estradiol ring (Estring), 1033t
Estradiol topical emulsion/gel/solution (Divigel, Elestrin, Estrogel, Estrasorb, Evamist), 1033t
Estradiol transdermal system, 1033t
Estramustine, 470t

Estrasorb (see Estradiol topical emulsion/gel/solution)
Estring (see Estradiol ring)
Estrogel (see Estradiol gel; Estradiol topical emulsion/gel/solution)
Estrogen/progestogen (EPT) therapy, 1031–1032t, 1035t, 1037
  adverse effects of, 1035
Estrogens, 503t, 980, 2252–2253
  androgen deprivation therapy, 2097
  for stress incontinence, 2253
Estrostep, for acne, 829
Eszopiclone (Lunesta), 1767t, 1768–1770
Etanercept, 881, 895, 896t, 904
  for PsA, 842–843
Ethacrynic acid, 580
  for HF, 277
Ethambutol, 53
  dosing of, 1337t
  for MAC, 1619
  optic neuritis and, 1437–1438
  for tuberculosis, 1429t, 1433
Ethanol, 1891
  for diabetes, 1146
Ethinyl estradiol
  for endometriosis, 1019
  OC formulations, 1016
Ethionamide, for tuberculosis, 1430t
Ethosuximide, 1279t
  for absence seizures, 1290–1291, 1291t
Ethylenediamine, 822t
Ethynodiol diacetate, 936–937t
Etidronate, for hypercalcemia, 589t, 590
Etodolac, 870t, 888t
Etomidate, 2198
  for pediatric intubation, 2200t
Etoposide, 469t, 470t, 1978–1979t, 1981t, 1987, 1990, 1996t, 2003–2005, 2018, 2040t
  for aggressive lymphomas, 2042
  for blood progenitor cell rescue, 2005

  and hepatic dysfunction, 1996t
  hypotensive reactions of, 2005
  for NSCLC, 2062t
  peripheral nerve toxicity of, 1986
  for rhabdomyosarcoma, 2010, 2011
  for SCLC, 2068–2069, 2068t

Etoricoxib, 1044

Etravirine (ETV), for HIV, 1580t

Etretinate, teratogenic effects, 973t

Eucalyptus, 1721

Evamist (see Estradiol topical emulsion/gel/solution)

Everolimus, 120t, 128, 226, 470t, 722

Evolocumab, 129–131

Exenatide, for type 2 diabetes, 1126–1127, 1135, 1136–1138

Ezetimibe, 130, 1306
  adverse effects, 122
  clinical pearls, 122
  drug interactions, 122
  efficacy, 121–122
  mechanism of action, 121, 121f
  pharmacokinetics/pharmacodynamics, 122
  place in therapy, 122

Ezogabine, 1279t, 1281
  for seizures, 1285t

F

Factive (see Gemifloxacin)

Famciclovir (FCV), 1648t
  adverse effects, 1647t
  for genital herpes, 1529–1530, 1530t
  for herpes zoster infection, 1652
  pharmacokinetics of, 1653t

Famotidine, 977, 1216t, 2163t
  H_2RA, 483t, 484
  for preventing SRMB, 515t

Fampridine, 1224

Fanapt (see Iloperidone)

Fansidar (see Sulfadoxine)

Fat-soluble vitamins, 453
  for patients with CF, 457t

FCV (see Famciclovir (FCV))

Febuxostat, 916
  drug interactions, 918t

Felbamate, 942t, 1279t, 1281

Felodipine, for chronic stable angina pectoris, 214

Femring (see Estradiol acetate vaginal ring)

Femtrace (see Estradiol acetate tablet)

Fennel, for dysmenorrhea, 1015

Fenofibrate, 124, 124t, 918

Fenofibric acids, 124, 124t

Fenoldopam (Corlopam), 335t
  for BP, 341
  for hypertensive crisis, 342
  for hypertensive emergencies, 342

Fenoprofen, 870t, 888t

Fentanyl, 1178, 1187t
  dosage of, 1199t, 1201t
  for opioid withdrawal syndrome, 1880
  for pediatric intubation, 2199t
Feraheme (see Ferumoxytol)
Ferric carboxymaltose, for anemia, 1931
Ferric citrate, 620t
Ferric gluconate, for anemia, 1931, 1932, 1933
Ferritin, for anemia, 1930
Ferrous fumarate, for anemia, 1930
Ferrous gluconate, for anemia, 1930
Ferrous sulphate, 1261t
  for anemia, 1930
Ferumoxytol, 614, 696
  for anemia, 1931, 1932, 1933
Fesoterodine, 2251
Fexofenadine (Allegra), 128, 433t
  for rhinitis, 437
Fibric acid, 124t, 914t
  adverse effects, 124
  clinical pearls, 125
  drug interactions, 125
  efficacy, 123–124
  mechanism of action, 123, 123f
  pharmacokinetics/pharmacodynamics, 124
  place in therapy, 124–125
Fibrinolytic therapy, 191–192
Fibronectin, 991
Fidaxomicin (Dificid), 1325t
15-methyl prostaglandin F_2^{α}-tromethamine, 997–998
Finasteride, 2257
  for BPH, 2257
  for hirsutism, 1012–1013
  for prostate cancer, 2099
Fingolimod, 1222, 1228–1229, 1229t
5-α-reductase inhibitors, 2098
5-aminosalicylic acid (5-ASA), 520
  for Crohn’s disease, 529
5-flucytosine (5-FC), 1400, 1624
  amphotericin B and, 1400
5-fluorouracil, 469t, 1614
5-HT_3 antagonists, for CINV, 471, 472t
Flagyl (see Metronidazole)
Flecainide, 1906t
  for AF, 315
  for HF, 275
  and PVC, 323
  for WPW, 320
FlexPen, 1086
FlexTouch, 1086, 1087
Flonase Sensimist (see Fluticasone furoate)
Floxin (see Ofloxacin)
Floxuridine, 469t
Fluconazole (Diflucan), 120t, 128, 942t, 1614–1616, 1624, 1624t, 1625, 1626t

adverse effects of, 1334t
for CAPD-associated peritonitis, 1476t
for chronic pulmonary blastomycosis, 1637
CNS penetration of, 1640
cryptococcal disease, 1643
dosing of, 1337t
for fungal endocarditis, 1400
for fungal infection, 1479
for sepsis, 2186t
for VVC, 1525t, 1526

Flucytosine, 1614–1615, 1625
adverse effects of, 1334t, 1643
and creatinine clearance, 1643
cryptococcal disease, 1643
dosing of, 1337t
and GI distress, 1643
for OIs, 1598
renal excretion of, 1643
risk factor C, 1637

Fludarabine, 469t, 470t, 1985–1986, 1991t, 1995t
for CLL, 2033
encephalopathic toxicity of, 1985
neurotoxicity of, 1985t

Fludrocortisone, in treatment of IDH, 657

Flumadine (see Rimantadine)

Flumazenil, 1744, 1746
hepatic encephalopathy, 553
for pediatric intubation, 2200t

FluMist, 1361
influenza vaccine, 1657

Flunisolide, 441t
for allergic rhinitis, 442
for BPD, 2176

Fluorocytosine, 1624t

Fluorometholone acetate, 1166

Fluoropyrimidine, for colon cancer, 2073

Fluoroquinolones, 460, 484, 1371, 1549, 1720
and antacids, 41
for bacterial prostatitis, 1504
for Campylobacter infection, 1459
for CAP, 1413
for CAPD-associated peritonitis, 1475
for COPD, 424
for gonorrhea, 1509
for infectious diarrhea, 1449
for MAC, 1619
for nontyphoidal salmonellosis, 1453–1454
for skin and soft tissue infections, 1549
for surgical procedures, 1345t
for TB, 1431

  for UTI, 1491, 1493
  for UTI in pediatric patients, 1497

Fluorouracil, 1972, 1977, 1978, 1978t, 1990
  for adverse effects, 2076–2077, 2080
  and cerebellar dysfunction, 1985
  for colon cancer, 2073
  encephalopathic toxicity of, 1985
  and hepatic dysfunction, 1996t
  neurotoxicity of, 1985t

Fluoxetine (Prozac or Sarafem), 1027t, 1738, 1738t, 1748, 1778
  for bipolar depression, 1847
  for depression, 2245
  for depressive disorders, 1819t, 1820t, 1821t
  for diabetes, 2226t
  for OCD, 1760
  for panic disorder, 1748
  for PTSD, 1754
  for Raynaud's disease, 171
  and sleep, 1774
  for vasomotor symptoms, 1036t

Fluphenazine, 1789t, 1797t, 1799t
  decanoate, 1795t
  for schizophrenia, 1793t

Flurazepam, 1768
  and sleep, 1772
  for treatment of insomnia, 1767t

Flurbiprofen, 870t, 888t

Flutamide, for prostate cancer, 2093

Fluticasone
  for BPD, 2176
  for chronic asthma, 396–397
  for COPD, 420t, 422
  for rhinitis, 442

Fluticasone furoate (Flonase Sensimist), 441t
  for allergic rhinitis, 442
  for chronic asthma, 396

Fluticasone propionate (Dymista), 441t
  for allergic rhinitis, 442

Fluvastatin, 46t, 55, 110t, 116, 117t, 120t

Fluvoxamine (Luvox), 1027t, 1738t, 1748
  for depression, 2245
  for depressive disorders, 1820t
  for diabetes, 2226t
  dosage, 1758
  drug interaction with smoking, 1906t
  for OCD, 1760
  for PTSD, 1754

Fluvoxamine CR, for SAD, 1752

Fluzone High-Dose, 1361

Folate
  alcohol withdrawal, 1896
  for anemia, 1936

Folic acid, 958, 961
  and pregnancy, 968, 969, 979
  recommended daily allowance (RDA), 969

  and women, 969

Fomepizole, 562

Fondaparinux, 189, 252
  for ACS, 241t
  for DVT, 187
  in patients with HIT, 657
  UFH and LMWH and, 177–178, 177t

Formaldehyde, 822t

Formoterol
  for COPD, 421, 421t, 422
  for EIA, 400

Fortaz (see Ceftazidime)

Fosamprenavir (FPV), 128, 914t
  for HIV, 1579t

Fosaprepitant (Emend), 472t

Foscarnet (Foscavir), 742, 1613, 1649t, 1651
  adjunctive therapy, 1608t
  adjusted dosage, 1610t
  advantages, 1608t
  adverse effects of, 1334t, 1608t, 1612, 1647t
  CrCl, 1610t
  disadvantages, 1608t
  dosing regimens, 1608t, 1612
  for herpes labialis, 1651
  important drug interactions, 1608t
  intravitreal administration, 1613
  monitoring requirement, 1609t
  normal dosage, 1610t
  precautions and contraindications, 1609t
  to prevent nephrotoxicity, 1612

Foscavir (see Foscarnet), 1649t

Fosfomycin, for UTI, 1489, 1489t, 1491

Fosinopril, 281, 281t, 2223
  in hypertension, 153t

Fosphenytoin, 55, 942t, 1288
  in SE, 1299
  for seizures, 1284t

FPV (see Fosamprenavir (FPV))

FreAmine HBC, 794t

FreAmine III, 794t

Frovatriptan, 1237, 1238t, 1239

FTC (see Emtricitabine (FTC))

Furazolidone, for giardiasis, 1707

Furosemide, 543–544, 546, 580, 589–590, 1991–1993, 2223
  doses of, 277
  for HF, 276–277
  for hypercalcemia, 589t
  for hypertension, 148
  for nephrotic edema, 574
  for PDA, 2179, 2180
  urine osmolality and, 579

Fusidic acid, 914t

G

Gabapentin (Neurontin), 1180, 1181t, 1187t, 1189, 1194t, 1195, 1224, 1242, 1271t, 1272, 1279t, 1281,

1845
  androgen deprivation therapy, 2097
  for diabetes, 1145
  for PHN, 1654
  for seizures, 1284t
  for vasomotor symptoms, 1036t
Gabapentinoids, 1193
Gabitril (see Tiagabine)
Gadolinium-based contrast (GBC) agents, 643
Galantamine
  for Alzheimer's disease, 2239
  for vascular dementia, 2242
Gallium nitrate, for hypercalcemia, 589t, 590
Gamma-glutamyl transferase (GGT), 1894
γ-Hydroxybutyric acid (GHB), 1882
Ganciclovir (Cytovene), 742, 743, 744, 1613, 1649t
  adjunctive therapy, 1608t
  adjusted dosage, 1610t
  advantages, 1608t
  adverse effects of, 1334t, 1608t, 1647t
  for CMV disease, 1607
  CrCl, 1610t
  disadvantages, 1608t
  dose-limiting toxicity, 1607
  dosing of, 1337t
  dosing regimens, 1608t
  ganciclovir-induced bone marrow suppression, 1607
  for herpes simplex keratitis, 1168
  important drug interactions, 1608t
  induction dose of, 1607
  intraocular implants, 1608–1609, 1613
  intravitreal administration, 1613
  mode of administration, 1607
  monitoring requirement, 1609t
  normal dosage, 1610t
  precautions and contraindications, 1609t
Ganciclovir-foscarnet combination, for CMV retinitis, 1612
Garamycin (see Gentamicin)
Gardasil, 1359
GBC agents (see Gadolinium-based contrast (GBC) agents)
Gefitinib, 470t
Gelclair, 1975
Gemcitabine (Gemzar), 469t, 1978t, 1994t
  for NSCLC, 2062t, 2064t
Gemfibrozil, 120t, 123, 124, 124t, 125, 606
Gemifloxacin (Factive), 1326t
Gemzar (see Gemcitabine)
Genistein, 1030
Gentamicin (Garamycin), 658, 659, 665, 669, 670–671, 822, 1165, 1325t, 1724
  adverse effects of, 1332t
  for bacterial endocarditis, 644, 645
  for CAPD-associated peritonitis, 1476t
  for chorioamnionitis, 996
  for CNS infections, 1373t

- for cystic fibrosis, 461t
- dosing of, 1337t
- for enterococcal endocarditis, 1397t, 1398
- for gram-negative aerobes, 1327t
- for NEC, 2183
- nephrotoxic antibiotic, 644
- for UTI, 1497t
- vancomycin and, 1398

Gentian violet, 1626
Geodon (see Ziprasidone)
GGT (see Gamma-glutamyl transferase (GGT))
GHB (see γ-Hydroxybutyric acid (GHB))
Ginger, for NVP, 976t
Ginseng, 942t
Glargine, 980
Glatiramer acetate, 1222
- adverse effects of, 1225
- patient characteristics and other factors associated with reduced adherence to, 1226t
- patient counseling points for, 1226t

Gleevec (see Imatinib)
Glimepiride, 127, 1122, 1140
- for type 2 diabetes, 1122, 1136, 1137

Glipizide, 127
- for type 2 diabetes, 1122

GLP (see Glucagon-like peptide-1 agonists (GLP))
Glucagon, 689t, 1140
- for hypoglycemia, 1107

Glucagon-like peptide-1 agonists (GLP)
- adverse effects of, 1126–1127
- contraindications and precautions of, 1127
- dosage and clinical use, 1127
- drug interactions, 1127
- efficacy of, 1127
- mechanism of action, 1126
- pharmacokinetics of, 1126

Glucarpidase, 1992
Glucocorticoids
- antenatal administration, 994
- for fetal lung maturation, 986
- for NVP, 976t
- for prostate cancer, 2094

Glucomannan, 765t
Glucosamine, 867
Glucose, 585–586
- administration, 611
- for hyperkalemia, 587t
- hypokalemia and, 583t
- tablets for hypoglycemia, 1107

Glucosidase inhibitors
- adverse effects of, 1125
- contraindications and precautions of, 1125

  dosage and clinical use, 1126
  drug interactions, 1125
  efficacy of, 1126
  mechanism of action, 1125
  pharmacokinetics of, 1125
Glutamatem, 1224
Glutamine, 1986
Glutathione, 1986
Glyburide, 127, 678, 981, 1001
  for type 2 diabetes, 1122
Glycerol, 792
Glycoprotein IIb/IIIa inhibitors, 1312
  , for ACS, 241t, 256t
Glycopyrrolate
  for COPD, 420t
  for end-of-life care, 89
Glycyrrhetinic acid, 1975
Gold, 881, 883
Golimumab, 881, 882, 895, 896t
  for PsA, 842–843
Gonadotropin-releasing hormone (GnRH) agonists, 1019–1020, 1020t
  adverse effects, 1022
  for depressive disorders, 1815t
  for endometriosis, 1021–1022
Gonadotropin-releasing hormone (GnRH) analogs, for IVF, 962–964
Gonadotropin-releasing hormone (GnRH) therapy, for prostate cancer, 2084, 2090
Goserelin (Zoladex), 1020t, 1021
Granisetron (Kytril), 472t
  for PONV, 478t
Grastek, for allergic rhinitis, 435t
Grazoprevir, for HAV, 1688, 1689
Green tea, 765t
Griseofulvin, 942, 942t, 1624, 1624t, 1627
  risk factor C, 1637
Guanabenz, 159, 2261t
Guanfacine, 159, 2261t
  for ADHD, 1868t, 1870
Guarana, 765t

Ketamine, 1182, 1885, 2131t
  for pediatric intubation, 2200t
Ketek (see Telithromycin)
Ketoconazole, 120t, 128, 484, 485, 486, 942t, 1624t, 1625, 1633, 1637, 1639, 1640
  antifungal agent, 41, 2093
    adverse effects of, 1334t
  for chronic pulmonary blastomycosis, 1637
  CNS penetration of, 1640
Ketoprofen, 870t
Ketorolac (Acular), 439t, 870t, 887, 888t
Ketotifen, 439t, 1165
Kinrix, 1356t
KOH (see Potassium hydroxide (KOH))
Kyleena, 948
Kytril (see Granisetron)

L
Labetalol (Normodyne; Trandate), 335t, 336t, 985t, 986
  for BP, 339, 346
  disadvantages of, 343
  for hypertension, 158–159, 159t, 340, 343
  parenteral to oral conversion, 343
  for pregestational diabetes, 979
Lacosamide, 1181t, 1279t, 1281, 1285t
Lactogen, 980
Lactulose, 2159t
  hepatic encephalopathy, 553
  and neomycin, 553–554
  and rifaximin, 553
LAIV (see Live attenuated influenza vaccine)
Lamictal (see Lamotrigine)
Lamivudine, 1679, 1680
  for HBV, 1678
  for HIV, 1577t
    in labor, 996, 997
    -related anemia, 1944
Lamotrigine, 942t, 1181t, 1187t, 1191, 1279t, 1281, 1845, 1846–1847, 1849t
  for absence seizures, 1290–1291, 1291t
  and carbamazepine, 1286–1287
  for diabetes, 1145
  for schizophrenia, 1809
  for seizures, 1284t, 1286–1287
  teratogenic effects, 973t
Lansoprazole, 483t, 484, 485, 502, 515t, 871, 1216t, 2163t
Lanthanum, 620t
Lanthanum carbonate, 620–621
Lantus (see Insulin glargine)
Lapatinib, 128, 470t, 1990, 2057
L-asparaginase, 2020t
Lastacaft (see Alcaftadine)
Latanoprost (Xalatan), 1151
Latuda (see Lurasidone)
L-Carnitine, 169, 659, 961
Lecithin, for RDS, 2170

Ledipasvir, for HAV, 1688, 1689
Leflunomide, 708, 712t, 713t, 881, 882
  adverse effects, 893–894
  and cholestyramine, 894
  dosage, 893
Lenalidomide, 470t, 1972, 1991t, 2037t, 2038
  neurotoxicity of, 1985t
  peripheral nerve toxicity of, 1986
Lenvatinib, 470t
Lepirudin
  antithrombin product, 656
  for heparin-induced thrombocytopenia, 178
Letrozole (aromatase inhibitor), 960, 1012t, 1013
Leucovorin, 1992, 2009–2010
  for Toxoplasma encephalitis, 1605–1606
Leukeran (see Chlorambucil)
Leukotriene
  for EIA, 401
  modifiers, 459
    for allergic rhinitis, 433
    for asthma, 397
  modifying agent therapy
    for rhinitis, 442–443
  for rhinitis, 442–443
Leuprolide (Lupron), 1020t, 1021
  for prostate cancer, 2094
Levalbuterol, for COPD, 419, 420t
Levemir (see Insulin detemir)
Levetiracetam, 1279t, 1281, 1845
  for seizures, 1285t, 1287, 2192
Levobunolol (Betagan), 1151
Levocabastine, 1165
Levocetirizine (Xyzal), 433t
  for rhinitis, 437
Levodopa, 1250t
  and adjunctive therapy, 1259
  drug interactions, 1261t
  metabolism in human body, 1259f
  for Parkinson’s disease, 1252–1253, 1257–1258, 1261
  for RLS, 1269
Levofloxacin (Levoquin), 494t, 1326t
  for aerobic gram-positive cocci, 1326t
  for CAPD-associated peritonitis, 1476t
  for COPD, 424
  dosing of, 1337t
  for skin and soft tissue infections, 1550
  for travelers’ diarrhea, 1461t
  for tuberculosis, 1430t
  for UTI, 1488t, 1497t
Levomilnacipran
  for depressive disorders, 1819t, 1821t
  for serotonin, 1826
Levonorgestrel, 936–938t, 948, 951
Levonorgestrel intrauterine system (IUS), 1016
Levonorgestrel-releasing IUD (Mirena), 948, 1033t

Levoquin (see Levofloxacin)
Levosimendan, 267
Levothyroxine (L-thyroxine), 88, 127, 942t, 971, 974, 1039–1040, 1041t, 1049, 1056
Lexapro (see Escitalopram)
Lialda (see Mesalamine)
Lidocaine, 484, 1177t, 1187t, 1975, 2131t
  for cardiopulmonary arrest, 331
  patches (Lidoderm), 1182t, 1190, 1654
  topical, 1654
  for ventricular arrhythmias treatment, 248
Lidoderm (Lidocaine patches), 1654
Liletta, 948
Linaclotide (Linzess), 535
Linagliptin, 1127–1128
Lindane, 1705t, 1711
  toxicity, 1711
Linezolid (Tedizolid, Zyvox), 1325t, 1393
  adverse effects of, 1333t
  for aerobic gram-positive cocci, 1326t
  for CAPD-associated peritonitis, 1476t
  for CNS infections, 1373t
  dosing of, 1337t
  for endocarditis, 1396, 1399
  for HAP, 1418–1419
  MRSA, 1550
  for skin and soft tissue infections, 1549
  with vancomycin, 1564
Linzess (see Linaclotide)
Liotrix, 1049
Lipid-lowering agents, 258
Lipopeptides, 1625
Liquid multivitamin, 457
Liraglutide (Saxenda), 764, 1126–1127, 1139
Lisdexamfetamine, for ADHD, 1868t
Lisinopril, 41, 281–282, 281t, 2223
  in hypertension, 153t
  for prostate cancer, 2086, 2094
Lispro, 980
Lithium, 214, 579, 1837
  and ACE inhibitors, 1843t
  and acetazolamide, 1843t
  and acne, 1841t
  adverse effects, 1841–1842, 1841t
  and antipsychotics, 1843t
  for bipolar depression, 1846, 1848
  for bipolar disorder, 1849t
  and caffeine, 1843t
  and carbamazepine, 1843t
  for critically ill patients, 1208
  for depressive disorders, 1817
  and diltiazem, 1843t

  - and diuretics, 1843t
  - dosage, 1841
  - drug–drug interactions, 1843t
  - drug–food interactions, 1843
  - half-life of, 1841
  - and hypothyroidism, 1842–1843
  - and lactation, 1003t
  - and methyldopa, 1843t
  - monitoring of, 1840t
  - and NSAIDs, 1843t
  - patient education, 1842
  - during pregnancy, 1843–1844
  - prelithium workup, 1840
  - psoriasis and, 833
  - for schizophrenia, 1809
  - and sodium, 1843t
  - and SSRIs, 1843t
  - teratogenic effects, 973t
  - and theophylline, 1843t
  - toxicity, 1842
  - and verapamil, 1843t
  - weight gain with, 1843

Lithium carbonate, 1244

Lithium–lamotrigine, 1847

Live attenuated influenza vaccine (LAIV), 1361

Lixivaptan, 579–580

LMWHs (see Low-molecular-weight heparins (LMWHs))

Local anesthetics, 1187t
  - for neuropathic pain, 1188
  - for pain management, 1177t

Lodoxamide (Alomide), 439t, 1165

Lomitapide, 120t
  - adverse effects, 127–128
  - clinical pearls, 128
  - drug interactions, 128
  - efficacy, 127
  - mechanism of action, 127
  - pharmacokinetics/pharmacodynamics, 127
  - place in therapy, 127

Lomustine, 470t, 1991, 1991t

Loniten (see Minoxidil)

Loop diuretics, 580
  - and AIN, 645
    - dosing, 270t
    - for hypertension, 140, 148, 149t
    - and hypokalemia, 583t

Loperamide, 1976
  - antidiarrheals, 536
  - diarrhea and, 1458
  - for infectious diarrhea, 1449
  - for travelers’ diarrhea, 1460

Lopinavir/ritonavir, 120t, 128, 942t
  - for HIV, 1579t
  - for SARS, 1660

Lorabid (see Loracarbef)

Loracarbef (Lorabid), 1326t
Loratadine (Claritin), 433t
  for rhinitis, 437
  and sleep, 1766
Lorazepam (Ativan), 55, 472t, 988, 1737t
  for acute agitation, 1846
  for Akathisia, 1800t
  alcohol withdrawal, 1896
  for end-of-life care, 89
  for LTCF, 2229
  for pediatric intubation, 2199t
  for schizophrenia, 1793t
  in SE, 1299
Lorazepam IV, for seizures, 2192
Lorcaserin (Belviq), for obesity, 763–764
Losartan, 55, 171, 257, 284, 918, 923–924
Losartan potassium, 154t
Loteprednol (Alrex), 439t
Lovastatin, 46t, 110t, 116, 117t, 120t, 125
  for end-of-life care, 88
Lovaza, 126
Low-dose aspirin therapy, 144
Low-molecular-weight heparins (LMWHs), 176, 177t
  advantages of, 237
  with renal impairment, 188t
  for thrombosis, 177
  UFH and, 177t
Loxapine, 1789t, 1797t, 1799t
  for schizophrenia, 1785, 1788
LSD (see Lysergic acid diethylamide (LSD))
L-thyroxine (see Levothyroxine)
Lubiprostone, 535
Lugol's solution, 1058, 1059t, 1065
  for thyroid storm, 1067
Luliconazole, 914t
Lumacaftor, CFTR corrector, 452
Lumigan (see Bimatoprost)
Lumiracoxib, 870
Lunesta (see Eszopiclone)
Lupron (see Leuprolide)
Lurasidone (Latuda), 1797t, 1799t, 1847
  for bipolar depression, 1847t, 1849t
  for hyperprolactinemia, 1803
  for schizophrenia, 1790, 1791t
Luvox (see Fluvoxamine)
Lyrica (see Pregabalin)
Lysergic acid diethylamide (LSD), 1003t, 1885
  for schizophrenia, 1783, 1783t
Lytic peptides, 1626

M

Macrolides, 1549
  adverse effects of, 1332t
  for inflammatory response in CF, 459
  for MAC, 1619

for skin and soft tissue infections, 1549

Mafenide acetate (Sulfamylon), 863

Magnesium, 27, 621, 988, 1986–1987
  and aluminum antacids, 482, 484
  and children, 2140t
  for dysmenorrhea, 1015
  and induction therapy, 1612
  for normal sinus rhythm, 328
  for PMS, 1024
  and pregnancy, 968
  and respiratory alkalosis, 1672

Magnesium choline salicylate, 888t

Magnesium hydroxide, 620t, 2159t

Magnesium sulfate, 988, 992, 1710

Maintenance therapy, 1608–1609t, 1759, 1841, 2017–2018
  for AIDS, 1615
  for BD, 1848–1850
  for CMV, 1601, 1607, 1612–1613
  for GER, 2164
  for HBV, 1680
  for IA, 2125
  with intermittent ATRA, 2027
  for MM, 2038
  for neuroblastoma, 2004
  for NSCLC, 2063–2064
  for OCD, 1759
  for pediatric ALL, 2014, 2017–2018
  for tocolysis, 994
  for Toxoplasma encephalitis, 1605–1607

Malarone (see Atovaquone-proguanil)

Malathion, 1711

Mammalian target of rapamycin (mTOR), 722

Mandol (see Cefamandole)

Mannitol, 581, 1158, 1991

MAOIs (see Monoamine oxidase inhibitors (MAOIs))

Maraviroc (MVC), 128, 1582
  for HIV, 1580t

Marijuana, 1888
  and lactation, 1003t

Marinol (see Dronabinol)

Matulane (see Procarbazine)

Maxipime (see Cefepime)

MCV4 (see Meningococcal conjugate vaccine (MCV4))

MDMA (see 3,4-methylenedioxymethamphetamine (MDMA))

Measles, mumps, rubella (MMR) vaccine, 1353, 1362

Mebendazole
  for amebic liver abscess, 1704t
  for ascariasis, 1703t
  for enterobiasis, 1703t
  for gastrointestinal disease, 1704t

  for giardiasis, 1704t
  for hookworm, 1704t
  for pinworm, 1708
Mechlorethamine, 469t, 1979t, 1981t
  for HL, 2041
Meclizine (Bonine), 468t, 975, 976t
Meclofenamate, 870t
Medroxyprogesterone (Progestins)
  for endometriosis, 1021–1022
  for polycystic ovary syndrome, 1012t
Medroxyprogesterone acetate, 947–948, 1033t
Mefloquine, 49, 1696, 1698t, 1701
  for depressive disorders, 1815t
Mefoxin (see Cefoxitin)
Megestrol, 88
Melatonin, 1768, 1776
  for sleep, 1861
Meloxicam, 870t, 887, 888t
Melphalan, 469t, 470t, 1979t, 1987, 1991t, 1995t, 2004, 2037t
  for blood progenitor cell rescue, 2005
Memantine, 88
  for Alzheimer's disease, 2239
MEN 1 (see Multiple endocrine neoplasia type 1)
Menactra, 1359
Menest (see Esterified estrogen)
Meningitis, for sepsis, 2186t
Meningococcal conjugate vaccine (MCV4), 1368
Menthol, 1626
Menveo, 1359
Meperidine, 677, 677t (see also Opioids)
  dosage of, 1199t
Mepivacaine, 1177t
Meradimate, 849t
Mercaptobenzothiazole, 822t
Mercaptopurine, 470t, 918t, 1996, 1996t, 2017
  for ALL, 2017t
  dosage, 2017–2018
  for T-cell lymphomas, 2020t
Merem (see Meropenem)
Meropenem (Merem), 1326t
  for CAPD-associated peritonitis, 1476t
  for CNS infections, 1373t
  for cystic fibrosis, 461t
  dosing of, 1337t
  for febrile neutropenia, 1562
  for gram-negative bacillary meningitis, 1378
  for meningitis, 1378
  for skin and soft tissue infections, 1550
  for UTI, 1497t
Mesalamine (Apriso; Asacol HD; Delzicol; Lialda; Pentasa), 520, 521t, 523, 523t
Mesalamine enema (Rowasa), 523t
Mesalamine suppository (Canasa), 523t
Mescaline, 1885
Mesna, 709, 1992–1993
Metaxalone, 1186t

Metformin, 644, 678, 980, 1137t (see also Biguanide)
  adverse effects of, 1112
  clinical use of, 1113
  contraindications and precautions of, 1112–1113
  for diabetes, 167
  doses of, 1133
  drug interactions, 1113
  efficacy of, 1113
  mechanism of action, 1112–1113
  for PCOS, 1012
  pharmacokinetics of, 1112
  pharmacologic therapy with, 1132–1133
  therapy, 1133
Methadone, 90–91, 1187t, 1906t (see also Opioids)
  consensus recommendations for, 1203t
  dosage of, 1201–1203, 1202t
  for opioid dependence in pregnancy, 1880
  for opioid withdrawal syndrome, 1878, 1879
  toxicity
    monitoring, 1203
    signs and symptoms, 1203
Methamphetamine, 434
  for ADHD, 1868t
  CNS stimulants, 1884
Methicillin, 692, 1548
  for skin and soft tissue infections, 1548
Methicillin-resistant Staphylococcus aureus (MRSA), 1379
Methimazole (Tapazole), 1042, 1059t, 1062, 1064–1065
  for thyroid storm, 1067
Methocarbamol, 1186t
  for nocturnal leg cramps, 173
Methotrexate (MTX), 469t, 470t, 524, 628, 708, 712t, 713t, 881, 882, 884, 899, 901, 903, 904, 925, 928, 1978t, 1979, 1985–1986, 1991t, 1992, 1995–1996t, 1996, 2022
  adverse effects of, 892–893
  for ALL, 2017t
  cytotoxic effects of, 2009–2010
  dosage, 892, 2017–2018
  and folate or folinic acid, 893
  for inflammatory bowel disease, 521t, 754
  interactions, 893
  intrathecal, problems of, 2016
  and liver biopsy, 893
  neurotoxicity of, 1985t
  and NSAIDs, 892–893
  for ophthalmopathy, 1067
  for osteosarcoma, 2008–2009
  for psoriasis, 836t, 840
  and pulmonary disorders, 893
  for T-cell lymphomas, 2020t
  teratogenic effects, 973t
Methyldopa, 157t, 984, 985t, 1261t, 2261t
  for hypertension in pregnancy, 159
  in patients with CKD, 617
  for pregestational diabetes, 979
Methylergonovine maleate, 997, 997t

Methylphenidate, 1778
  for ADHD, 1867t
Methylprednisolone, 696, 721, 725, 728, 738, 925, 928
  injections, 626
  for NVP, 976t
Methyl salicylate, 1187t
Methylxanthines, for apnea, 2189
Metipranolol (Optipranolol), 1151
Metoclopramide (Reglan), 41, 472t, 1261t, 2163, 2163t
  for diabetes, 1145
  for NVP, 975, 976t
  for PONV, 478t
  prokinetic agents, 508
Metolazone, 270
Metoprolol, 220, 1062, 1272, 2261t
  in acute setting, 253
  in HFrEF, 287–288
  for MI, 253
Metoprolol succinate, 258
  in hypertension, 159t
Metoprolol tartrate, for hypertension, 159t, 253
Metronidazole, 493–494t, 496, 531, 942t, 1370, 1706, 2152
  adverse effects of, 1527

Mitomycin-C, 1981t
Mitotane, 470t
Mitoxantrone, 469t, 1222, 1979t, 1988
  adverse effects of, 1230–1231
  monitoring required for, 1231t
  for prostate cancer, 2095
MMF (see Mycophenolate mofetil (MMF))
MMR vaccine (see Measles, mumps, rubella (MMR) vaccine)
Modafinil, 942t, 1224, 1777–1779
  for ADHD, 1871
Moexipril, in hypertension, 153t
Molindone, for schizophrenia, 1785, 1788
Mometasone/formoterol (Dulera), 396, 816
Mometasone furoate (Nasonex), 441t
  for allergic rhinitis, 442
Monoamine oxidase-b inhibitors, 1261t
  adverse effects, 1257
  dosage of, 1257
  for Parkinson’s disease, 1253, 1256–1257, 1264
Monoamine oxidase inhibitors (MAOIs), 1748
  for anxiety disorders, 1748
  for panic disorder, 1748

- and sleep, 1774

Monobactams
- adverse effects of, 1332t
- for UTI, 1497t

Monocid (see Cefonicid)

Monoclonal antibodies, 1981, 1984
- alemtuzumab, 723
- basiliximab, 723

Montelukast (Singulair), 440t

MOPP, 2041

Moricizine, 323

Morphine, 677, 677t, 942t, 1178, 1187t, 2131t, 2198 (see also Opioids)
- for ACS, 241t
- dosage of, 1199t, 1202, 1202t
- for end-of-life care, 88–89
- for opioid dependence, 1881
- for pediatric intubation, 2199t

Morphine sulfate, 248

Moxifloxacin (Avelox), 1326t
- for aerobic gram-positive cocci, 1326t
- for anaerobes, 1328t
- for CNS infections, 1373t
- dosing of, 1337t
- for skin and soft tissue infections, 1549, 1552
- for tuberculosis, 1430t

MPA (see Mycophenolic acid (MPA))

MRSA (see Methicillin-resistant Staphylococcus aureus (MRSA))

mTOR (see Mammalian target of rapamycin (mTOR))

MTX (see Methotrexate (MTX))

Mucous membrane spray (Zolpimist), 1767t

Multiple endocrine neoplasia type 1 (MEN 1), 501

Multitargeted tyrosine kinase inhibitors, 1989–1990

Multivitamins, 88
- alcohol withdrawal, 1896

Mupirocin, 819

MVC (see Maraviroc (MVC))

Mycifradin (see Neomycin)

Mycophenolate mofetil (MMF), 626, 709, 712t, 713t, 928, 942t
- for FSGS patients, 629
- in liver transplantation, 738–739
- and mycophenolate sodium, 721
- therapy for Wegener granulomatosis, 628

Mycophenolic acid (MPA), 721

N

Nabilone (Cesamet), 472t, 1204

Nabumetone, 888t

NAC (see N-acetylcysteine (NAC))

N-acetyl-b-d-glucosaminidase, 461

N-acetylcysteine (NAC)
- for acetaminophen toxicity, 80–82
- antioxidant, 643
- duration of therapy of, 81
- efficacy of, 81
- intravenous, 80

  monitoring efficacy of, 81
  oral, 80–81
  in pregnancy, 80
  route of administration of, 80
  toxicity from, 81–82
N-acetyl glucosamine, 1990
N-acetyl-p-benzoquinone imine (NAPQI), 79
Nadolol, 1271t
Nadroparin, 1312
Nafarelin (Synarel), 1020t, 1021
Nafcillin (Oxacillin; Unipen), 1325t, 1349, 2131t
  for aerobic gram-positive cocci, 1326t
  for CAPD-associated peritonitis, 1476t
  for CNS infections, 1373t
  dosing of, 1337t
  for PVE, 1392t
  for sepsis, 2186t
  for skin and soft tissue infections, 1548
Naftifine, 1624t
Nalidixic acid, 1454
Naloxone, 1179
  for opioid toxicity, 74
  for opioid withdrawal syndrome, 1877, 1880
  for pediatric intubation, 2200t
Naltrexone, 1899–1900
  for developmental disorders, 1859
  for opioid withdrawal syndrome, 1880
Naltrexone/Bupropion (Contrave), 764
Naphazoline (Privine), 434t, 439t
Naphthyl, 822
NAPQI (see N-acetyl-p-benzoquinone imine (NAPQI))
Naproxen, 499, 870–871, 870t, 887, 888t, 1187t
  and AKI, 637
  for dysmenorrhea, 1015
  for JIA, 902
  sodium, 1015
Naratriptan, 1237, 1238t, 1239
Narcotics
  analgesics, 696
  GERD and, 503t
Nasacort AQ (see Triamcinolone acetonide)
Nasalcrom (cromolyn sodium), 440t
Nasonex (see Mometasone furoate)
Natalizumab, 524, 1222–1223
  adverse effect of, 529
  for inflammatory bowel disease, 522t
    adverse effects of, 1231
    recommendations for use of, 1231t
Nateglinide, 1116, 1141
  for type 2 diabetes, 1113
Navelbine (see Vinorelbine)
N-desalkylflurazepam, 1772

Nebcin (see Tobramycin)
Nebivolol, 158–159, 159t
Necitumumab, 469t
Nedocromil, 1165
Nedocromil (Alocril), 439t, 1165
Nefazodone (Serzone), 128, 1027t, 1828
  for depressive disorders, 1819t, 1820t, 1821t
Nelarabine, 469t, 1985–1986
  encephalopathic toxicity of, 1985
  neurotoxicity of, 1985t
Nelfinavir (NFV), 120t, 128, 942t, 1579t
Neomycin (Mycifradin), 819, 822, 822t, 1325t
  hepatic encephalopathy, 553
Neo-Synephrine (see Phenylephrine)
NephrAmine, 794t
Nephrotoxins, 631
Neptune krill oil, 1015
Nesiritide, 297–298
Netilmicin (Netromycin), 1325t
  adverse effects of, 1332t
Netromycin (see Netilmicin)
Netupitant (Akynzeo), 472t, 473, 474t, 476
Neupro (see Rotigotine)
Neuraminidase inhibitors, 1415
Neurokinin 1 receptor antagonists, 471–473
Neuroleptics, 1261t
Neurontin (see Gabapentin)
Neutralizing anti-EPO antibodies, 615
Neutral protamine Hagedorn (NPH), 1087
  insulin, 980
Nevirapine, 42, 942t
  for HIV, 1579t
Nexavar (see Sorafenib)
NFV (see Nelfinavir (NFV))
Niacin, 123, 1306
  for diabetes, 1146
Nicardipine (Cardene IV), 335t, 993
  for chronic stable angina pectoris, 214
  for hypertension, 345
  for postoperative hypertension, 344–345
Nickel sulfate, 822t
Nicotine
  cardiovascular effects of, 1904
  and heartburn, 977
  pharmacologic effects, 1904–1905
  replacement therapy, 1910, 1914, 1921
Nicotine gum, for smoking cessation, 1911–1913t
  adverse reactions, 1916
  disadvantages of, 1916
  dosage, 1915–1916
  patient education, 1916
Nicotine inhaler, for smoking cessation, 1911–1913t, 1918–1919
Nicotine lozenge, for smoking cessation, 1911–1913t

  adverse reactions, 1916
  disadvantages, 1916
  dosage, 1916
  patient education, 1916

Nicotine nasal spray, for smoking cessation, 1911–1913t
  advantages, 1918
  adverse reactions, 1918
  dosage, 1918
  patient education, 1918

Nicotine patch, for smoking cessation, 1911–1913t
  adverse reactions, 1915
  and dermatologic conditions, 1915
  disadvantages of, 1915
  dosage, 1915
  patient education, 1915

Nifazodone, 120t

Nifedipine, 214, 339, 923, 985t, 993, 2261t
  for Raynaud's disease, 171

Nikkomycins, 1626

Nilotinib, 128, 470t, 1990, 2031

Nilutamide, for prostate cancer, 2093

Nipent (see Pentostatin)

Nipride (see Nitroprusside)

Nitazoxanide, 1706
  for diarrhea by C. parvum, 1453
  for giardiasis, 1704t

Nitrates, 214
  for angina, 221
  for cardiac syndrome X, 229
  GERD and, 503t
  for HF, 271
  and hydralazine, 294
  oral, 294
  organic, 215t

Nitro-Bid IV (see Nitroglycerin)

Nitrofurantoin, 977, 1500
  adverse effects of, 1494
  for chronic antimicrobial therapy, 1499t
  for cystitis, 1489
  for UTI, 1489t

Nitroglycerin (NTG; Nitro-Bid IV; Nitro-Stat IV; Tridil), 335t, 2207t
  for ACS, 242t
  administration, 547
  for chest pain, 340
  CNS stimulants, 1883
  for hypertensive emergencies, 343–344
  for MI, 253

Nitroimidazoles, 1526

Nitropress (see Nitroprusside)

Nitroprusside (Nipride, Nitropress), 335–336t, 2207t
  cyanide toxicity from, 341–342
  doses of, 341
  hemodynamic effects of, 341
  for HTN and LV dysfunction, 297
  for hypertensive emergency, 340–341

  sodium, 341–342
  thiocyanate toxicity from, 342
Nitro-Stat IV (see Nitroglycerin)
Nivolumab, 469t, 2066
Nizatidine, 977, 1216t, 2163t
  H_2RA, 483t, 484
NMDA (see N-methyl-D-aspartate (NMDA))
N-methyl-D-aspartate (NMDA), 1781, 1885
  for Alzheimer's disease, 2238
N,N-diethyl-m-toluamide (DEET), 1701
  skin repellents (Repel Sportsmen), 1721
Non–angiotensin-converting enzyme inhibitor vasodilator therapy, 293–294
Non-aspirin NSAIDs, 491
Nondihydropyridines, 345, 605
Nonsteroidal antiinflammatory drugs (NSAIDs), 248, 460, 694, 1633, 1720, 2009
  for acute gout, 909, 913
  adverse effects, 1015–1016
  and AIN, 645
  common cold, 1661
  contraindications, 1016
  for critically ill patients, 1208
  for drug-induced lupus, 692
  for dysmenorrhea, 1014
  effects on kidney, 890–891
  for endometriosis, 1019
  GERD and, 503t
  and GI bleeding, 887
  induced anaphylaxis, 694
  for JIA, 901, 902, 904
  and methotrexate, 892–893
  for migraine headache, 1240, 1242
  for OA, 867, 870–872, 870t, 871f
  for PMS, 1025
  for postoperative pain management, 1180
  for psoriasis, 834, 842
  for RA, 881–882, 887–891
  and sodium content, 275
  for systemic lupus erythematosus, 706–707, 712t, 713t
  for tension-type headache, 1245
  teratogenic effects, 973t
  ulcers from, 489, 489t, 490–491, 490t
Norcuron (see Vecuronium)
Norepinephrine (NE), 265, 689t, 1733, 2207t, 2208
  for cardiogenic shock, 365
  for postoperative cardiac failure, 363t
  for SBP, 363–364
  for septic shock, 370–371
Norethindrone, 936–938t, 1021–1022
Norethindrone acetate, 1033t
Norfloxacin (Noroxin), 549, 1326t
  for chronic antimicrobial therapy, 1499t
  for UTI, 1489t
Norgestimate, 936–937t
Norgestrel, 936–937t
Normodyne (see Labetalol)

Noroxin (see Norfloxacin)
Nortriptyline, 1181t, 1187t, 1191 (see also Antidepressants)
  for depressive disorders, 1819t, 1821t
Novamine, 794t
Novantrone (see Mitoxantrone)
Novolin N, 1087
NovoLog (see Insulin aspart)
NPH (see Neutral protamine Hagedorn (NPH))
NSAIDS (see Nonsteroidal antiinflammatory drugs (NSAIDs))
NTG (see Nitroglycerin (NTG))
Nystatin, 1624, 1624t, 1626t, 1634

O
Obinutuzumab, 469t
Ocrelizumab, 1223
Octinoxate, 849t, 852
Octisalate (octyl salicylate), 849t, 852
Octocrylene, 849t, 852
Octreotide, 502, 549, 803
  administration, 555
  for variceal bleeding, 513
Ocular therapies, for rhinitis, 438
Ocupress (see Carteolol)
Ofatumumab, 469t
Ofloxacin (Floxin), 942t, 1326t
Olanzapine (Zyprexa), 472t, 474t, 475–476, 1267, 1739, 1797t, 1799t, 1837, 1849t
  for acute agitation, 1846
  for acute mania, 1844–1845, 1845t
  for anticholinergic, 1801
  for BD, 1997t
  for bipolar disorder, 1849t
  for CINV, 473
  drug interaction with smoking, 1906t
  for dyslipidemia, 1804
  for end-of-life care, 88
  for FGAs, 1803
  for hyperprolactinemia, 1803
  for OCD, 1757
  for schizophrenia, 1788, 1791t, 1792, 1793, 1793t
Olanzapine–fluoxetine, 1997t
  for bipolar depression, 1847t, 1849t
Olanzapine pamoate, 1795t
Olaparib, 470t
Olmesartan, 127, 154t
Olodaterol, 420t, 421, 422
Olopatadine, 439t, 440t, 1165
  for allergic rhinitis, 432
Olsalazine (Dipentum), 523t
  for inflammatory bowel disease, 521t
Omacetaxine, 469t
Omalizumab (Xolair)

for allergic rhinitis, 435
for asthma, 400
side effects of, 400
Ombitasvir, 1688
Omega-3 fatty acids
adverse effects, 126
for ASD, 1856
clinical pearls, 126
drug interactions, 126
for dysmenorrhea, 1015
efficacy, 126
mechanism of action, 125
pharmacokinetics/pharmacodynamics, 126
place in therapy, 126
Omeprazole, 228, 483t, 1216t, 2163t
PPI, 484, 485
for preventing SRMB, 515t
Omnaris (see Ciclesonide)
Omnicef (see Cefdinir)
Omnipen (see Ampicillin)
Omtryg, 126
Ondansetron
for NVP, 975, 976, 976t
for PONV, 478t
Ondansetron (Zofran), 472t
for NVP, 975, 976, 976t
ODT, for nausea and vomiting, 91–92
for PONV, 478t
Ophthalmic therapies, for allergic rhinitis, 434
Opiates, for osteoarthritis, 2228
Opioids, 1182t, 1196t
associated with hepatic encephalopathy, 552
for breakthrough pain management, 1201
chronic, assessment of, 1196
in critically ill patients, 1211, 1212t
discontinuing, 1196–1197
for neuropathic pain, 1188
for OA, 872
risk addiction of, 1195–1196, 1195t
risk management of, 1194
side effect management, 1203, 1203t
Oprelvekin, 1972
Optipranolol (see Metipranolol)
Optivar (see Azelastine)
OPV (see Oral polio vaccine (OPV))
Oralair, for allergic rhinitis, 435t
Oral analgesics, for burn injuries, 863
Oral anticoagulation, 195t
Oral azithromycin, 463
Oral bisphosphonates, 454
Oral contraceptives
for IVF, 961–962
for migraine headache, 1237
Oral corticosteroids, 526
Oral electrolyte solutions, 2161t

Oral fluoroquinolones, 464
Oral iron preparations, 613t
Oral norfloxacin, 549
Oral polio vaccine (OPV), 1358
Orbactiv (see Oritavancin)
Oritavancin (Orbactiv)
  adverse effects of, 1333t
  for aerobic gram-positive cocci, 1326t
Orlistat (Xenical, Alli), 762–763
Orphenadrine citrate, 1186t
Ortho Tri-Cyclen, 829, 830, 1923
Oseltamivir (Tamiflu), 1649t
  adverse effects of, 1647t
  for influenza, 1415t, 1656
  pharmacokinetics of, 1653t
Osmotic diuretics, 581
Ospemifene (Osphena), 1037
Osphena (see Ospemifene)
OTC products (see Over-the-counter (OTC) products)
Over-the-counter (OTC) products, 40
  antisecretory drugs, 488
Oxacillin (see Nafcillin)
Oxaliplatin, 469t, 1978–1979t, 1981t, 1996
  for adverse effects, 2076–2077, 2080
  for colon cancer, 2073
  neurotoxicity of, 1986–1987
  peripheral nerve toxicity of, 1986–1987
  and peripheral neuropathies, 1986–1987
Oxaprozin, 888t
Oxazepam, 1737t, 1746
Oxazolidinone, 1399
Oxcarbazepine, 942t, 1181t, 1187t, 1279t, 1281
  for acute mania, 1845
  for diabetes, 1145
  for seizures, 1285t, 1286
Oxiconazole, 1624t
Oxybenzone, 849t, 852
Oxybutynin chloride, 2251
Oxycodone, 499, 1187t
  dosage of, 1199t
Oxygen therapy, 689t, 1244, 1659
Oxymetazoline (Afrin), 434t
Oxyquinolines, 1626
Oxytocin, 988–989
  administration of, 990
  adverse effects, 990–991
  dosage, 990
  and lactation, 999
  mechanism of action, 990
  for postpartum hemorrhage, 997, 997t
  and uterine activity, 990

P

PAAFs (see Pediatric amino acid formulations (PAAFs))
PABA (see Para-aminobenzoic acid (PABA))

Paclitaxel (Taxol), 226, 469t, 942t, 1978–1979t, 1981t, 1982t, 1987, 1990
  for breast cancer, 2053
  neurotoxicity of, 1985t
  for NSCLC, 2062t, 2063t, 2064t
  peripheral nerve toxicity of, 1986
Padimate O, 849t, 852

  in oral electrolyte solutions, 2161t
  for pernicious anemia, 1935
  and renal dysfunction, 1991
  and respiratory alkalosis, 1672
  and TLS, 2027
  in WHO formula, 2160
Potassium bicarbonate, 1916
Potassium chloride, 584

  for metabolic alkalosis, 564
Potassium dichromate, 822t
Potassium hydroxide (KOH), 1626
Potassium iodide, 1624t
Potassium-sparing diuretics, 148, 150

Potassium supplementation
  doses of, 279
  for HF, 278–279
Povidone iodine, 1624t
PPIs (see Proton-pump inhibitors (PPIs))
Pralatrexate, 469t
Pramipexole, 1193, 1250t, 1254, 1254t, 1267, 1269
Pramlintide, 1129
Prasugrel, 244, 246–247t
  and aspirin, for ACS, 242t
Pravastatin, 41, 46t, 110t, 116, 120t, 125
Praziquantel, 1705t, 1710
  for flukes, 1704t
  side effects of, 1710
Prazosin, 157t, 923, 2261t
  in patients with CKD, 617
  for PTSD, 1754
  for Raynaud's disease, 171
Precef (see Ceforanide)
Prednisolone, 721, 925, 1654
Prednisolone acetate, 1165–1166
Prednisone, 721–722, 925, 2037t, 2040t, 2042
  for AECOPD, 1409
  for ALL, 2017t
  for COPD, 424
  cryptococcal disease, 1641
  for drug eruptions, 821, 823
  for HL, 2041
  for hypercalcemia, 591
  for ophthalmopathy, 1066–1067
  for prostate cancer, 2094
  for radiographic opacities and hypoxemia, 326
  for rhinitis, 442
  for T-cell lymphomas, 2020t
Pregabalin (Lyrica), 1180, 1181t, 1187t, 1194t, 1195, 1271t, 1272, 1279t, 1281
  androgen deprivation therapy, 2097
  for diabetes, 1145
  for PHN, 1654
  for SAD, 1752
  for seizures, 1284t, 1286
  for vasomotor symptoms, 1036t
Premarin (see Conjugated equine estrogen)
Premphase, 1033t
Prempro, 1033t
Prevnar, 1360

Prilocaine, 1177t
Primaquine, 1696, 1699t
Primaxin (see Imipenem-cilastatin)
Primidone, 942t, 1271t, 1272
Pristiq (see Desvenlafaxine)
Privine (see Naphazoline)
PRL (see Prolactin (PRL))
Probenecid, 43, 917
Probiotics
  for CDAD, 1466
  for gastroenteritis, 2161
  for infectious diarrhea, 1449
Procainamide, 325
  for tachycardia, 1802
  for WPW, 320
Procaine, 1177t
Procarbazine (Matulane), 470t, 1982t, 1985, 1998
  encephalopathic toxicity of, 1985
  for HL, 2041
  neurotoxicity of, 1985t
Prochieve (see Progesterone vaginal gel)
Prochlorperazine (Compazine), 472t, 1240
  for end-of-life care, 89
  for NVP, 975, 976t
  for PONV, 478t
Procyclidine, 1800t
Proferrin-ES, heme iron product, 613
Progesterone, 965, 980
  in assisted reproductive technology, 965t
  GERD and, 503t
  vaginal suppository, 1033t
Progesterone vaginal gel (Prochieve, Crinone), 1033t
Progestin-bisphosphonate, 1022
Progestins (Medroxyprogesterone)
  for endometriosis, 1019
  for polycystic ovary syndrome, 1012t
Prokinetic agents, 508
  for GER, 2163, 2163t
Prolactin (PRL), 980, 999
Promethazine (Phenergan), 91, 468t, 472t
  for NVP, 975, 976t
  for PONV, 478t
Prometrium (see Micronized progesterone)
Propafenone, 315
  for WPW, 320
Propionic acid, 1626
Propofol, 1213
  for pediatric intubation, 2200t
Propranolol, 550, 1241, 1271–1272, 1271t, 2131t, 2261t
  for Akathisia, 1799, 1800t
  drug interaction with smoking, 1906t
  in hypertension, 159t
  for hyperthyroidism, 1059t
  for MI, 253
  for PTSD, 1754

- **Proprotein convertase subtilisin/kexin type 9 (PCSK9)**
  - adverse effects of, 131
  - clinical pearls, 131
  - efficacy, 129–130
  - mechanism of action, 129, 130f
  - pharmacokinetics/pharmacodynamics of, 130–131

SERMs (see Selective estrogen receptor modulators (SERMs))
Seroquel (see Quetiapine)

Serotonin, 1224
  androgen deprivation therapy, 2097
Serotonin and norepinephrine reuptake inhibitors (SNRIs), 1748
  androgen deprivation therapy, 2097
  for critically ill patients, 1208
  for hot flushes, 1036
  for stress incontinence, 2252
Serotonin (5-HT) receptors
  LSD, 1886
Sertraline (Zoloft), 1027t, 1738t, 1748, 1749
  for depression, 2245
  for depressive disorders, 1819t, 1820t, 1821t
  for diabetes, 2226t
  for OCD, 1760
  for panic disorder, 1748
  for prostate cancer, 2086
  for SAD, 1752
  and sleep, 1774
  in treatment of IDH, 657
  for vasomotor symptoms, 1036t
Serum aminoglycoside, 461–462
Serum immunoglobulin E antibodies, 455–456
Serum precipitins, 455–456
Serzone (see Nefazodone)
Sevelamer, 619–620
  carbonate, 620t
  hydrochloride, 620t
17-α hydroxyprogesterone (17-OHP), 995–996
Sildenafil, 924, 2265
  and ED, 2265
Silenor (see Doxepin)
Silodosin, 2257
  for BPH, 2257
Siltuximab, 469t
Silvadene (see Silver sulfadiazine cream)
Silver sulfadiazine cream (Silvadene; Aquacel Ag; ConvaTec), 863
Simeprevir, 1687–1688
Simvastatin, 46t, 55, 57, 57t, 110t, 116, 117, 117t, 120t, 125, 258
Sinecatechins, 1532
Sinemet CR (see Carbidopa–Levodopa (CR))
Singulair (see Montelukast)
Sipuleucel-T, 2095
Sirolimus, 120t, 128, 226, 722
Sitagliptin, 128, 1127–1128
  for type 2 diabetes, 1135, 1139
Sivestro (see Tedizolid)
6-mercaptopurine (6-MP)
  for Crohn’s disease, 529–531
  for inflammatory bowel disease, 521t, 523–524
  for T-cell lymphomas, 2020t
Skyla, 948
SMX (see Sulfamethoxazole (SMX))
SNRIs (see Serotonin and norepinephrine reuptake inhibitors (SNRIs))
Sodium
  and children, 2140t

- loss due to diarrhea, 2142
- in oral electrolyte solutions, 2161t
- and respiratory alkalosis, 1672
- in WHO formula, 2160

Sodium bicarbonate, 643, 977
- adverse effects of, 361
- -carbonic acid system, 611
- hyperkalemia and, 586, 587t
- in metabolic acidosis, 562–563
- for preventing SRMB, 515t
- for salicylate toxicity, 70
- for TCA toxicity, 77–78

Sodium carbonate, 1916

Sodium ferric gluconate complex, 614

Sodium–glucose transporter 2 (SGLT2) inhibitors
- adverse effects of, 1130
- contraindications and precautions of, 1130
- for diabetes, 2225
- dosage and clinical use, 1130
- drug interactions, 1130
- efficacy of, 1130
- pharmacokinetics of, 1129–1130

Sodium oxybate, 1778–1779

Sodium polystyrene sulfonate (SPS), 586
- for hyperkalemia, 587t
- side effects, 586

Sodium stibogluconate, 1705t

Sodium thiosulfate, 1624t

Sodium zirconium cyclosilicate, for hyperkalemia, 586

Sofosbuvir, 1688–1689

Solifenacin, 2251–2252

Somatostatin
- analogues, 502
- for variceal bleeding, 513

Sonata (see Zaleplon)

Sonidegib, 470t

Sorafenib (Nexavar), 470t, 1990

Sorbitol, 67, 2156t

Sordarins, 1626

Sotalol
- for AF, 316–317
- and QTc, 327
- for tachycardia, 1802

Spectinomycin, 1508

Spectracef (see Cefditoren)

Spectrobid (see Bacampicillin)

Spiriva Respimat, for asthma, 399

Spironolactone (Antiandrogen), 543, 546, 580–581, 2261t
- for acne, 829
- for hirsutism, 1012
- for hypertension, 140, 157
- for polycystic ovary syndrome, 1012t

Sprycel (see Dasatinib)

SPS (see Sodium polystyrene sulfonate (SPS))

SQV (see Saquinavir)

SSRIs (see Selective serotonin reuptake inhibitors (SSRIs))
SSZ (see Sulfasalazine (SSZ))
Starch, 1627
Statins, 373
Stavudine (d4T), for HIV, 996, 1577t
Steroids
  for septic shock, 372
Stiripentol, 914t
St. John's-wort, 42, 942t
  for depression, 44
Streptogramin, 1399

Streptokinase, 250
Streptomycin, 1325t, 1724
  teratogenic effects, 973t
  for tuberculosis, 1430t, 1433
Streptozocin, 469t, 1979t, 1996t
Succinylcholine, 2200t
Sucralfate, 483t, 1216t, 2163t
  for gastric mucosal protection, 486
  for mild cases of GERD, 508–509
  in preventing SRMB, 514, 515t
Sucroferric oxyhydroxide, 620t
Sudafed (see Pseudoephedrine)
Sudafed PE (see Phenylephrine)
Sulconazole, 1624t
Sulfadiazine, 1326t
  for Toxoplasma encephalitis, 1606
Sulfadoxine (Fansidar), 1326t
Sulfamethoxazole (SMX), 204, 1370
  for chronic antimicrobial therapy, 1499t
  for cystic fibrosis, 461t
  for UTI, 1489t
Sulfamylon (see Mafenide acetate)
Sulfapyridine, 520
Sulfasalazine (Azulfidine; SSZ), 521t, 523t, 881, 882, 884, 892, 894
  for inflammatory bowel disease, 754
  for ulcerative colitis, 526
Sulfonamides, 2131t
  and AIN, 645
    adverse effects of, 1333t
    for RMSF, 1725
Sulfonylurea, 55, 1117–1123
  adverse effects of, 1122–1123
  contraindications and precautions of, 1123
  for diabetes, 167
  dosage and clinical use of, 1123
  drug interactions of, 1123
  efficacy of, 1123
  mechanism of action, 1122
  pharmacokinetics of, 1122

Sulindac, 637, 870t, 888t
Sulisobenzone, 849t
Sumatriptan, 1237–1238, 1238t, 1240, 1243–1244
  adverse effects of, 1238
  drug interactions of, 1238
Sunitinib, 470t, 1977, 1990
  and hypertension, 1990
Sunscreen, 827, 830, 831
Suppressive therapy, 1601
  2002 USPHS/IDSA guidelines, 1601
  for Toxoplasma encephalitis, 1606
Suprax (see Cefixime)
Surface-active agents
  for GER, 2163–2164, 2163t
Sutent (see Sunitinib)
Suvorexant (Belsomra), 1767t, 1770
Symbicort (see Budesonide/formoterol)
Symmetrel (see Amantadine)
Synarel (see Nafarelin)
Synthetic conjugated estrogens (Enjuvia), 1033t
Systemic agents, 1624t
  antifungals, 1629t
Systemic antihistamines, 819

T
Tabloid (see Thioguanine)
Tacrine, 942t
  drug interaction with smoking, 1906t
Tacrolimus, 120t, 721–722, 819, 820, 942t
  in liver transplantation, 736–737
Tadalafil, 2265
  for BPH, 2257
  and ED, 2265
Tafluprost (Zioptan), 1151, 1152
Talc, 1627
Talinolol, 128
Tamiflu (see Oseltamivir)
Tamoxifen, 1972
Tamsulosin, 2256
  for BPH, 2256
Tannic acid, 1626
Tanning pills, 856
Tapazole (see Methimazole)
Tarceva (see Erlotinib)
Tasigna (see Nilotinib)
Tasimelteon, 1906t
Tasmar (see Tolcapone)
Tauroursodeoxycholic acid, 765
Tavist (see Clemastine)
Taxanes, 1981t
  for prostate cancer, 2094
Taxol (see Paclitaxel)
Tazarotene, 827, 829, 858
  for psoriasis, 835t, 838
Tazobactam, 491t

for cystic fibrosis, 461t

TDF (see Tenofovir Disoproxil Fumarate (TDF))

Tedizolid (Sivestro), 1325t
  adverse effects of, 1333t
  for aerobic gram-positive cocci, 1326t

Teflaro (see Ceftaroline)

Tegaserod, 534

Telaprevir, 120t, 128, 914t, 1686
  for HAV, 1687

Telavancin (Vibativ), 1326t, 1393, 1419
  adverse effects of, 1333t
  for skin and soft tissue infections, 1549

Telbivudine, 1680

Televancin, 1326t

Telithromycin, 120t, 128
  adverse effects of, 1333t

Telithromycin (Ketek), 1325t

Telmisartan, 154t

Temazepam (Restoril), 1737t, 1768, 1772–1773
  for LTCF, 2229
  and sleep, 1774
  for treatment of insomnia, 1767t

Temodar (see Temozolamide)

Temozolamide (Temodar), 469t

Temozolomide, 470t

Temsirolimus, 469t, 1990

Tenecteplase (TNK), 237

Teniposide, 1979t

Tenofovir, 673

Tenofovir alafenamide, 1678, 1679–1680

Tenofovir Disoproxil Fumarate (TDF), 1577t

Tenofovir disoproxil fumarate, 1678, 1679

Terazosin, 157t, 2256, 2261t
  for BPH, 2256
  in patients with CKD, 617

Terbinafine, 1624t, 1628

Terconazole, 1525t, 1624t

Teriflunomide, 1223, 1230

Teriparatide, 2277t, 2286

Terlipressin, 547–548, 554–555

Tesofensine, 765

Tetracaine, 1177t

Tetracycline, 493–494t, 1325t
  GERD and, 503t

Tetracyclines, 484, 496–497, 828, 830, 942t, 1720
  adverse effects of, 1333t
  and dyspepsia, 487
  for osteoporosis, 2274
  for RMSF, 1725
  for TBRF, 1725
  teratogenic effects, 973t
  for tularemia, 1725

TGC (see Third-generation cephalosporin (TGC))

Thalidomide, 470t, 1972, 2037t
  peripheral nerve toxicity of, 1986

teratogenic effects, 973t
Thalomid (see Thalidomide)
Theophylline, 484, 485, 486, 487, 917t, 918t, 942t, 2131t
for apnea, 2189
for asthma, 393
for chronic asthma, 397–399
for COPD, 424
doses of, 397–398, 398t
drug interactions, 398–399
drug interaction with smoking, 1906t
and dyspepsia, 487
factors affecting, 399t
GERD and, 503t
and lithium, 1843t
toxicity of, 398
Thiamine, alcohol withdrawal, 1896
Thiazide diuretics, 580, 609, 891, 917t
for BPD, 2174
for hypertension, 140
and hypokalemia, 583t
for vascular dementia, 2242
Thiazide-like diuretics, and AIN, 645
Thiazides, 270
for hypertension, 147–148, 148–149t
Thiazolidinediones
adverse effects of, 1124
contraindications and precautions of, 1124
dosage and clinical use, 1125
drug interactions, 1124–1125
efficacy of, 1125
mechanism of action, 1123
pharmacokinetics of, 1124
Thioamides, 1042, 1057, 1065
administration of, 1060–1061
adverse effects, 1062
and agranulocytosis, 1062–1063
disadvantages of, 1058
dosage, 1060–1061
duration of, 1061

---

and granulocytopenia, 1062–1063
and hepatitis, 1062
monitoring of, 1061
precautions, 1061
rashes from, 1062
remission rates with, 1063
Thioguanine (Tabloid), 470t, 1978t
for T-cell lymphomas, 2020t
Thiomersal, 822t
Thiopental, 1672, 2198
Thiopurine, 56, 56t, 917t

Thioridazine, 1789t, 1797t, 1799t
  for schizophrenia, 1788
Thiotepa, 469t, 2004
  neurotoxicity of, 1985t
Thiothixene, 1789t, 1797t, 1799t
Thioxanthene, 1789t
Thiram, 822t
Third-generation cephalosporin (TGC)
  for aerobic gram-positive cocci, 1326t
  for gram-negative aerobes, 1327t
3-hydroxy-3-methyl-glutaryl coenzyme A inhibitors
  adverse effects, 116–118
  clinical pearls, 120–121
  diabetes, 118–119
  drug interactions, 119–120
  efficacy, 115–116
  mechanism of action, 115
  pharmacokinetics/pharmacodynamics, 116
  place in therapy, 119
  reaction catalyzed by, 116f
3,4-methylenedioxymethamphetamine (MDMA; Ecstasy), 1885
3tC (see Lamivudine)
Thymoglobulin and antithymocyte globulin, 725–726
Thymol, 1626
Thyrotropin-α, 1069
Tiagabine, 1279t, 1281, 1845
  for seizures, 1285t, 1286
Tianeptine, 1856
Ticagrelor, 246–247t
  and aspirin, for ACS, 242t
Ticarcillin, 583t
  for cystic fibrosis, 461t
Ticlopidine, 1307t, 1314
  for diabetes, 168
  for PAD, 168
Tigecycline, 1325t
  for aerobic gram-positive cocci, 1326t
  dosing of, 1338t
  for gram-negative aerobes, 1327t
Timentin, 1325t
  for aerobic gram-positive cocci, 1326t
  for gram-negative aerobes, 1327t
Timolol, 2261t
  for glaucoma, 1150
  for MI, 253
Timoptic, 1150 (see also Timolol)
Timoptic XE, 1151
Tindamax (see Tinidazole)
Tinidazole, 1706
  for amebic liver abscess, 1704t
  for gastrointestinal disease, 1704t
  for giardiasis, 1703t
  for trichomoniasis, 1526–1527
  Tinzaparin, 177t, 188t
  LMWH, 656

Tioconazole, 1624t
Tiotropium, 420t, 421–423
Tiotropium plus olodaterol
  for COPD, 421
Tipiracil, 470t
Tipranavir (TPV), 120t, 914t, 942t, 1580t
Tirofiban, 237
Tissue amebicide, 1706
Titanium dioxide, 849t
TIV (see Trivalent inactivated vaccine (TIV))
Tizanidine, 942t, 1186t, 1224
  drug interaction with smoking, 1906t
TKIs (see Tyrosine kinase inhibitors (TKIs))
TMP (see Trimethoprim (TMP))
TMP-SMX (see Trimethoprim-sulfamethoxazole (TMP-SMX))
TNF-α inhibitors, for psoriasis, 842–843
TNK (see Tenecteplase (TNK))
Tobacco, 1948–1949
TOBI podhaler, 462–463
Tobramycin (Nebcin), 460, 462, 1325t, 1724
  adverse effects of, 1332t
  for CAPD-associated peritonitis, 1476t
  for CNS infections, 1373t
  for cystic fibrosis, 461t
  dosing of, 1339t
  for gram-negative aerobes, 1327t
  for inhalation, 462–463
  for UTI, 1497t
Tobramycin Podhaler, 461t
Tocilizumab, 881, 883, 896t, 897, 899, 903–904
Tofacitinib, 882
Toki-shakuyaju-san, 1015
Tolbutamide, 1140
Tolcapone (Tasmar), 1251t
  pharmacologic and pharmacokinetic properties of, 1263t
Tolindate, 1626
Tolmetin, 870t, 888t
Tolnaftate, 1624t
Tolterodine tartrate, 2251
Tolvaptan, 128
  for HF, 267
  for hyponatremia, 579
Tonabersat, 1242
Topamax (see Topiramate)
Topical protectants, for burn injuries, 863
Topical steroids, 523
Topiramate, 942t, 1181t, 1242, 1244, 1271t, 1272, 1279t, 1281, 1845, 1900–1902
  for ASD, 1856
  for diabetes, 1145
  for seizures, 1285t, 1286
  teratogenic effects, 973t
Topotecan, 128, 469t, 470t, 1991t
Torsemide, 647, 580
  for HF, 277
Toujeo (see Insulin glargine)

Toxin binders
  for CDAD, 1466
TPV (see Tipranavir (TPV))
Trabectedin, 469t
Tramadol, 867, 1182t
  for diabetes, 1145
  for OA, 872
Trametinib, 470t
Trandate (see Labetalol)
Trandolapril, 281, 281t
  in hypertension, 153t
Tranexamic acid, 942t
Tranquilizers, 552
Transdermal fentanyl
  dosage of, 1199–1201
  transition to, 1201
Transderm-Scop (see Scopolamine)
Tranylcypromine, 1751
Trastuzumab (Herceptin), 469t, 475, 1982t, 1987, 1989
  for breast cancer, 2053, 2057
Travasol, 794t
Travatan (see Travoprost)
Travoprost (Travatan), 1151
Trazodone, 1769, 1827
  for agitated behaviors, 2243
  for serotonin, 1826
  and sexual response, 2261t
  and sleep, 1774
  for sleep, 1861
Treanda (see Bendamustine)
Treprostinil, 924
Tresiba (see Insulin degludec)
Tretinoin, 470t, 827, 858
  for AML, 2027
Trexall (see Methotrexate)
Triacetin, 1626
Triamcinolone, 442
Triamcinolone acetonide (Nasacort AQ), 441t
Triamterene, 543, 580–581
  and hyperkalemia, 585
  for hypertension, 148
Triazolam (Halcion), 1737t, 1767–1768
  for treatment of insomnia, 1767t
Triazoles, 1624, 1625, 1636, 1637, 1639
Trichloroacetic acid, 1532
Tricyclic antidepressants (TCAs), 71, 77–78, 942t, 1261t, 1856
  for ADHD, 1871
  for anxiety disorders, 1748
  for critically ill patients, 1208
  drug interaction with smoking, 1907t
  GERD and, 503t
  for pain management, 1188, 1189, 1195
  for panic disorder, 1748
  for PTSD, 1754
  and sexual response, 2261t

Tridil (see Nitroglycerin)
Trifluoperazine, 1789t, 1797t, 1799t
Trifluridine, 470t, 1167, 1647t
  for adverse effects, 2081
Trihexyphenidyl, 1250t

---

  for Akathisia, 1800t
  for Parkinsonism, 1799
Triiodothyronine, 1049
Trileptal (see Oxcarbazepine)
Trimethoprim (Trimpex; TMP), 973t, 1326t, 1370
  for chronic antimicrobial therapy, 1499t
  for cystic fibrosis, 461t
  sulfamethoxazole and, 1499t
  for UTI, 1489t
Trimethoprim-sulfamethoxazole (Bactrim; Septra; TMP-SMX), 418, 828, 1326t, 1368, 2009
  alternatives, 1603–1604
  for CNS infections, 1373t
  for cystitis, 1489
  dosing of, 1339t
  hematologic side effects, 1603
  hypersensitivity (skin rash) reaction, 1603
  for OIs, 1602–1603
  for PJP, 1602–1603
  for skin and soft tissue infections, 1547
  for toxoplasmosis, 1606
  for UTI, 1489t
Trimpex (see Trimethoprim)
Triptans, 1237
  dosing and comparative pharmacokinetic parameters of, 1238t
  second-generation, 1239
Trisodium citrate, 656
Trivalent inactivated vaccine (TIV), 1361
Trolamine salicylate, 849t
TrophAmine, 2150, 2152
Troponin, 233, 235
Trospium chloride, 2251
Trusopt (see Dorzolamide)
Tums, 713–714
Turpentine, 822t
Twinrix, 1356t
Twisthaler, 395
Tykerb (see Lapatinib)
Tyrosine kinase inhibitors (TKIs), 2031
  for cancer, 1958–1959

U

Ulipristal, 951
Ultram (see Tramadol)
Ultrarapid opiate detoxification (UROD), 1879
Umeclidinium, 420t

Umeclidinium plus vilanterol, 421
Unasyn, 1325t
  for aerobic gram-positive cocci, 1326t
  for anaerobes, 1328t
  for gram-negative aerobes, 1327t
Undecylenic acid, 1624t
Unipen (see Nafcillin)
Urea, 579, 581
Uricase, 917
UROD (see Ultrarapid opiate detoxification (UROD))
Ursodiol, 2152
Ustekinumab, 842–843

V
Vaccination
  for HBV, 1690
  hepatitis A vaccine, 1666–1667, 1666t
    dosage, 1666, 1666t
    with HBV vaccine, 1666
    indications for, 1667
  hepatitis B vaccines
    adverse effects, 1674
    dosage, 1673
    duration of vaccine-induced immunity, 1673–1674
    immune response to, 1673
    indications for, 1674
    and infants, 1673
    with Recombivax HB, 1673
    universal, 1674
  herpes zoster vaccine (Zostavax), 1652
  for Lyme disease, 1721
  for malaria, 1701
  for OIs, 1598
  for prostate cancer, Sipuleucel-T, 2095
  teratogenic effects, 973t
Vagifem (see Estradiol hemihydrate tablets)
Vaginal prostaglandin E2, 989
Valacyclovir (Valtrex; VCV), 743, 1648t
  adverse effects, 1647t
  for genital herpes, 1529–1530, 1530t
  for herpes labialis, 1651
  for herpes zoster infection, 1652
  pharmacokinetics of, 1653t
Valcyte (see Valganciclovir)
Valganciclovir (Valcyte), 743, 1613, 1649t
  adjunctive therapy, 1608t
  adjusted dosage, 1610t
  advantages, 1608t
  adverse effects, 1647t
  for CMV primary prevention, 1613–1614
  for CMV retinitis, 1607, 1609
  CrCl, 1610t
  disadvantages, 1608t
  dosing regimens, 1608t
  important drug interactions, 1608t

  monitoring requirement, 1609t
  normal dosage, 1610t
  precautions and contraindications, 1609t
  select adverse effects, 1608t
Valproate (VPA), 1242, 1279t, 1837
  for absence and primary generalized tonic-clonic seizures, 1292–1294
  for absence seizures, 1290–1291, 1291t
  adverse effects, 1839–1840
  and alopecia, 1840
  for bipolar disorder, 1849t
  for developmental disorders, 1858
  dosage, 1839
  and gastrointestinal complaints, 1839
  and hyperammonemic encephalopathy, 1840
  for mania, 1839–1840
  monitoring of, 1839
  for seizures, 1284t
  and weight gain, 1839–1840
  weight gain with, 1839–1840
Valproic acid, 942t, 1837, 2131t
  dose–response curve, 972
  for schizophrenia, 1809
  teratogenic effects, 973t
Valrubicin, 469t
Valsartan, 257
  for hypertension, 154t
  for treatment of HF, 271
Valtrex (see Valacyclovir)
Vancocin (see Vancomycin)
Vancomycin (Vancocin), 658–659, 661, 662, 693–694, 1326t, 1349, 1371, 1380, 1394
  adverse effects of, 1333t
  for aerobic gram-positive cocci, 1326t
  for anaerobes, 1328t
  for CAPD-associated peritonitis, 1476t
  for cardiac surgery prophylaxis, 1392
  for CDAD, 1465–1466
  for CNS infections, 1373t
  for CSF shunt infection, 1379
  dosing of, 1339t
  for enterococcal endocarditis, 1397t
  for febrile neutropenia, 1564
  gentamicin and, 1398
  for HAP, 1418
  high-risk medication, 635–636
  MRSA, 1550
  for MRSA endocarditis, 1394–1396
  for NEC, 2183
  for PVE, 1392t
  renal failure, dosing of drugs, 674–675
  for sepsis, 2186t
  for skin and soft tissue infections, 1548, 1549
Vandetanib, 470t
Vanillylmandelic acid (VMA), 2003
Vantin (see Cefpodoxime proxetil)
Vaqta, 1357

Vardenafil, 2265
  and ED, 2265
Varenicline
  adverse reactions, 1920
  for depressive disorders, 1815t
  dosage, 1920
  patient education, 1920
  pharmacokinetics, 1920
  for smoking cessation, 1909, 1914
Varivax, 1362, 1363
Varubi (see Rolapitant)
Vasepa, 126
Vasodilators
  for ACS, 247–248
  for IC, 168–169
Vasopressin, 547, 2207t, 2208
  for cardiopulmonary arrest, 330–331
  for postoperative cardiac failure, 363t
  for septic shock, 371
  in treatment of IDH, 657
Vasopressin receptor antagonists (VRAs), 579–580
Vasotec IV (see Enalaprilat)
VCV (see Valacyclovir (VCV))
Vecuronium, 2200t

Vedolizumab
  for CD, 527–528
  for inflammatory bowel disease, 522t
  for UC, 527–528, 529
Velban (see Vinblastine)
Velcade (see Bortezomib)
Vemurafenib, 470t
Venetoclax, 470t
Venlafaxine (Effexor, Effexor XR), 1027t, 1182t, 1188, 1238, 1245, 1738t, 1986
  androgen deprivation therapy, 2097
  for depressive disorders, 1819t, 1820t
  for diabetes, 2226t
  for panic disorder, 1748
  for serotonin, 1826
  for vasomotor symptoms, 1036t
Venlafaxine ER, 1821t
Venlafaxine IR
  for depressive disorders, 1821t
  for hot flushes, 1036
  for PMDD, 1025
Venlafaxine XR 1738t, 1748, 1751, 1752
  for PTSD, 1754
  for SAD, 1752
Venofer (see Iron sucrose)
VePeSid (see Etoposide)
Verapamil, 120t, 128, 155, 169, 214, 609, 1061, 1244, 2261t

- for AF, 314
- for HF, 275
- for HFpEF, 271, 272
- for nocturnal leg cramps, 173
- in patients with CKD, 617
- for thyroid storm, 1067

Vesanoid (see Tretinoin)
Vibativ (see Telavancin)
Viberzi (see Eluxadoline)
Vidarabine, 1648
- for herpes encephalitis, 1646

Vigabatrin, 1279t
Vilanterol, 420t, 421
Vilazodone, 1827
- for depressive disorders, 1819t, 1821t

Vinblastine, 469t, 1978–1979t, 1981t, 1996t, 2040t
- and autonomic neuropathy, 1987
- and cranial neuropathies, 1987
- gonadal toxicity of, 1998
- neurotoxicity of, 1985t
- peripheral nerve toxicity of, 1986

Vinca alkaloids, 1981t
- gonadal toxicity of, 1998

Vincristine, 469t, 1979t, 1981t, 1987, 2005, 2040t, 2042
- for ALL, 2017t
- and autonomic neuropathy, 1987, 2015
- for HL, 2041
- intrathecal, problems of, 2016
- neurotoxicity of, 1985–1986, 1985t
- peripheral nerve toxicity of, 1986
- for rhabdomyosarcoma, 2010, 2011
- for T-cell lymphomas, 2020t

Vindesine, 1979t
Vinorelbine, 469t, 1979t
- neurotoxicity of, 1985t
- for NSCLC, 2062t, 2064t
- peripheral nerve toxicity of, 1986

Virazole (see Ribavirin)
Vismodegib, 470t
Vistaril (see Hydroxyzine)
Vistide (see Cidofovir)
Vitamin A, 612
- and pregnancy, 968
- teratogenic effects, 973t

Vitamin B, 1015
Vitamin B_6 (see Pyridoxine)
Vitamin B_{12}, 486
- for pernicious anemia, 1935

Vitamin C (see Ascorbic acid)
Vitamin D
- for endometriosis, 1021
- nutritional vitamin D, 621
- and pregnancy, 968
- for pulmonary exacerbations, 454
- receptor agonist, 621–622

    - calcitriol, 621–622
    - doxercalciferol, 622
    - paricalcitol, 622

Vitamin E, 657–658, 961, 1015, 1986
- for diabetic neuropathy, 1986
- for dysmenorrhea, 1015
- and pregnancy, 968
- for prostate cancer, 2099

Vitamin K
- dependent clotting factors, 180t
- and pregnancy, 968
- for pulmonary exacerbations, 454
- supplementation in pregnant women, 1298
- warfarin and, 195–196

VMA (see Vanillylmandelic acid (VMA))

Vorapaxar, 169, 244
- for ACS, 243t

Voriconazole, 59, 120t, 128, 942t, 1569, 1624, 1624t, 1625, 1628, 1633, 1634, 1639
- adverse effects, 1334t, 1639
- dosing of, 1339t

Vorinostat, 470t

Vortioxetine, 1827
- for depressive disorders, 1819t, 1821t

Votrient (see Pazopanib)

VPA (see Valproate)

Vraylar (see Cariprazine)

W

Warfarin, 41, 42–43, 44, 54–55, 95, 128, 204, 484, 485, 486, 942t, 1307t, 1314–1315
- for ACS, 243t, 258–259
- action of, 180f
- adverse effects of, 194
- alcohol ingestion and, 196–197
- anticoagulant therapy, 192
- and clotting factors, 1057
- dosing adjustments, 197, 197t
- drug interactions with, 203–205, 204t
- drug interaction with smoking, 1907t
- effects of, 192t
- factors influence, 195–197
- frequency of follow-up, 197
- genetic factors and, 197
- hemorrhage from, 194
- initiation dosing algorithm, 193f
- intensity and duration of, 193–194
- interactions with disease states, 196t
- international normalized ratio monitoring, 198t
- overanticoagulation, management of, 197–198
- in pregnancy, 198–200
- protocol for, 193t
- purple toe syndrome from, 194
- skin necrosis from, 194
- for stroke prophylaxis, 2242
- teratogenic effects, 973t
- therapy, initiation of, 192–193

vitamin K and, 178, 180–181, 195–196
Wool alcohols, 822t

X

Xalatan (see Latanoprost)
Xanax (see Alprazolam)
Xanthine oxidase
    and pregnancy, 970
Xeloda (see Capecitabine)
Xerese (see Acyclovir and Hydrocortisone cream)
Xifaxan (see Rifaximin)
Xolair (see Omalizumab)
Xylometazoline, 434t
Xyzal (see Levocetirizine)

Y

Yaz, 829
Yerba mata, 765t
Yoga, 1024

Z

Zalcitabine, 1944
Zaleplon (Sonata), 1768–1770
    for treatment of insomnia, 1767t
Zanamivir (Relenza), 1415t, 1649t
    adverse effects, 1647t
    for influenza, 1656
    pharmacokinetics of, 1653t
Zanosar (see Streptozocin)
ZDV (see Zidovudine (ZDV))
Zelapar (see Selegiline)
Zemplar (see Paricalcitol)
Zerbaxa (see Ceftolozane/tazobactam)
Zetonna (see Ciclesonide)
Z-hypnotics, 1768, 1770, 1776
Zidovudine (ZDV), 996, 1578t
    GERD and, 503t
    for HIV-related anemia, 1944
Zileuton, 397
Zinacef (see Cefuroxime)
Zinc, 961, 1661
    for gastroenteritis, 2161
    and pregnancy, 968
Zinc lozenges, 1661
Zinc oxide, 849t
Zioptan (see Tafluprost)
Ziprasidone (Geodon), 1267, 1739, 1797t, 1799t
    for acute agitation, 1845

---

    for acute mania, 1845, 1845t
    for bipolar disorder, 1849t

  for dyslipidemia, 1804
  for hyperprolactinemia, 1803
  for schizophrenia, 1788, 1789, 1792t, 1793, 1793t
Zithromax (see Azithromycin)
Ziv-aflibercept, 469t
  for colon cancer, 2073, 2078
Zofran (see Ondansetron)
Zoladex (see Goserelin)
Zoledronic acid, 589t, 590, 2038, 2277, 2277t, 2278
  androgen deprivation therapy, 2097
Zolinza (see Vorinostat)
Zolmitriptan, 1238t, 1239, 1244
Zoloft (see Sertraline)
Zolpidem, 1768–1770, 1776
  for sleep, 1861
  for treatment of insomnia, 1767t
Zolpimist (see Mucous membrane spray)
Zomig (see Zolmitriptan)
Zonegran (see Zonisamide)
Zonisamide, 1279t, 1281, 1845
  for seizures, 1285t, 1286
Zostavax (see Zoster vaccine)
Zoster vaccine (Zostavax), 1363
Zosyn (see Piperacillin-tazobactam)
Zotarlimus, 226
Zovirax (see Acyclovir (ACV))
Zyprexa (see Olanzapine)
Zyrtec (see Cetirizine)
Zyvox (see Linezolid)

Subject Index

Note: Page number followed by f and t indicates figures and tables respectively

A

AA (see Amino acid (AA))

AAA (see Aromatic amino acids (AAA))

AAAs (see Aromatic amino acids (AAAs))

AAN (see American Academy of Neurology (AAN))

AAO (see American Academy of Opthalmology (AAO))

AAOS (see American Academy of Orthopedic Surgery (AAOS))

AAP (see American Academy of Pediatrics (AAP))

AASK (see African American Study of Kidney Disease and Hypertension (AASK))

AASLD (see American Association for Study of Liver Diseases (AASLD))

AB (see Acute bronchitis (AB))

ABCs (see Airway, breathing, and circulation (ABCs))

Abdominal pain, clinical relevance of, 1194–1195, 1195t

Abdominal radiograph, in iron toxicity, 71–72

ABG (see Arterial blood gas (ABG))

ABI (see Ankle-to-brachial index (ABI))

Abnormal impulse conduction, 308–309

Abnormal impulse formation, 308

Abortion, 968

ABPM (see Ambulatory blood pressure monitoring (ABPM))

Abscesses, 1477
- in brain, 1380–1383, 1381t
- hepatic, with amebiasis, 1702
- intra-abdominal, 1477

Absence seizures, 1274, 1290–1291, 1291t
- and tonic-clonic seizures, 1291–1294

Absolute neutrophil count (ANC), 33, 1554, 1565, 2068–2069
- hematologic laboratory values for, 21t

Absorption spectrum, 851

ABW (see Actual body weight (ABW))

Academy of Nutrition and Diabetics, 781–782

ACAT (see Acetyl CoA acetyl transferase (ACAT))

ACC (see American College of Cardiology (ACC))

Accelerated rejection, 727

ACCORD (see Action to Control Cardiovascular Risk in Diabetes (ACCORD))

ACCP (see American College of Chest Physicians (ACCP))

Accreditation Council for Pharmacy Education (ACPE), 96

ACE (see Angiotensin-converting enzyme (ACE))

ACEI (see Angiotensin-converting enzyme inhibitors (ACEIs))

Acetaminophen toxicity, stages of, 79–80

Acetylcholine, 482

Acetyl CoA acetyl transferase (ACAT), 101
ACG (see American College of Gastroenterology (ACG))
Acid–base disorders, 556–567
  acid–base physiology, 556–558, 557f, 558t
  evaluation of, 558–559, 559t
  metabolic alkalosis, 563–564, 563t
  mixed, 566–567
  respiratory acidosis, 564–565, 564t
  respiratory alkalosis, 565–566, 566t
Acid–base physiology, 556–558, 557f, 558t
Acid-fast bacilli (AFB) stain, 1325
Acidification, 43
Acidosis
  in ALF, 1671
  in CHD, 2209
  in infants, 2148
  lactic, 2206
  metabolic, 1672, 2133, 2142, 2148
    in infants, 2150
    in NEC, 2181, 2182
    and pediatric shock, 2201
    in RDS, 2170
    in VLBW infants, 2184
  in PDA, 2179
  renal tubular, 2011
  respiratory, in BPD, 2174
  from salicylate toxicity, 69
  sepsis-induced, 2205
Acid suppression empiric test, 506–507
ACIP (see Advisory Committee on Immunization Practice (ACIP))
ACLS (see Advanced Cardiac Life Support (ACLS))
Acne, 816, 825–831
  with androgens, 1964t
  clinical presentation of, 826
  comedonal, 827–828, 827t
  definition of, 826
  diagnosis of, 826
  epidemiology of, 826
  with lithium, 1841t
  maculopapular, 827t, 828–830
  nodular, 827t, 830–831
  pathophysiology of, 826
  and PCOS, 1007–1008
  scarring, 827
  treatment of, 826–827, 827t
    nonpharmacologic therapy, 826–827
    pharmacotherapy, 827
Acneiform eruptions, 821
ACOS (see Asthma-COPD Overlap Syndrome (ACOS))
ACPE (see Accreditation Council for Pharmacy Education (ACPE))
Acquired immunodeficiency syndrome (AIDS), 1596, 1613
  CD4+ lymphocytes and, 1597
  depression in, 1828
  diagnosis of, 1574
  fatal hypocalcemia in, 1612

    fungal infections and, 1622
    incidence and mortality rate, 1572
    and infections, 1342, 1572
    opportunistic infections with
        in asymptomatic HIV-infected patients, 1597
        incidence rate, 1597
    PCP and, 1601
    PPD skin test and, 1440–1441
    retinitis and, 1607
    Toxoplasma encephalitis and, 1605
ACR (see American College of Rheumatology (ACR))
Acropachy, 1042
ACS (see Acute coronary syndrome (ACS))
ACT (see Activated clotting time (ACT))
Action in Diabetes and Vascular Disease a Controlled Evaluation (ADVANCE), 1079

Action potential duration (APD), 307
Action to Control Cardiovascular Risk in Diabetes (ACCORD), 608–609, 1079
    -Blood Pressure (ACCORD-BP) trial, 136–137
Activated charcoal, use of, 66–67, 77
Activated clotting time (ACT), 655–656
Activated partial thromboplastin time (aPTT), 35, 177, 181, 647, 1322
    ratio, 657
Active disease, TB and, 1424
    treatment of, 1428–1434, 1428t
Activities of daily living (ADLs), 867
Actual body weight (ABW), 184
ACUITY trial (see Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial)
Acupuncture, 443
Acute asthma, 385–394
    β_2-adrenergic agonist therapy, 388–393
    assessment of, 385–388
    corticosteroid therapy, 394
    respiratory failure and, 393
    short-acting inhaled β_2-agonists for, 394
Acute bleeding, treatment, 548t
Acute bronchitis (AB), 1405–1407
    causative organism, 1406t
    clinical diagnosis of, 1406–1407
    clinical presentation of, 1405–1406
    definition of, 1405
    drug therapy for, 1405
    epidemiology of, 1405
    incidence of, 1405
    microbiology of, 1406
    pathophysiology of, 1405
    patient education, 1407
    treatment of, 1406–1407
Acute Catheterization and Urgent Intervention Triage Strategy (ACUITY) trial, 254–255
Acute CF exacerbations, 464

Acute cholangitis, 1471–1473
Acute cholecystitis, 1471–1473
  clinical presentation/diagnosis of, 1471–1472
  definition of, 1471
  etiology of, 1472
  treatment of, 1472
Acute coronary syndrome (ACS), 147, 211, 232
  algorithm for, 234f
  cardiac biomarker elevation in, 235f
  clinical presentation of, 232–233, 249–250
    anterior vs. inferior infarction, 250
    laboratory abnormalities, 249
    risk stratification, 250
    STEMI and NSTEMI, 250
    therapeutic objectives, 250
  complications of, 235–236
  diagnosis of, 233
  epidemiology of, 232
  glycoprotein IIb/IIIa in, 256t
  hallmark symptoms for, 232
  laboratory changes in, 233, 235
  lifestyle modifications, 239
  pathophysiology of, 232
  pharmacotherapies for, 238–243t
  risk stratification of, 235, 236t
  thrombus formation and, 233f
Acute decompensated heart failure (ADHF), 267
Acute Dialysis Quality Initiative, 631
Acute exacerbation of chronic obstructive pulmonary disease (AECOPD), 1407–1409
  clinical presentation of, 1407–1408
  definition of, 1407
  diagnosis of, 1407–1408
  epidemiology of, 1407
  pathophysiology of, 1407
  severity of, 1408
  treatment for, 1408–1409
Acute glomerulopathies, 640–641
  NSAID-induced, 641
  poststreptococcal, 640
  rapidly progressive, 640–641
Acute gut inflammation, 1209
Acute headaches, 1234
Acute heart failure, hemodynamic profile of, 296f
Acute hemorrhagic shock
  causes of, 353
  hypertonic saline for, 355
  treatment of, 353–357
Acute interstitial nephritis (AIN), 636–637
Acute kidney injury (AKI), 630–649
  biomarkers, 635
  BUN assessment in, 636
  causes of, 633t
  clinical course, 632
  crystal-induced, 646, 646t
  definition of, 631, 632t

- epidemiology of, 631
- functional, 634
- history and physical examination in, 635
- intrinsic, 634–635, 639–641
- laboratory evaluation in, 635–637, 636t
- pathogenesis of, 632–635, 633t, 634f
- phases of
  - diuretic phase, 632
  - oliguric phase, 632
  - recovery phase, 632
- postrenal, 635, 645–646, 646t
- prerenal and functional AKI, 637–639
- prognosis for, 632
- supportive management of, 646–649, 648f, 649t
- tubulointerstitial diseases and, 641–645, 642f, 643–644t
- urinalysis and, 636–637, 636t
- urinary sediments and, 636t

Acute Kidney Injury Network (AKIN), 631

Acute liver failure (ALF)
- and HBV, 1671–1672
- primary therapy for, 1672

Acute lung injury (ALI), 779, 780

Acute lymphoblastic leukemia (ALL), 2011–2019
- age factor, 2012
- B-cell lineage, 2012
- and bone marrow blasts, 2013
- clinical presentation of, 2011–2012
- clinical variables, 2012

Verbal description scales (VDS), 1175t
Very low density lipoproteins (VLDL), 102–103, 103t, 1073
Veterans Affairs Diabetes Trial (VADT), 1079
VF (see Ventricular fibrillation (VF))

VF (see Ventricular flutter (VF))
Vibrio cholerae, 2161
Vibrio cholerae, infection from, 1451
Vibrio parahaemolyticus, infection from, 1452
Viral gastroenteritis, 1447t, 1450–1451
Viral infection, 701
  and systemic lupus erythematosus, 701
Viral infections
  common cold, 1661
  of Hantavirus, 1658–1659
  herpes simplex, 1646–1651
  influenza, 1655–1657
  middle east respiratory syndrome, 1660
  respiratory syncytial virus (RSV), 1657–1658
  severe acute respiratory distress syndrome (SARS), 1660
  varicella-zoster (VZV), 1651–1655
  West Nile virus (WNV), 1659–1660
  Zika virus, 1660–1661
Virchow's Triad, 175
Virilizing tumors, and congenital malformations, 971
Visceral pain, 1173
  treatment of, 1174
Visual analog scale (VAS), 1175t
Vital capacity (VC), 383
Vitamin D biotransformation, 618f
Vitamin K epoxide reductase (VKOR), 178
Vitamin K Epoxide Reductase Complex subunit 1 (VKORC1), 54
Vitamin K-hydroquinone (KH2), 44
Vitamins, 748
  and mineral supplementation, 456–457, 457t
  PN and, 801–802, 801t
VKOR (see Vitamin K epoxide reductase (VKOR))
VLDL (see Very low density lipoproteins (VLDL))
VMS (see Vasomotor symptom (VMS))
Volume regulation, 572
  disorders in, 572–574
    sodium depletion, 572–573
    sodium excess, 573–574
Vomiting, 463 (see also Nausea and vomiting)
  clinical presentation of, 2158–2159
  definition of, 466
  pathogenesis, 2158–2159
  and pazopanib, 1963t
VRAs (see Vasopressin receptor antagonists (VRAs))
VTE (see Venous thromboembolism (VTE))
Vulvovaginal candidiasis (VVC), 1522–1525
  causative agents of, 1522
  complicated, 1525–1526
  differential diagnosis of, 1523–1524
  patient counseling in, 1524–1525
  in pregnancy, 1526
  recurrent, 1526, 1526t
  risk factors for, 1524
  signs and symptoms, 1522
  treatment of, 1524

- vaginal discharge in, 1523

VVC (see Vulvovaginal candidiasis (VVC))

VZV (see Varicella-zoster virus (VZV))

W

Waist-to-hip ratio (WHtR), 757

Water, 748
- in body, 569–570
- homeostasis, 572

Water restriction, 542

WBC (see White blood count (WBC); White blood cells (WBCs))

WBI (see Whole bowel irrigation (WBI))

Wegener granulomatosis, 626–628

Weight, 2130–2131
- and AmB formulations, 1633
- and dehydration, 2139–2141, 2141t, 2160
- and giardiasis, 1707
- loss, 761
  - with alcohol, 2224
  - behavior therapy for, 762
  - with bupropion, 1827
  - in CML, 2029–2030
  - and CPAP, 1777
  - dietary supplements for, 765
  - diets for, 761
  - for hypertension prevention, 138, 144
  - in leukemias, 2032
  - physical activity for, 762
  - and PN, 796
- and parenteral nutrient requirements, 2140t
- and PCP therapy, 1604
- for SGAs, 1803
- and tapeworm infections, 1709
- and terbinafine, 1628
- type 1 diabetes and, 1074
- type 2 diabetes and, 1075

Western blot tests, 1582

Western Ontario and McMaster Universities (WOMAC), 868

West Haven Criteria (WHC), 551

West Nile virus (WNV), 1659–1660

WFSBP (see World Federation of Societies of Biological Psychiatry (WFSBP))

WHC (see West Haven Criteria (WHC))

White blood cells (WBCs), 33–34, 356

White blood count (WBC), 2030
- in iron toxicity, 72

White-coat hypertension, 135–136

WHO (see World Health Organization (WHO))

Whole bowel irrigation (WBI), 67
- in iron ingestion, 72

WHtR (see Waist-to-hip ratio (WHtR))

Willis–Ekbom disease (see Restless legs syndrome (RLS))

Wilms tumor, 2006–2008, 2006t
- chemotherapy, 2007–2008
- clinical presentation of, 2006, 2007–2008
- diagnosis, 2006

  epidemiology, 2006
  pathophysiology, 2006
  staging, 2006, 2006t
  treatment of, 2006–2008
Windup, pain and, 1172
Wintrobe indices (see RBC indices)
WNV (see West Nile virus (WNV))
Wolff–Chaikoff effect, 1058
Wolff-Parkinson-White (WPW) syndrome, 319f, 320–321
WOMAC (see Western Ontario and McMaster Universities (WOMAC))
Women's Health Initiative, 870

World Federation of Societies of Biological Psychiatry (WFSBP), 1837, 1846–1847
World Health Organization (WHO), 409, 957
  obesity and, 757
Wounds, classification of, 860, 1344t
WPW (see Wolff-Parkinson-White (WPW) syndrome)

X
Xerosis (dry skin), 813, 813t
Xerostomia, 1973–1974

Y
Yale-Brown Obsessive-Compulsive Symptom Checklist (Y-BOCS), 1758
Yellow zone, of PEF, 402
Youth Risk Behavior Survey, 855

Z
ZES (see Zollinger–Ellison syndrome (ZES))
Zika virus, 1660–1661
Zollinger–Ellison syndrome (ZES), 489
  clinical assessment and diagnosis, 502
  epidemiology, 501–502
  pathophysiology, 502
  treatment, 502
